Definition 9241.10 (RH compiler-flow target)**.** *An* RH compiler-flow target *is a certified compiler flow C_{RH} such that, for every complex history s and every RH zero event flow $S_0(s)$, there exists an RH skew event flow $S_{\mathrm{skew}}(s)$ satisfying*

$$\mathsf{Compiles}_{C_{\mathsf{RH}}}(S_0(s), S_{\mathrm{skew}}(s)).$$

Theorem 9241.11 (Compiler-flow target implies BEDC-RH)**.** *If an RH compiler-flow target exists and its recognizer exports are accepted through the GroundCompiler certificate gate, then the BEDC statement* RH *holds.*

Proof. Let s be a complex history with $\mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s)$. By the premise packet discipline of chapter 550, this hypothesis is represented by an accepted RH zero event flow $S_0(s)$, recognized by a generated recognizer R_0. Applying the compiler flow C_{RH} gives an output event flow $S_{\mathrm{skew}}(s)$ recognized as an RH skew event flow. The recognition judgment for the output supplies $\mathsf{hsame}(\Re(s) - 1/2, 0_{\mathbb{R}})$. This is the $\mathsf{OnCritLine}(s)$ witness of Definition 9239.7. Since s was arbitrary, the required Π-statement is inhabited. □

9241.4 Mirror closure and orbit collapse

Definition 9241.12 (Mirror map)**.** *For a complex history s, write*

$$J(s) = 1 - \overline{s}.$$

The fixed points of J are exactly the histories whose real component is $1/2$:

$$s = J(s) \quad \Longleftrightarrow \quad \Re(s) = 1/2.$$

Theorem 9241.13 (Functional-equation rows give mirror closure)**.** *Assume a zeta event-flow packet contains the $\mathsf{ZetaCont}^{\uparrow}$ row, the functional-equation row, the completed-zeta row, conjugation transport, pole non-escape, and Gamma-boundary ledgers. Then it can support a mirror compiler-flow target of the form*

$$\mathsf{ZeroEventFlow}_{\mathsf{RH}}(s) \to \mathsf{ZeroEventFlow}_{\mathsf{RH}}(J(s)).$$

Proof. Recognition of the input zero event flow reads $\mathsf{ZetaCont}(s) = 0$ inside the critical strip. The completed-zeta row transports this zero read to the completed carrier, the functional-equation row reflects the completed carrier across $s \mapsto 1 - s$, and conjugation transport supplies the real-structure step. The pole and Gamma-boundary ledgers are exactly the non-escape rows needed to return from the completed carrier to the non-trivial zeta-zero surface. The resulting output packet is therefore a recognized zero event flow for $J(s)$. □

Corollary 9241.14 (Mirror closure is weaker than RH)**.** *The existence of the mirror compiler-flow target of Definition 9241.13 does not, by itself, prove* RH.

Proof. Mirror closure transports a zero at s to a zero at $J(s)$. It does not identify the two histories. Since $J^2(s) = s$, a mirror orbit has the form $\{s\}$ or $\{s, J(s)\}$; the first case is equivalent to $\Re(s) = 1/2$, while the second is a two-point orbit off the critical line. The Riemann Hypothesis asserts that every non-trivial zero orbit is of the first kind. That orbit-collapse row is not supplied by mirror closure alone. □

Definition 9241.15 (Zero-orbit collapse packet)**.** *A* zero-orbit collapse packet *for s is a finite packet containing an RH zero code for s, the mirror row $J(s)$, the mirror zero code for $J(s)$, and an* $\mathsf{hsame}(s, J(s))$ *row. By the fixed-point calculation in Definition 9241.12, this is equivalently a skew-zero packet for s.*

Corollary 9241.16 (GroundCompiler-normal form of RH)**.** *At the GroundCompiler-facing layer, the RH obligation is the production of a recognized zero-orbit collapse event flow:*

$$\mathsf{ZeroEventFlow}_{\mathsf{RH}}(s) \to \mathsf{ZeroOrbitCollapseEventFlow}_{\mathsf{RH}}(s) \to \mathsf{SkewZeroEventFlow}_{\mathsf{RH}}(s).$$

Proof. The first arrow supplies the missing orbit-collapse witness $\mathsf{hsame}(s, J(s))$ from a recognized zero event flow. The second arrow is the algebraic readback of Definition 9241.12: the fixed-point condition for J is exactly the critical-line condition. Thus the composite is the zero–skew transformer of Definition 9241.3, and conversely any zero–skew transformer supplies the collapse row by reading $\Re(s) = 1/2$ as $s = J(s)$. □

9241.5 Relation to finite analysis routes

The event-flow formulation separates three kinds of RH-facing work. The channel layer is only the lossless display layer: by Definition 9208.17 and Definition 9208.19, it preserves event boundaries and recovers decoded event flows from legal channel strings. By Definition 9241.6 and Definition 9241.9, neither the terminator 11 nor the displayed glyph 0 carries a zero reading. The recognizer layer reads particular event flows as zeta-zero, critical-strip, mirror, or skew-zero packets, but a recognized input packet still contributes only the premise of Definition 9239.8. The proof layer is the additional compiler or proof flow that produces the missing collapse or skew-zero row.

This separation explains the status of the existing RH witness catalogue. The critical-line witness packet of chapter 548 is a possible output surface for the skew-zero row. The critical-strip barrier packet of chapter 705 is a possible route to that row by showing that every region bounded away from the critical line is bounded away from zero. The Riemann zero-count ledger of chapter 573 supplies finite height-window accounting, but it becomes a route to RH only when combined with exhaustion, multiplicity, boundary, and transport ledgers that cover all zero records in the requested window. In each case the deciding question is not whether a readable event flow exists, but whether the accepted flow exports the skew-zero or orbit-collapse row required by Definition 9241.3.

9241.6 Analytic continuation as projection recovery

The same boundary discipline explains why analytic continuation is the appropriate semantic model for the zeta side of the RH target. A convergent series expression is not the whole analytic carrier. It is a local projection of that carrier on a domain where the expression is readable. For zeta, the Dirichlet series is the projection of ZETA on the window $\Re(s) > 1$, the eta expression is another compatible projection on a larger window, and the functional-equation expression is a reflected projection with its own pole, Gamma, branch, and transport ledgers.

Principle 9241.17 (Projection recovery)**.** *Analytic continuation is not an instruction to assign values to a divergent local expression. It is the recovery of one invariant analytic carrier from local projection slices whose domains, overlaps, exceptional loci, and transport ledgers are displayed.*

Remark 9241.18 (EventFlow analogue)**.** *The GroundCompiler channel layer is the finite combinatorial analogue of the same rule. A bare glyph stream is not an event flow because event boundaries may have been erased; by Definition 9207.7, distinct event flows can have the same flattened display. The legal channel encoding restores the boundary ledger through* 11 *terminators, while recognizer and certificate gates restore semantic roles. In the analytic layer, a bare formula without its domain, overlap, branch, pole, and transport ledger likewise cannot be promoted to the global zeta carrier. In both settings, the object is the stable carrier recovered from compatible local records, not any single display slice.*

Concretized in §550: Critical-strip zeta-zero witness packets provide the recognized zero-event input surface for the RH zero–skew EventFlow target.

Concretized in §548: Critical-line witness packets provide the skew-zero output surface for any accepted zero–skew transformer.

Concretized in §581: The zeta functional-equation ledger supplies mirror-zero transport rows while leaving zero-orbit collapse as the RH-specific missing certificate.

Chapter 9242

EventFlow Certificate Flow for Primes, Zeta, and RH

chapter 9241 places the Riemann Hypothesis at the compiler-facing layer as a transformer from recognized zero-event packets to recognized critical-line packets. The present chapter records the certificate-flow substrate below that transformer. It shows how prime recognition, zeta recovery, and the RH fixed-point target are separated into finite EventFlow rows. This separation does not prove RH. It turns the conjecture into a fixed-output certificate target whose missing row is visible.

9242.1 Boundary before semantics

Definition 9242.1 (Channel fixed boundary)**.** *For an event flow $S = (w_0, \ldots, w_{n-1})$, the channel layer records a source event-flow row E, a legal channel-code row C, a decoder row D, and a round-trip witness row R:*

$$E \to C \to D \to R.$$

The round-trip row asserts only

$$\mathsf{Decode}(\mathsf{Compile}(S))\mathsf{hsame}S.$$

It recovers the event boundaries and the event sequence. It does not recover primehood, zeta values, zerohood, or proof rows.

Lean packages this finite substrate as
Lean4 (definition) `BEDC.Derived.RHRoute.EventflowCertificate.EventflowStep`
,
Lean4 (definition) `BEDC.Derived.RHRoute.EventflowCertificate.FlowLinked`
, and
Lean4 (definition) `BEDC.Derived.RHRoute.EventflowCertificate.CertificateFlow`
; the certificate transport is validated by
Lean4 ✓ `BEDC.Derived.RHRoute.EventflowCertificate.flow certificate sound`
.

Proposition 9242.2 (Channel reconstruction is a boundary fixed point)**.** *Every accepted legal-channel read makes the source event flow a fixed point of the compile-decode composite:*

$$(\mathsf{Decode} \circ \mathsf{Compile})(S)\mathsf{hsame}S.$$

Proof. The accepted read must pass through the displayed rows E, C, D, R. The row C stores the legal channel code of the source flow named by E, the row D stores the decoder read, and R identifies the decoded output with the source event flow up to hsame. Hence the compile-decode composite returns the same event sequence and no semantic classifier has yet been applied. □

Corollary 9242.3 (Terminator rows are not zeta-zero rows)**.** *If the channel representation uses* 11 *as event terminator, each occurrence of* 11 *records only the end of one raw event. A zeta-zero reading can appear only after a generated recognizer accepts a whole decoded packet as a* $\mathsf{ZeroCode}_{\mathsf{RH}}$ *or* $\mathsf{ZeroEventFlow}_{\mathsf{RH}}$ *surface.*

Proof. This is the channel-level specialization of Definition 9241.6. The terminator belongs to the legal-code row, while a zero row belongs to a later recognizer and certificate gate. □

9242.2 Prime flow as factorization fixed point

Definition 9242.4 (Arithmetic event packets)**.** *A natural-number event packet* $\mathsf{NatFlow}(n)$ *is a recognized finite EventFlow packet exposing*

$$n, \quad \mathsf{Nat}^{\uparrow}, \quad \mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}}, \quad \mathsf{ContRoute}, \quad \mathsf{Pkg}.$$

A split event packet $\mathsf{SplitFlow}(n; a, b)$ *exposes natural-number rows for* a, b, n *together with a multiplication row*

$$a \cdot b\mathsf{hsame}n.$$

The split is non-trivial when both displayed factors are separated from the unit row.

Definition 9242.5 (Prime event flow)**.** *A prime event flow* $\mathsf{PrimeFlow}(p)$ *is a natural-number event packet for* p *together with a strict row* $p > 1$ *and a refusal row excluding every non-trivial split packet* $\mathsf{SplitFlow}(p; a, b)$.

Definition 9242.6 (Factorization normalizer)**.** *The factorization normalizer* $\mathsf{FactNorm}$ *sends a recognized natural-number packet to the finite multiset of prime packets generated by its displayed factorization route. A singleton output is written* $[p]$.

Proposition 9242.7 (Prime flow is the atomic factorization fixed point)**.** *For a recognized natural-number packet* p *with* $p > 1$,

$$\mathsf{PrimeFlow}(p) \quad \Longleftrightarrow \quad \mathsf{FactNorm}(p)\mathsf{hsame}[p].$$

Proof. If $\mathsf{PrimeFlow}(p)$ holds, the refusal row excludes all non-trivial split packets. The factorization normalizer therefore cannot expose a proper product decomposition and returns the singleton packet $[p]$. Conversely, if $\mathsf{FactNorm}(p)\mathsf{hsame}[p]$ while a non-trivial split $p\mathsf{hsame}a \cdot b$ existed with both factors separated from the unit row, the normalizer would have to continue through the factorization routes of a and b, yielding a non-singleton prime packet list. This contradicts the displayed singleton row. Hence no non-trivial split exists, and the packet is prime. □

Remark 9242.8 (No arithmetic self-assertion)**.** *The fixed-point reading of Definition 9242.7 is not a bare self-assertion that* p *is prime. It is a factorization readback: the object is atomic because the recognized multiplication-split flow returns the same prime packet and no proper split packet.*

9242.3 Zeta as socket recovery flow

Definition 9242.9 (Prime-local and Dirichlet event projections)**.** *For a recognized prime packet* $\mathsf{PrimeFlow}(p)$ *and a complex history* s*, the prime-local channel event is*

$$\mathsf{PrimeChan}_p(s) = p^{-s}.$$

On the right half-plane $\Re(s) > 1$*, the Euler event projection and Dirichlet event projection are*

$$\mathsf{EulerFlow}(s) = \prod_{p \in \mathsf{PrimeFlow}} (1 - p^{-s})^{-1}, \qquad \mathsf{DirichletFlow}(s) = \sum_{n \geq 1} n^{-s}.$$

Definition 9242.10 (Zeta event-flow socket)**.** *A zeta event-flow socket is a finite packet*

$$Z = (B, E, A, P, F, T, G, H, C, N)$$

whose rows are read as follows:

$$B : \mathsf{ZetaBasic}^{\uparrow} \textit{ source on } \Re(s) > 1, \quad E : \eta\textit{-half-plane handoff},$$
$$A : \mathsf{AnaCont}^{\uparrow} \textit{ handoff}, \quad P : \textit{pole ledger at } s = 1,$$
$$F : \textit{functional-equation factor ledger}, \quad T : \textit{trivial-zero ledger},$$
$$G : \mathsf{Gamma}^{\uparrow} \textit{ boundary row}, \quad H : \mathsf{hsame} \textit{ transports},$$
$$C : \textit{finite } \mathsf{Cont} \textit{ routes}, \quad N : \mathsf{NameCert} \textit{ row}.$$

This is the EventFlow reading of the $\mathsf{ZetaContinuationSocket}^{\uparrow}$ *packet.*

Proposition 9242.11 (Zeta recovery from prime-local flow and socket rows)**.** *On* $\Re(s) > 1$*,*

$$\mathsf{DirichletFlow}(s)\mathsf{hsame}\mathsf{EulerFlow}(s).$$

Together with the rows of Definition 9242.10, this right-half-plane agreement recovers the global meromorphic carrier ZETA *as a compatible projection packet rather than as a single series expression.*

Proof. Absolute convergence on $\Re(s) > 1$ permits grouping by the displayed factorization routes. Each natural-number index decomposes uniquely as a finite product of prime packets:

$$n = \prod_p p^{k_p}.$$

Therefore

$$n^{-s} = \prod_p p^{-k_p s},$$

and the sum over positive indices becomes the product of local geometric series

$$\sum_{n \geq 1} n^{-s} = \prod_p \sum_{k \geq 0} p^{-ks} = \prod_p (1 - p^{-s})^{-1}.$$

This supplies the prime-local projection row. The zeta socket then adds the eta handoff, analytic-continuation handoff, pole ledger, functional-equation ledger, Gamma-boundary row, transports, and finite continuation routes. These rows form the compatible recovery surface for ZETA. □

Corollary 9242.12 (Zeta is not exhausted by its series projection)**.** *The event-flow reading of* ZETA *is not the bare row* $\sum_{n\geq 1} n^{-s}$*. It is the recovered carrier obtained from the Dirichlet row, Euler prime row, eta handoff, analytic-continuation handoff, pole row, functional-equation row, Gamma boundary, transport rows, and local NameCert row.*

Proof. The Dirichlet row is only one projection on $\Re(s) > 1$. The remaining rows of Definition 9242.10 are necessary to read the same carrier outside that window and to preserve its pole, mirror, trivial-zero, and transport ledgers. □

9242.4 RH as fixed-output target

Definition 9242.13 (Prime-unitary balance event flow)**.** *For a complex history* s*, a prime-unitary balance event flow is a recognized packet exposing, for every prime packet* $\mathsf{PrimeFlow}(p)$*, the centered channel row*

$$U_p(s) = p^{1/2}p^{-s} = p^{1/2-s}$$

and the unit-amplitude witness

$$|U_p(s)|\,\mathsf{hsame1}.$$

Definition 9242.14 (Prime-balanced RH compiler target)**.** *The prime-balanced RH compiler target is a certified compiler or proof flow* $C^{\mathrm{prime}}_{\mathsf{RH}}$ *with type*

$$C^{\mathrm{prime}}_{\mathsf{RH}} : \mathsf{ZeroEventFlow}_{\mathsf{RH}}(s) \to \mathsf{PrimeUnitaryBalanceFlow}_{\mathsf{RH}}(s).$$

Expanded through the recognized rows, it is the target

$$(\mathsf{ZETA}(s)\mathsf{hsame0}_{\mathbb{C}} \wedge \mathsf{InCritStrip}(s)) \to \forall p \in \mathsf{PrimeFlow},\ \left|p^{1/2-s}\right|\,\mathsf{hsame1}.$$

Proposition 9242.15 (Prime-balanced compiler target is an RH witness)**.** *An accepted prime-balanced RH compiler target supplies the same mathematical content as the zero–skew transformer of Definition 9241.3.*

Proof. Definition 9243.7 identifies the prime-unitary output packet with the critical-line row $\Re(s)\mathsf{hsame1}/2$. Thus a compiler flow from a recognized zero event packet to a recognized prime-unitary balance packet yields the skew-zero output row required by Definition 9241.3. Conversely, a zero–skew transformer gives the prime-unitary output by reading $\Re(s)\mathsf{hsame1}/2$ through the normalized prime-channel amplitude formula. □

Definition 9242.16 (Zero-orbit collapse event flow)**.** *Let* $J(s) = 1 - \overline{s}$*. A zero-orbit collapse event flow for* s *is a finite packet containing*

$$\mathsf{ZeroEventFlow}_{\mathsf{RH}}(s), \quad \mathsf{ZeroEventFlow}_{\mathsf{RH}}(J(s)), \quad \mathsf{hsame}(s, J(s)),$$

together with the displayed transport, route, provenance, and local naming rows.

Proposition 9242.17 (RH is zero-orbit collapse)**.** *The BEDC statement* RH *is equivalent to the existence of a total target*

$$\mathsf{ZeroEventFlow}_{\mathsf{RH}}(s) \to \mathsf{ZeroOrbitCollapseFlow}_{\mathsf{RH}}(s).$$

Proof. If RH holds, a recognized non-trivial zero packet has $\Re(s)\mathsf{hsame1}/2$. The mirror calculation of Definition 9241.12 then gives $\mathsf{hsame}(s, J(s))$, and the functional-equation mirror rows supply the companion zero packet for $J(s)$ when the zeta socket rows are displayed. This is the zero-orbit collapse packet. Conversely, if every zero event flow has an accepted collapse packet, its $\mathsf{hsame}(s, J(s))$ row implies $\Re(s)\mathsf{hsame1}/2$ by the same mirror calculation, hence supplies $\mathsf{OnCritLine}(s)$ for every critical-strip zero packet. □

9242.5 Fixed-point stratification

Principle 9242.18 (Certified fixed points only)**.** *The EventFlow reading admits fixed points only as displayed certificate rows: channel round-trip rows, factorization singleton rows, projection-recovery rows, mirror-collapse rows, and fixed-output witness rows. It does not admit bare self-reference, host-level fixed-point principles, or self-application oracles.*

Theorem 9242.19 (Three fixed-point layers)**.** *The EventFlow reconstruction of primes, zeta, and RH separates three fixed-point layers:*

$$\mathsf{PrimeFlow}(p) \iff \mathsf{FactNorm}(p)\mathsf{hsame}[p],$$

$$P_i(\mathrm{Rec}((D_i, f_i)_i))\mathsf{hsame} f_i \quad \textit{for each displayed zeta projection row,}$$

and

$$\mathsf{RH} \iff \forall s,\ \mathsf{ZeroEventFlow}_{\mathsf{RH}}(s) \to \mathsf{ZeroOrbitCollapseFlow}_{\mathsf{RH}}(s).$$

Proof. The first equivalence is Definition 9242.7. The second is the projection-recovery discipline of Definition 9242.11: recovering the carrier from compatible local rows and projecting back to any displayed window returns that window's row. The third is Definition 9242.17. Each layer is a certified readback or fixed-output row, not a self-application principle. □

Remark 9242.20 (Generator fixed-point boundary)**.** *The same discipline is enforced by the* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet. A fixed-output witness is accepted only through the displayed rows* $G, L, Q, W, O, H, C, P, N$*; any diagonal or self-application attempt outside those rows remains a* GAP *boundary. The RH target therefore asks for a finite output witness, not for a host theorem that a proof generator must have a fixed point.*

Concretized in §829: GroundCompiler event-flow audit packets separate source events, channel rows, generated recognizers, certificate gates, transport, provenance, and local naming before any arithmetic or zeta meaning is read.

Concretized in §1094: Flow-level round-trip packets supply the compile-decode boundary fixed point for legal channel reads.

Concretized in §64: Prime packets supply the multiplication-split refusal rows used by the factorization fixed-point reading.

Concretized in §570: Zeta-continuation socket packets supply the finite zeta recovery rows $B, E, A, P, F, T, G, H, C,$

Concretized in §556: Generator fixed-point packets supply the fixed-output witness boundary and reject host-level self-application routes.

Concretized in §550: Critical-strip zeta-zero witness packets supply the recognized zero-event input surface consumed by the RH compiler targets.

Concretized in §548: Critical-line witness packets supply the recognized output surface equivalent to prime-unitary balance and zero-orbit collapse.

Chapter 9243

Prime-Local Balance and the RH Critical Surface

chapter 9239 states RH as the constructive implication from a critical-strip zeta-zero witness to an $\mathsf{OnCritLine}$ witness, and chapter 9241 rewrites the same obligation as a zero–skew transformer. The present chapter isolates a compatible prime-local reading of the critical line. It does not prove RH. It identifies $\Re(s) = 1/2$ as the common unit-modulus surface of the normalized prime channels that appear in the Euler-product projection of ζ.

9243.1 Zeta as a recovered carrier

Definition 9243.1 (Zeta prime-projection tower)**.** *Let $D_{>1}$ denote the half-plane $\Re(s) > 1$. The zeta prime-projection tower is the displayed packet*

$$\Pi_\zeta^{\mathrm{prime}} = \big(\zeta_D,\ (\mathsf{PrimeChan}_p)_{p\in\mathsf{Prime}^\uparrow},\ \mathsf{EulerProj},\ \mathsf{EtaRow},\ \mathsf{AnaCont}^\uparrow,\ \Gamma_\infty,\ \mathsf{FunctionalEquation},\ \mathsf{Pole}_{s=1}\big),$$

where

$$\zeta_D(s) = \sum_{n\geq 1} n^{-s}, \qquad \mathsf{PrimeChan}_p(s) = p^{-s}, \qquad \mathsf{EulerProj}(s) = \prod_{p\in\mathsf{Prime}^\uparrow} (1-p^{-s})^{-1}$$

on $D_{>1}$. The row Γ_∞ denotes the archimedean completion channel, and $\mathsf{Pole}_{s=1}$ denotes the simple-pole ledger consumed by the continuation packet.

Definition 9243.2 (Zeta recovery carrier)**.** *The BEDC-facing ZETA carrier is the analytic object recovered from the compatible projection rows*

$$\mathsf{DirichletSeries}_\zeta(s) = \sum_{n\geq 1} n^{-s} \quad \textit{on} \quad \Re(s) > 1,$$

$$\mathsf{Euler}_\zeta(s) = \prod_{p\in\mathsf{Prime}^\uparrow} (1-p^{-s})^{-1} \quad \textit{on} \quad \Re(s) > 1,$$

$$\mathsf{ZetaCont}^\uparrow, \quad \mathsf{Gamma}^\uparrow\textit{-completion rows}, \quad \textit{functional-equation mirror rows},$$
$$\textit{pole ledgers}, \quad \textit{zero ledgers}, \quad \textit{branch and transport ledgers.}$$

The Dirichlet series is therefore a readable projection of the carrier on its half-plane of absolute convergence, not the carrier by itself. Equivalently,

$$\mathsf{ZETA} = \mathrm{Rec}_{\mathsf{AnaCont}}(\Pi_\zeta^{\mathrm{prime}}),$$

where the recovery symbol records the compatible analytic-continuation, completion, pole, and transport rows rather than a primitive ambient function.

Principle 9243.3 (No projection exhausts zeta)**.** *No single projection row exhausts* ZETA*. A series expression, an Euler product, a completed functional-equation expression, and a zero ledger are compatible readings of the same recovered carrier only when their domains, overlaps, exceptional loci, and transport rows are displayed in the same certificate surface.*

Proposition 9243.4 (Euler product as prime-local gluing)**.** *On the half-plane $\Re(s) > 1$, the Dirichlet projection and the Euler prime-local projection agree:*

$$\zeta_D(s) = \mathsf{EulerProj}(s) = \prod_{p \in \mathsf{Prime}^{\uparrow}} (1 - p^{-s})^{-1}.$$

Thus the right-half-plane zeta projection is the multiplicative gluing of the prime-local channels $\mathsf{PrimeChan}_p(s) = p^{-s}$*.*

Proof. The absolute convergence of $\sum_{n \geq 1} n^{-s}$ on $\Re(s) > 1$ permits term grouping. The finite prime-factorization row supplied by $\mathsf{Prime}^{\uparrow}$ writes each positive index uniquely as a finite product

$$n = \prod_p p^{k_p}.$$

Hence

$$n^{-s} = \prod_p p^{-k_p s}.$$

Summing over positive indices is therefore equivalent, under the displayed absolute-convergence modulus, to multiplying the local geometric sums

$$\sum_{k \geq 0} p^{-ks} = (1 - p^{-s})^{-1}.$$

This is precisely the Euler-product theorem consumed by Definition 71.16. □

This principle is the analytic counterpart of Definition 9241.17. The Euler product displays the finite-prime channels. The $\mathsf{Gamma}^{\uparrow}$ row displays the archimedean channel. The functional-equation ledger displays the mirror symmetry. The critical line appears only after these rows have been assembled into the completed self-dual carrier.

9243.2 Prime-local channel normalization

Definition 9243.5 (Prime-local channels)**.** *For a displayed prime row $p \in \mathsf{Prime}^{\uparrow}$ and a complex history $s = \sigma + it$, the prime-local channel and its critical normalization are written*

$$\mathsf{PrimeChan}_p(s) = p^{-s}, \qquad \mathsf{UnitPrimeChan}_p(s) = p^{1/2} p^{-s}.$$

The centered amplitude row is

$$\mathsf{Amp}_p(s) = |\mathsf{UnitPrimeChan}_p(s)|\,.$$

Equivalently,

$$\mathsf{UnitPrimeChan}_p(s) = p^{1/2-\sigma} e^{-it \log p}.$$

Definition 9243.6 (Prime-unitary balance)**.** *The predicate* $\mathsf{PrimeUnitaryBalance}_\zeta(s)$ *holds when every displayed prime row has unit normalized amplitude:*

$$\mathsf{PrimeUnitaryBalance}_\zeta(s) :\Longleftrightarrow \forall p \in \mathsf{Prime}^\uparrow, \left|p^{1/2}p^{-s}\right| \mathsf{hsame1}.$$

This is a predicate on the prime-channel projection of the zeta carrier. It does not assert that a zero has been found, counted, or located.

Theorem 9243.7 (Prime-unitary balance is the critical line)**.** *For a complex history* $s = \sigma + it$ *and any displayed prime row* $p > 1$*,*

$$\left|p^{1/2}p^{-s}\right| = 1 \quad \Longleftrightarrow \quad \sigma = 1/2.$$

Consequently, on the $\mathsf{Prime}^\uparrow$ *packet,* $\mathsf{PrimeUnitaryBalance}_\zeta(s)$ *is equivalent to* $\mathsf{OnCritLine}(s)$*.*

Lean4 ✓ `BEDC.Derived.RHRoute.UnitaryBalance.singlePrimeUnitaryBalanceSurface norm one`

Proof. By the channel definition,

$$p^{1/2}p^{-s} = p^{1/2}p^{-(\sigma+it)} = p^{1/2-\sigma}p^{-it} = p^{1/2-\sigma}e^{-it\log p}.$$

The factor $e^{-it\log p}$ has modulus one, so

$$\left|p^{1/2}p^{-s}\right| = p^{1/2-\sigma}.$$

If $\sigma = 1/2$, this modulus is $p^0 = 1$ for every displayed prime. Conversely, if the modulus is one for a displayed prime $p > 1$, then $p^{1/2-\sigma} = 1$. Positivity and separation of the displayed prime row force $1/2 - \sigma = 0$, hence $\sigma = 1/2$. The BEDC predicate $\mathsf{OnCritLine}(s)$ is precisely the constructive read of $\Re(s)\mathsf{hsame}1/2$ from Definition 9239.7. □

Remark 9243.8 (Scope of the unit-modulus readout)**.** *The unit-modulus calculation*

$$|a^{1/2-s}| = 1 \quad \Longleftrightarrow \quad \Re(s) = 1/2$$

uses only a displayed real base $a > 1$*; primality is not needed for this geometric readout. Primes enter because the zeta carrier supplies prime-indexed Euler-product channels. The substantive prime-to-zero content is therefore not the unit-modulus equivalence itself but the boundary route that connects prime-channel skew to zero-ledger exclusion, represented by the prime-skew defect interface of Definition 9241.3.*

Corollary 9243.9 (Prime-channel amplitude tilt)**.** *Let*

$$\delta(s) = \Re(s) - 1/2.$$

Then for every displayed prime row p*,*

$$|\mathsf{UnitPrimeChan}_p(s)| = p^{-\delta(s)}.$$

Thus an off-line skew is read in the Euler-product projection as a coherent amplitude tilt across all prime-local channels.

Proof. Substitute $\sigma = \Re(s)$ into $\left|p^{1/2}p^{-s}\right| = p^{1/2-\sigma}$ and rewrite $1/2 - \sigma$ as $-\delta(s)$. □

Corollary 9243.10 (Prime-channel tilt detects off-line reads)**.** *For any displayed prime row $p > 1$,*

$$|\mathsf{UnitPrimeChan}_p(s)| \neq 1 \quad \Longleftrightarrow \quad \Re(s) \neq 1/2.$$

Equivalently, a critical-strip zero off the critical line is exactly a zero record carrying prime-local amplitude tilt.

Proof. This is the contrapositive reading of Definition 9243.7 at the displayed prime row $p > 1$, together with the amplitude formula of Definition 9243.9. □

9243.3 Prime-balanced form of RH

Definition 9243.11 (Prime-balanced RH)**.** *The prime-balanced form of the Riemann Hypothesis is the proposition*

$$\mathsf{PrimeBalancedRH}_\zeta :\Longleftrightarrow \forall s, \mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s) \Longrightarrow \mathsf{PrimeUnitaryBalance}_\zeta(s).$$

Equivalently, in the event-flow notation of Definition 9241.1, it asks for a total transformer

$$\mathsf{ZeroCode}_{\mathsf{RH}}(s) \to \mathsf{PrimeUnitaryBalance}_\zeta(s).$$

Proposition 9243.12 (Prime-balanced RH is equivalent to BEDC-RH)**.** *The proposition* $\mathsf{PrimeBalancedRH}_\zeta$ *is equivalent to the BEDC statement* RH *of Definition 9239.7. This is a scoped reparameterization of the same zero-ledger implication through the fixed-line prime-unitary readout, not an independent prime-side proof.*

Proof. The premise $\mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s)$ is exactly the premise of Definition 9239.7 and the premise packet of Definition 9241.1. By Definition 9243.7, the conclusion $\mathsf{PrimeUnitaryBalance}_\zeta(s)$ is equivalent to $\mathsf{OnCritLine}(s)$. Substitution of equivalent conclusions in the same dependent implication gives the equivalence with RH. Under Definition 9241.3, the same conclusion is the skew-zero output row written through prime-channel amplitudes instead of through the real offset $\delta(s)$ alone. □

Corollary 9243.13 (No prime-amplitude tilt form)**.** *The BEDC statement* RH *is equivalent to the assertion that no displayed critical-strip zero packet carries a displayed prime-channel amplitude tilt:*

$$\neg\exists s,\ \mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s) \wedge \exists p \in \mathsf{Prime}^{\uparrow},\ \left|p^{1/2}p^{-s}\right| \neq 1.$$

Proof. By Definition 9243.12, RH is equivalent to the implication from a critical-strip zero packet to $\mathsf{PrimeUnitaryBalance}_\zeta(s)$. Expanding Definition 9243.6 gives unit amplitude for every displayed prime row. A counter-witness to that universal row is exactly a displayed prime-channel amplitude tilt on a displayed critical-strip zero packet. □

Definition 9243.14 (Prime-channel RH witness)**.** *The prime-channel RH witness type is*

$$\mathsf{PrimeRHWitness}_\zeta = \prod_s (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)) \to \prod_{p \in \mathsf{Prime}^{\uparrow}} \mathsf{hsame}\left(\left|p^{1/2}p^{-s}\right|, 1\right).$$

The ordinary RH witness type is

$$\mathsf{RHWitness}_\zeta = \prod_s (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)) \to \mathsf{OnCritLine}(s).$$

Proposition 9243.15 (Prime and ordinary RH witnesses are equivalent)**.** *There is a canonical equivalence*

$$\mathsf{PrimeRHWitness}_\zeta \simeq \mathsf{RHWitness}_\zeta.$$

Proof. For each s, Definition 9243.7 identifies the prime-unitary output row with $\mathsf{OnCritLine}(s)$. Applying this pointwise to the common input packet $\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)$ converts a prime-channel witness into an ordinary witness and conversely. The two conversions are inverse because both read the same equality $\Re(s)\mathsf{hsame}1/2$ through different projection rows. □

Remark 9243.16 (Prime balance is not an Euler-factor proof)**.** *The implication in Definition 9243.11 is not a claim that a single Euler factor proves* RH*. A factor* $(1-p^{-s})^{-1}$ *is only one local prime projection. It does not carry the non-trivial zero locus of* ζ*, and it does not supply analytic continuation, a pole ledger, a* $\mathsf{Gamma}^{\uparrow}$ *boundary, or the functional-equation mirror row. The critical axis is a feature of the completed recovered carrier, while a single normalized prime channel only exhibits the amplitude test that any point on that axis must pass.*

9243.4 Archimedean completion and the central surface

Definition 9243.17 (Completed zeta surface)**.** *The completed zeta surface is the recovery packet whose displayed analytic core has the classical shape*

$$\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$$

together with the functional-equation row

$$\xi(s) = \xi(1-s).$$

The finite-prime rows enter through the Euler-product projection of ζ*. The archimedean row enters through the* $\pi^{-s/2}\Gamma(s/2)$ *factor. The factor* $s(s-1)$ *records the pole-cancellation ledger at* $s=1$ *and* $s=0$*.*

Proposition 9243.18 (The critical surface is self-dual)**.** *Inside the completed zeta surface, the line* $\Re(s) = 1/2$ *is the fixed surface of the mirror* $s \mapsto 1-s$ *on the real component. The prime-unitary balance predicate of Definition 9243.6 is the finite-prime amplitude read of the same central normalization.*

Proof. The functional-equation row identifies the completed carrier at s with the completed carrier at $1-s$. The real components of s and $1-s$ agree exactly when $\Re(s) = 1/2$. By Definition 9243.7, this equality is also equivalent to unit normalized amplitude for every displayed prime-local channel. Therefore the same central surface has two compatible reads: a mirror fixed-surface read through the completed carrier and a unit-amplitude read through the Euler-product projection. □

Proposition 9243.19 (Prime mirror inversion)**.** *Let* $J(s) = 1-\overline{s}$ *be the mirror map of Definition 9241.12, and write*

$$U_p(s) = p^{1/2-s}.$$

For every displayed prime row p*,*

$$U_p(J(s)) = \frac{1}{\overline{U_p(s)}}.$$

Consequently,

$$|U_p(J(s))| = |U_p(s)|^{-1}.$$

Proof. Write $s = \sigma + it$. Then

$$U_p(s) = p^{1/2-\sigma} e^{-it\log p}, \qquad \overline{U_p(s)} = p^{1/2-\sigma} e^{it\log p},$$

so

$$\frac{1}{\overline{U_p(s)}} = p^{\sigma-1/2} e^{-it\log p}.$$

Since

$$J(s) = 1 - \overline{s} = 1 - \sigma + it,$$

one also has

$$U_p(J(s)) = p^{1/2-(1-\sigma+it)} = p^{\sigma-1/2} e^{-it\log p}.$$

The displayed equality follows, and taking moduli gives the amplitude inversion row. □

Corollary 9243.20 (Fixed mirror amplitude surface)**.** *The critical line is the unique surface on which every displayed normalized prime channel is fixed in amplitude by the mirror J:*

$$s = J(s) \quad \Longleftrightarrow \quad \forall p \in \mathsf{Prime}^{\uparrow},\ |U_p(s)| = 1.$$

Proof. If $s = J(s)$, Definition 9243.19 gives $|U_p(s)| = |U_p(s)|^{-1}$ for every displayed prime row. Since the channel amplitude is positive, $|U_p(s)| = 1$. Conversely, if every normalized prime-channel amplitude is one, then Definition 9243.7 gives $\Re(s) = 1/2$, which is equivalent to $s = J(s)$ by Definition 9241.12. □

Remark 9243.21 (Role of the archimedean row)**.** *The finite-prime channels explain the local amplitude test, but they do not by themselves determine the completed self-dual carrier. The $\pi^{-s/2}\Gamma(s/2)$ row supplies the archimedean channel that normalizes the functional equation into the $s \leftrightarrow 1-s$ mirror form. Without that row, the expression still has prime-local projections, but the central self-dual surface is not a closed recovery certificate.*

9243.5 Projection tower reading

Principle 9243.22 (Projection tower lifting)**.** *After ζ has been recovered as a meromorphic carrier on $\mathsf{Complex}^{\uparrow} \setminus \{1\}$, further structural work is not a larger complex-domain continuation. It is a lifting through projection towers:*

$$\zeta(s) \to \xi(s) \to \textit{prime-local channel packets} \to \textit{explicit-formula ledgers} \to \textit{adelic zeta-integral packets} \to \mathsf{LFunction}^{\uparrow}$$

Each arrow adds rows that explain how a displayed projection is recovered from or compared with a richer carrier. It does not license an unstated branch, zero oracle, or ambient analytic primitive.

Remark 9243.23 (Schematic L-function generalization)**.** *The same surface reading has a schematic counterpart for any displayed $\mathsf{LFunction}^{\uparrow}$ carrier whose packet contains a Dirichlet-series row, an Euler product row, prime-local factors, archimedean completion rows, analytic continuation, a functional equation, and pole or branch ledgers. Its central line is the fixed surface of its completed functional-equation mirror, and the analogue of prime-unitary balance is the assertion that all normalized finite-prime channels have unit amplitude on that surface. This is a schema-level reading of the generalized RH shape, not a closed theorem about all L-carriers.*

Proposition 9243.24 (Norm-local central unit surface)**.** *Let v be a displayed finite local channel of an* $\mathsf{LFunction}^{\uparrow}$ *carrier, and let $N(v) > 1$ be its local norm. For*

$$U_v(s) = N(v)^{1/2-s},$$

one has

$$|U_v(s)| = 1 \quad \Longleftrightarrow \quad \Re(s) = 1/2.$$

Proof. Writing $s = \sigma + it$ gives

$$U_v(s) = N(v)^{1/2-\sigma} e^{-it \log N(v)}.$$

The phase factor has modulus one, hence

$$|U_v(s)| = N(v)^{1/2-\sigma}.$$

Since $N(v) > 1$, this modulus is one exactly when $1/2 - \sigma = 0$. □

Theorem 9243.25 (Prime-local projection normal form)**.** *The RH projection reading is the conjunction of the following equivalent normal forms:*

$\mathsf{ZETA} = \mathrm{Rec}_{\mathsf{AnaCont}}(\textit{Dirichlet projection}, \textit{prime-local projection}, \textit{archimedean completion}, \textit{functional equation}, \textit{pole l}$

$$\mathsf{PrimeUnitaryBalance}_{\zeta}(s) \Longleftrightarrow \Re(s) = 1/2 \Longleftrightarrow s = J(s),$$

and

$$\mathsf{RH} \Longleftrightarrow \forall s,\ \mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s) \Longrightarrow \mathsf{PrimeUnitaryBalance}_{\zeta}(s).$$

Proof. The recovery line is Definition 9243.2 read through the prime-projection tower of Definition 9243.1. The second line combines Definition 9243.7 with the fixed-point characterization of Definition 9241.12. The third line is exactly Definition 9243.12. □

Concretized in §64: The prime-local channel rows are indexed by the finite $\mathsf{Prime}^{\uparrow}$ NameCert surface.

Concretized in §71: The Euler-product projection supplying p^{-s} channels is read through the $\mathsf{ZetaBasic}^{\uparrow}$ half-plane certificate.

Concretized in §580: The zeta-continuation witness packet supplies the continuation, pole, trivial-zero, and Gamma-boundary rows consumed before a zero-facing carrier can be read.

Concretized in §581: The zeta functional-equation ledger supplies the completed-carrier mirror row whose fixed surface is the critical line.

Concretized in §548: Critical-line witness packets provide the finite $\mathsf{OnCritLine}$ output surface equivalent to prime-unitary balance.

Concretized in §103: The $\mathsf{LFunction}^{\uparrow}$ interface provides the schematic family carrier for the corresponding central-line balance reading.

Chapter 9244

Finite Prime Windows and Local–Global RH Gluing

chapter 9243 identifies the critical line with unit amplitude on the normalized prime-local channels. This chapter records the proof-program boundary suggested by that reading. Finite prime windows give auditable local tests, but a finite window is not the recovered zeta carrier. A local proof route reaches RH only after the finite-prime rows, the archimedean completion row, the functional equation, and the zero ledger are glued into one carrier-level exclusion.

9244.1 Finite Prime Windows

Definition 9244.1 (Finite prime window)**.** *A finite prime window is a finite displayed set*

$$S \subseteq \mathsf{Prime}^{\uparrow}.$$

For s in the zeta carrier, its window amplitude readout is

$$\mathsf{Amp}_S(s) := \big(\mathsf{Amp}_p(s)\big)_{p \in S},$$

where Amp_p is the centered amplitude row of Definition 9243.5. The unit-window predicate is

$$\mathsf{UnitWindow}_S(s) := \prod_{p \in S} \big(\mathsf{Amp}_p(s) = 1\big).$$

Theorem 9244.2 (Nonempty finite windows detect the half surface)**.** *If S is nonempty, then*

$$\mathsf{UnitWindow}_S(s) \iff \mathsf{OnCritLine}(s).$$

Proof. If $\mathsf{UnitWindow}_S(s)$ holds, choose a displayed row $p \in S$. The window predicate gives $\mathsf{Amp}_p(s) = 1$, and Definition 9243.7 gives $\mathsf{OnCritLine}(s)$. Conversely, if $\mathsf{OnCritLine}(s)$ holds, then the same theorem gives $\mathsf{Amp}_p(s) = 1$ for every displayed prime row, hence for every $p \in S$. □

Definition 9244.3 (Finite-window RH target)**.** *For a finite prime window S, define*

$$\mathsf{RH}_S := \prod_s \big(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{UnitWindow}_S(s)\big).$$

Theorem 9244.4 (Nonempty finite-window RH has full RH strength)**.** *If S is nonempty, then*

$$\mathsf{RH}_S \iff \mathsf{RH}.$$

Proof. Substitute the equivalence of Definition 9244.2 into the output predicate of Definition 9244.3. The result is exactly the BEDC statement of Definition 9239.7. □

Principle 9244.5 (Window localization changes the interface, not the strength)**.** *Proving the unit-window target for any nonempty finite prime window already has the strength of* RH*. The local route is useful only as a change of interface: it exposes how an off-line zero would appear as coherent amplitude defect in every prime-local channel. It does not make a single Euler factor into a zero carrier.*

9244.2 Local Defect Rows

Definition 9244.6 (Prime defect row)**.** *Let*

$$s = 1/2 + \delta(s) + i\tau(s).$$

For a displayed prime row p, define the local defect row

$$D_p(s) := \log \mathsf{Amp}_p(s).$$

By Definition 9243.9,

$$D_p(s) = -\delta(s) \log p.$$

Definition 9244.7 (Finite-window total defect)**.** *For a finite prime window S, define*

$$D_S(s) := \sum_{p \in S} D_p(s).$$

Equivalently,

$$D_S(s) = -\delta(s) \sum_{p \in S} \log p.$$

Theorem 9244.8 (Apart non-fixed rows create local defects)**.** *If $|\delta(s)| \geq \varepsilon$ for some $\varepsilon : \mathbb{Q}_{>0}$, then for every displayed prime row p,*

$$|D_p(s)| \geq \varepsilon \log p.$$

Proof. By Definition 9244.6,

$$|D_p(s)| = |\delta(s)| \log p.$$

Since $p > 1$, the displayed prime row has $\log p > 0$. The premise $|\delta(s)| \geq \varepsilon$ therefore gives the stated lower bound. □

Theorem 9244.9 (Finite-window defect accumulation)**.** *If $|\delta(s)| \geq \varepsilon$ for some $\varepsilon : \mathbb{Q}_{>0}$, then for every finite prime window S,*

$$|D_S(s)| \geq \varepsilon \sum_{p \in S} \log p.$$

Proof. The equality in Definition 9244.7 gives

$$|D_S(s)| = |\delta(s)| \sum_{p \in S} \log p.$$

The lower bound follows from $|\delta(s)| \geq \varepsilon$. □

9244.3 Carrier Gluing

Definition 9244.10 (Completed gluing surface)**.** *The completed gluing surface for a zeta row consists of the compatible packet*

$$\mathsf{FinitePrimeRows}+\mathsf{ArchimedeanRow}+\mathsf{FunctionalEquation}+\mathsf{PoleLedger}+\mathsf{ZeroLedger}+\mathsf{BranchTransport}.$$

Here $\mathsf{ArchimedeanRow}$ *denotes the* $\pi^{-s/2}\Gamma(s/2)$ *completion row. This surface is the carrier-level context of Definition 9243.2.*

Theorem 9244.11 (Pure finite windows are not zero carriers)**.** *A pure finite prime window can detect amplitude defect, but it cannot by itself decide whether the recovered zeta carrier has a non-trivial zero at the displayed row.*

Proof. By Definition 9244.8, finite prime windows read off local amplitude defects. By Definition 9243.3 and Definition 9243.2, the non-trivial zero ledger belongs to the recovered carrier assembled from Dirichlet, Euler, continuation, archimedean, functional-equation, pole, zero, branch, and transport rows. A pure finite prime window contains only a finite part of the Euler-product projection and omits the archimedean and zero-ledger rows. It therefore is not a carrier on which zeta-zero exclusion can be closed. □

Definition 9244.12 (Local-global zero exclusion)**.** *The local-global zero exclusion target is*

$$\mathsf{LocalGlobalZeroExclusion}_\zeta := \prod_{c:\mathcal{C}_\zeta} (\mathsf{ApartNonFix}_J(c) \to \mathsf{Apart}_0(\zeta(c))).$$

It is the assertion that a critical-strip row with positive distance from the mirror fixed surface cannot glue, through the completed zeta carrier, to a zero ledger.

Theorem 9244.13 (Local-global zero exclusion is the local proof target)**.** *Assume the bias readout is located and that* $\mathsf{Apart}_0(\zeta(c))$ *contradicts* $Z_\zeta(c)$*. Then* $\mathsf{LocalGlobalZeroExclusion}_\zeta$ *supplies the source fixed section* $\mathsf{ZeroFix}_\zeta$*, hence the BEDC-RH section target.*

Proof. The type of Definition 9244.12 is the apart orbit exclusion type of Definition 9334.3. Applying Definition 9334.7 yields $\mathsf{ZeroFix}_\zeta$. The equivalence between this fixed section and the BEDC-RH section target is Definition 9334.4. □

Principle 9244.14 (Local–global RH proof format)**.** *The local proof format has four displayed obligations: local defect rows for apart non-fixed inputs, finite-window accumulation of those defects, archimedean normalization into the completed carrier, and zero-ledger exclusion for completed rows carrying the defect. The composition of these obligations is exactly* $\mathsf{LocalGlobalZeroExclusion}_\zeta$*; without the final completed carrier step, the route remains a local projection analysis rather than an RH proof.*

Concretized in §8765: Finite prime-window gluing is realized as finite prime-row, defect-row, gluing-ledger, zero-boundary, transport, replay, provenance, and local NameCert data.

Chapter 9245

Prime Window Recursive Tower

chapter 9244 describes the local prime-window proof target for RH. The present chapter records the recursive tower form of the same target. Each layer is read through finite prime windows; layer transitions are allowed only through displayed readback, predicate inheritance, and certified recursive return; an exception must therefore become visible in some finite prime-window readout before it can be transported as a tower-internal object.

Concretized in §8765: FinitePrimeWindowGluingUp realizes the finite prime-window gluing route as displayed prime rows, defect rows, zero-boundary request, transport, replay, provenance, and local NameCert data.

9245.1 Prime-Window Layer Data

Definition 9245.1 (Prime-window tower layer)**.** *A prime-window tower layer is a concept layer*

$$\mathcal{L}_n = (R_n, \sim_n, P_n, \Lambda_n, \mathsf{Cert}_n, \mathsf{Aud}_n)$$

over the source carrier, together with a readout

$$P_n : T \to R_n$$

and, for each successor step, a readback map

$$\rho_{n+1} : R_{n+1} \to R_n$$

such that

$$\rho_{n+1}(P_{n+1}(t)) \sim_n P_n(t).$$

Definition 9245.2 (Layer prime coding)**.** *A layer prime coding for $\mathcal{L}_n$ is a code-readback pair*

$$\mathrm{code}_n : R_n \to \mathbb{N}, \qquad \mathrm{decode}_n : \mathrm{im}(\mathrm{code}_n) \to R_n$$

with certificate

$$\mathrm{decode}_n(\mathrm{code}_n(r)) \sim_n r.$$

Definition 9245.3 (Layer prime-window split)**.** *For a finite prime window $S \subseteq \mathsf{Prime}^{\uparrow}$, the S-window split of the layer R_n is the readout*

$$\Pi_{n,S} : R_n \to \mathbb{N}^S, \qquad \Pi_{n,S}(r) := \big(v_p(\mathrm{code}_n(r))\big)_{p \in S}.$$

Theorem 9245.4 (Finite windows are layer quotients)**.** *For any layer n and finite prime window S, equality of $\Pi_{n,S}(r)$ and $\Pi_{n,S}(r')$ means that r and r' are indistinguishable by every displayed prime-coordinate readout in S.*

Proof. By Definition 9245.3, equality of the two S-window values is precisely the family of equalities

$$v_p(\mathrm{code}_n(r)) = v_p(\mathrm{code}_n(r'))$$

for all $p \in S$. These are exactly the displayed prime-coordinate reads available inside the finite window. □

9245.2 Readback and Recursive Return

Definition 9245.5 (Prime-code compatible readback)**.** *The successor readback $\rho_{n+1} : R_{n+1} \to R_n$ is prime-code compatible when there is a displayed map*

$$\kappa_{n+1} : \mathbb{N} \to \mathbb{N}$$

such that

$$\mathrm{code}_n(\rho_{n+1}(r)) = \kappa_{n+1}(\mathrm{code}_{n+1}(r)).$$

Theorem 9245.6 (Prime-window inheritance)**.** *If ρ_{n+1} is prime-code compatible, then every finite S-window readout on layer n pulls back along ρ_{n+1} to the corresponding finite coordinate family on layer $n+1$:*

$$\Pi_{n,S}(\rho_{n+1}(r)) = \big(v_p(\kappa_{n+1}(\mathrm{code}_{n+1}(r)))\big)_{p\in S}.$$

Proof. Expand Definition 9245.3:

$$\Pi_{n,S}(\rho_{n+1}(r)) = \big(v_p(\mathrm{code}_n(\rho_{n+1}(r)))\big)_{p\in S}.$$

Substitute the compatibility equality of Definition 9245.5. The displayed formula follows. □

Definition 9245.7 (Prime recursive return)**.** *The prime recursive return at layer n is the composite*

$$R_n \xrightarrow{\mathrm{code}_n} \mathbb{N} \xrightarrow{p\mapsto v_p} \mathbb{N}^{(\mathsf{Prime}^{\uparrow})} \xrightarrow{\mathrm{rec}} \mathbb{N} \xrightarrow{\mathrm{decode}_n} R_n,$$

where

$$\mathrm{rec}(a) := \prod_{p\in\mathsf{Prime}^{\uparrow}} p^{a_p}$$

for finite-support exponent families.

Theorem 9245.8 (Recursive return closes on the layer)**.** *Assume unique factorization for $\mathrm{code}_n(r)$ and the decode certificate of Definition 9245.2. Then the prime recursive return sends r back to an equivalent row:*

$$\mathrm{decode}_n\big(\mathrm{rec}(p \mapsto v_p(\mathrm{code}_n(r)))\big) \sim_n r.$$

Proof. Unique factorization gives

$$\mathrm{rec}(p \mapsto v_p(\mathrm{code}_n(r))) = \mathrm{code}_n(r).$$

The decode certificate then gives $\mathrm{decode}_n(\mathrm{code}_n(r)) \sim_n r$. □

9245.3 No-Exception Invariant

Definition 9245.9 (Layer zero carrier and window no-exception)**.** *Let $\mathcal{Z}_n \subseteq R_n$ be the layer-visible critical-strip zeta-zero carrier. For a nonempty finite prime window S, define*

$$\mathsf{NoExc}_n(S) := \prod_{z \in \mathcal{Z}_n} \mathsf{UnitWindow}_S(z).$$

The corresponding exception type is

$$\mathsf{Exc}_n(S) := \sum_{z \in \mathcal{Z}_n} \neg\mathsf{UnitWindow}_S(z).$$

Theorem 9245.10 (Nonempty window no-exception is layer RH)**.** *For a nonempty finite prime window S, the predicate $\mathsf{NoExc}_n(S)$ is equivalent to the layer statement that every visible zero row lies on the half surface.*

Proof. For each $z \in \mathcal{Z}_n$, Definition 9244.2 identifies $\mathsf{UnitWindow}_S(z)$ with $\mathsf{OnCritLine}(z)$. Taking the dependent product over $\mathcal{Z}_n$ gives the stated equivalence. □

Theorem 9245.11 (No-exception inheritance)**.** *Suppose the successor readback preserves the layer zero carriers and the finite-window readouts. Then*

$$\mathsf{NoExc}_n(S) \to \mathsf{NoExc}_{n+1}(S).$$

Proof. Let $z_{n+1} \in \mathcal{Z}_{n+1}$. Zero-carrier preservation gives $\rho_{n+1}(z_{n+1}) \in \mathcal{Z}_n$. From $\mathsf{NoExc}_n(S)$ one gets $\mathsf{UnitWindow}_S(\rho_{n+1}(z_{n+1}))$. Window-readout preservation transports this row to $\mathsf{UnitWindow}_S(z_{n+1})$. Since z_{n+1} was arbitrary, $\mathsf{NoExc}_{n+1}(S)$ follows. □

Corollary 9245.12 (Recursive no-exception propagation)**.** *If $\mathsf{NoExc}_{n_0}(S)$ holds at one layer and every later successor step satisfies the hypotheses of Definition 9245.11, then $\mathsf{NoExc}_m(S)$ holds for every $m \geq n_0$.*

Proof. Iterate Definition 9245.11 along the finite interval from n_0 to m. □

9245.4 Prime-Recursive RH Target

Theorem 9245.13 (Exception visibility in finite windows)**.** *If a row s has a positive off-line bias witness $|\delta(s)| \geq \varepsilon$, then every nonempty finite prime window sees a failure of the unit-window predicate.*

Proof. By Definition 9244.8, every displayed prime row has a nonzero local defect. Hence for each p in a nonempty window, $\mathsf{Amp}_p(s) \neq 1$, so $\mathsf{UnitWindow}_S(s)$ fails. □

Theorem 9245.14 (Prime-recursive no-exception target)**.** *Assume the tower has layer prime codings, prime-code compatible readbacks, recursive returns closed by unique factorization, readback preservation of zero carriers and finite-window readouts, and the completed-carrier exclusion target*

$$\mathsf{LocalGlobalZeroExclusion}_\zeta.$$

Then the tower has no RH exception: every critical-strip zeta-zero row projects to the half surface.

Proof. The finite prime-window apparatus makes any positive off-line bias visible by Definition 9245.13. The recursive return theorem Definition 9245.8 keeps the finite-window analysis inside the same layer, and Definition 9245.11 transports no-exception rows through compatible readbacks. The only remaining global step is the completed-carrier exclusion target Definition 9244.12. By Definition 9244.13, that target supplies the source fixed section and therefore the BEDC-RH section target. □

Principle 9245.15 (Prime-recursive no-exception boundary)**.** *The formal content of the prime-window recursive tower is not that every local factor closes* RH*. It is that any noncentral radial defect must be visible in finite prime windows, must survive only through certified readback and recursive return, and must finally fail to glue to the completed zeta zero ledger. The named target remains* $\mathsf{LocalGlobalZeroExclusion}_{\zeta}$*.*

Chapter 9246

Local–Global Zero Exclusion Target

chapter 9244 and chapter 9245 reduce the local prime-window route to one remaining object:

$$\mathsf{LocalGlobalZeroExclusion}_\zeta.$$

The present chapter records that object as the proof target. It does not introduce another route layer. It separates the local finite-window algebra, the source-compatibility rows, the archimedean completion row, and the carrier-level incompatibility obligation.

9246.1 Target Statement

Definition 9246.1 (Local-global zero exclusion target)**.** *The target is the dependent product*

$$\mathsf{LocalGlobalZeroExclusion}_\zeta := \prod_{c:\mathcal{C}_\zeta} (\mathsf{ApartNonFix}_J(c) \to \mathsf{Apart}_0(\zeta(c))).$$

Equivalently, it says that a critical-strip row separated from the mirror fixed surface by a positive rational witness cannot carry a zeta-zero row inside the completed zeta carrier.

Definition 9246.2 (Zero-ledger fixed-half geometry)**.** *The zero-ledger fixed-half geometry is the inclusion-style statement*

$$\mathsf{ZeroLedger}_\zeta \subseteq \mathrm{Fix}(J),$$

read internally as

$$\prod_{c:\mathcal{C}_\zeta} (Z_\zeta(c) \to J_\zeta(c) = c).$$

The notation does not introduce a host-side point set of zeros. It is the source fixed-section target of Definition 9334.3, read inside the completed zeta carrier of Definition 9254.13.

Definition 9246.3 (Zero, fixed, and off-fixed subcarriers)**.** *Let $\mathbb{G}^0_\zeta$ denote the RH-neutral zeta carrier of Definition 9250.17. The zero-ledger, fixed-half, and off-fixed subcarriers are the pullback carriers*

$$\mathbb{Z}_\zeta := \sum_{g:\mathbb{G}^0_\zeta} \mathsf{ZeroLedger}(g),$$

$$\mathbb{H}_\zeta := \sum_{g:\mathbb{G}^0_\zeta} \mathsf{FixHalf}(g),$$

and

$$\mathbb{O}_\zeta := \sum_{g:\mathbb{G}^0_\zeta} \mathsf{ApartNonFix}_J(g).$$

They are not compared as unrelated types. They are subcarriers over the same ambient recovered carrier, and their projections to $\mathbb{G}^0_\zeta$ carry the SameSource or SameCarrier certificates required for any containment, intersection, or apartness claim.

Principle 9246.4 (Containment, not orthogonality)**.** *The RH geometry is not an orthogonality claim between $\mathbb{Z}_\zeta$ and $\mathbb{H}_\zeta$. It is the factorization of the zero-ledger projection through the fixed-half subcarrier, equivalently the containment*

$$\mathbb{Z}_\zeta \subseteq \mathbb{H}_\zeta.$$

The apartness target concerns $\mathbb{Z}_\zeta$ and the off-fixed subcarrier $\mathbb{O}_\zeta$:

$$\mathbb{Z}_\zeta \cap \mathbb{O}_\zeta = \varnothing$$

with a positive-apartness witness rather than a bare empty-intersection assertion.

Principle 9246.5 (Recovered-carrier geometry, not point-set geometry)**.** *The geometric ambient object for the RH target is $\mathbb{G}^0_\zeta$, not the complex plane regarded as a bare point set. The complex coordinate s is a readout of a recovered carrier row whose data include Dirichlet, Euler, continuation, archimedean-completion, functional-equation, pole-ledger, zero-ledger, branch-transport, and prime-fingerprint projections. Consequently the traditional statement*

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \Re(s) = 1/2$$

is the complex-plane projection of the carrier containment

$$\mathbb{Z}_\zeta \subseteq \mathbb{H}_\zeta.$$

Equivalently, it is the assertion that the zero-ledger projection from the recovered carrier factors through the fixed-half subcarrier before any external complex-plane reading is taken.

Principle 9246.6 (Fixed half as rational center with phase fiber)**.** *The fixed-half subcarrier is not an irrational-number subcarrier. Its center row is the rational half value $1/2$. The residual freedom on the fixed surface is the phase fiber*

$$s = \frac{1}{2} + i\tau,$$

read in centered prime channels as

$$U_p(s) = e^{-i\tau \log p}.$$

Thus irrational, transcendental, logarithmic, and phase data may occur in the fiber over the fixed center, while the fixed-half equation itself is the rational-center row $\Re(s) = 1/2$.

Theorem 9246.7 (Geometric compression of RH)**.** *The geometric statement*

$$\mathsf{ZeroLedger}_\zeta \subseteq \mathrm{Fix}(J)$$

is the same RH target as the section form $\mathsf{Sec}_{\mathsf{RH}}$.

Proof. By Definition 9246.2, the displayed inclusion is the product

$$\prod_{c:\mathcal{C}_\zeta} (Z_\zeta(c) \to J_\zeta(c) = c),$$

which is $\mathsf{ZeroFix}_\zeta$ in Definition 9334.3. The equivalence with $\mathsf{Sec}_{\mathsf{RH}}$ is Definition 9334.4. □

Theorem 9246.8 (Local-global zero exclusion gives the RH witness target)**.** *Assume the real bias readout is located and that* $\mathsf{Apart}_0(\zeta(c))$ *contradicts* $Z_\zeta(c)$*. Then Definition 9246.1 supplies the BEDC-RH witness target of Definition 9239.8.*

Proof. The target is the apart orbit exclusion used in Definition 9334.7. That theorem supplies $\mathsf{ZeroFix}_\zeta$. By Definition 9334.4, the source fixed section is equivalent to the BEDC-RH section form, which is the constructive witness target of Definition 9239.8. □

9246.2 Finite-Window Algebra

Definition 9246.9 (Prime-window packet)**.** *For a nonempty finite prime window* S *and a row* s*, the prime-window packet consists of the finite data*

$$\mathsf{PrimeWindow}_S(s) := (S,\ (p \in S),\ U_p(s),\ \mathsf{Amp}_p(s),\ D_S(s),\ \mathsf{UnitWindow}_S(s)),$$

together with the certificate rows of Definition 9244.1 and Definition 9244.7.

Theorem 9246.10 (Prime-window defect formula)**.** *If*

$$s = 1/2 + \delta(s) + i\tau(s),$$

then for every nonempty finite prime window S*,*

$$|D_S(s)| = |\delta(s)| \sum_{p \in S} \log p.$$

Consequently, $|D_S(s)| = 0$ *if and only if* $\mathsf{OnCritLine}(s)$*.*

Proof. The equality is Definition 9244.9 with the lower-bound premise specialized to equality through Definition 9244.7. Since each $\log p$ is positive and S is nonempty, the sum is positive. Thus $|D_S(s)| = 0$ exactly when $|\delta(s)| = 0$, equivalently when $\Re(s) = 1/2$, which is $\mathsf{OnCritLine}(s)$ by Definition 9239.7. □

9246.3 Carrier Compatibility Obligations

Definition 9246.11 (Zeta-carrier source compatibility)**.** *The zeta-carrier source compatibility obligation is the row*

$$\mathsf{ZetaCarrierCompatibility}_S(s)$$

asserting that the zero-ledger read of s *and the prime-window read* $\mathsf{PrimeWindow}_S(s)$ *are two projections of the same source row, with a displayed readback witness:*

$$\mathsf{SameSource}(\mathsf{ZeroLedger}(s), \mathsf{PrimeWindow}_S(s)).$$

Definition 9246.12 (Archimedean completion obligation)**.** *The archimedean completion obligation is the carrier row*

$$\mathsf{ArchimedeanCompletionRow}(s)$$

which supplies the $\pi^{-s/2}\Gamma(s/2)$ *completion term and the functional-equation mirror transport needed to enter the completed carrier:*

$$\mathsf{FinitePrimeRows} + \mathsf{ArchimedeanRow} + \mathsf{FunctionalEquation} \to \mathsf{CompletedCarrier}.$$

Definition 9246.13 (Defect-zero incompatibility)**.** *The central analytic obligation is*

$$\mathsf{DefectZeroIncompatibility}$$

with type

$$\prod_s (\mathsf{InCritStrip}(s) \times \mathsf{CompletedCarrier}(s) \times \sum_{S \subset_{\mathrm{fin}} \mathsf{Prime}^{\uparrow}} (S \neq \varnothing) \times (|D_S(s)| > 0) \to \mathsf{Apart}_0(\zeta(s))).$$

9246.4 Positive Defect Certificates

Definition 9246.14 (Finite radial energy)**.** *For a nonempty finite prime window* S *and positive weights* $(w_p)_{p\in S}$*, the finite radial energy of a row* s *is*

$$E_S(s) := \sum_{p\in S} w_p \big(\log |p^{1/2-s}|\big)^2.$$

Using the centered form

$$p^{1/2-s} = p^{-\delta(s)} e^{-i\tau(s)\log p},$$

this energy is

$$E_S(s) = \delta(s)^2 \sum_{p\in S} w_p (\log p)^2.$$

Proposition 9246.15 (Finite radial energy detects the fixed half)**.** *For every nonempty finite prime window* S *with positive weights,*

$$E_S(s) = 0 \quad \Longleftrightarrow \quad \mathsf{OnCritLine}(s).$$

Proof. The weight sum

$$\sum_{p\in S} w_p (\log p)^2$$

is positive because S is nonempty, every displayed weight is positive, and every prime has $\log p > 0$. Hence $E_S(s) = 0$ exactly when $\delta(s)^2 = 0$, equivalently $\delta(s) = 0$. This is the fixed-half condition $\Re(s) = 1/2$, namely $\mathsf{OnCritLine}(s)$. □

Definition 9246.16 (Constructive bad-zero packet)**.** *For a displayed positive rational* q*, a constructive bad-zero packet is*

$$\mathsf{BadZero}_q(s) := \mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \big(|\delta(s)| \geq q\big).$$

The third row is a positive radial-defect certificate. It is stronger than the bare negation $\delta(s) \neq 0$ *and is the form consumed by finite-window apartness arguments.*

Proposition 9246.17 (Bad zeros create finite radial energy)**.** *If* $\mathsf{BadZero}_q(s)$ *holds and* S *is a nonempty finite prime window with positive weights, then*

$$E_S(s) \geq q^2 \sum_{p \in S} w_p (\log p)^2 > 0.$$

Proof. The defect row of Definition 9246.16 gives $|\delta(s)| \geq q$. Squaring and substituting into Definition 9246.14 gives the displayed lower bound. The right-hand weight sum is positive by the proof of Definition 9246.15, so the energy is positive. □

Principle 9246.18 (No tail absorption row)**.** *Finite radial energy is a certificate interface, not a completed-carrier exclusion by itself. The missing carrier-level row is the assertion that a positive finite-window radial defect cannot be absorbed by the remaining Euler tail, the archimedean completion row, or the functional-equation transport while still carrying a zero ledger:*

$$\mathsf{CompletedCarrier}(s) \times \sum_{S \subset_{\mathrm{fin}} \mathsf{Prime}^{\uparrow}} (E_S(s) > 0) \Longrightarrow \mathsf{Apart}_0(\zeta(s)).$$

This is the radial-energy presentation of Definition 9246.13. It must be proved as a carrier-rigidity statement; it is not a consequence of finite enumeration alone.

Theorem 9246.19 (Bad-zero contradiction route)**.** *Assume source compatibility, archimedean completion, and the no-tail absorption row of Definition 9246.18. Assume also that* $\mathsf{Apart}_0(\zeta(s))$ *contradicts* $\mathsf{ZetaZero}(s)$*. Then no constructive bad-zero packet exists.*

Proof. Assume $\mathsf{BadZero}_q(s)$. Choose a nonempty finite prime window S with positive weights. By Definition 9246.17, this packet supplies $E_S(s) > 0$. Source compatibility identifies this finite-window defect with a projection of the same source row as the zero ledger, and the archimedean completion row places the data in the completed carrier. The no-tail absorption row yields $\mathsf{Apart}_0(\zeta(s))$, contradicting the $\mathsf{ZetaZero}(s)$ component of Definition 9246.16. □

9246.5 Obligation Assembly

Theorem 9246.20 (Four obligations assemble the target)**.** *Suppose the following rows are supplied for every relevant critical-strip row: prime-window packets with the defect formula, zeta-carrier source compatibility, archimedean completion into the completed carrier, and Definition 9246.13. Then* $\mathsf{LocalGlobalZeroExclusion}_\zeta$ *holds.*

Proof. Let $c : \mathcal{C}_\zeta$ and assume $a : \mathsf{ApartNonFix}_J(c)$. Choose a nonempty finite window S. By Definition 9246.10, the apart witness gives $|D_S(c)| > 0$. Source compatibility identifies the zero-ledger row and the prime-window row as projections of the same source item. The archimedean completion row places the finite-prime data in the completed carrier. Applying Definition 9246.13 yields $\mathsf{Apart}_0(\zeta(c))$, which is the required output of Definition 9246.1. □

Definition 9246.21 (Geometric rigidity contradiction schema)**.** *The geometric rigidity contradiction schema is the proof route*

$$\mathsf{ZeroLedger}(c) \times \mathsf{ApartNonFix}_J(c) \times \mathsf{CompletedCarrier}(c) \longrightarrow \bot$$

obtained by first strengthening the off-fixed premise to a positive finite-window defect and then applying the carrier-level incompatibility row

$$\mathsf{DefectZeroIncompatibility}.$$

Its constructive form is the stronger output

$$\mathsf{ApartNonFix}_J(c) \to \mathsf{Apart}_0(\zeta(c)),$$

which is exactly Definition 9246.1.

Theorem 9246.22 (Rigidity contradiction is constructive apartness)**.** *Assume zeta-carrier source compatibility, archimedean completion, the prime-window defect formula, and Definition 9246.13. Then every instance of the geometric rigidity contradiction schema is witnessed by positive apartness from zero.*

Proof. Let $c : \mathcal{C}_\zeta$ and assume $a : \mathsf{ApartNonFix}_J(c)$. By Definition 9246.10, a nonempty finite prime window supplies a positive defect $|D_S(c)| > 0$. Source compatibility identifies the zero-ledger, prime-window, archimedean, and functional-equation reads as projections of the same source row. The archimedean completion row places this data inside the completed carrier. Applying Definition 9246.13 gives $\mathsf{Apart}_0(\zeta(c))$. If a zero-ledger witness is also present, this apartness contradicts that zero witness; without the zero witness it is already the constructive output of Definition 9246.1. □

Principle 9246.23 (Geometric content of the remaining target)**.** *The fixed-half translations of Definition 9254.10 identify the same surface through real part, mirror fixedness, prime-unitary balance, information bias, Laplace bias, and* OnCritLine *witnesses. What remains is not another translation of that surface. It is the positive-apartness incompatibility*

$$(\mathcal{C}_\zeta \setminus \mathrm{Fix}(J)) \cap \mathsf{ZeroLedger}_\zeta = \varnothing$$

read constructively as

$$\mathsf{ApartNonFix}_J(c) \to \mathsf{Apart}_0(\zeta(c)).$$

Principle 9246.24 (No further route layer)**.** *The remaining mathematical task is not another projection layer, another route classifier, or another exception vocabulary. It is the carrier-level incompatibility row Definition 9246.13: a completed zeta carrier row with positive finite-window radial defect cannot also be a zero ledger.*

Concretized in §9056: finite NameCert carrier for the local-global zero exclusion target

Chapter 9247

Finite Hermitian Rouche Start for ξ

This chapter records the finite self-adjoint starting object for the RH route. It is deliberately phrased as a certificate interface. The construction of O_N uses only finite prime-power data through $\Lambda(n)$, a finite archimedean Γ-kernel quadrature, and finite Hilbert data. No zeta-zero list, zero-count table, or inverse spectral datum is an input. The chapter also separates two statements that must not be conflated: Rouche domination on the outer rectangle gives equality of zero counts in that rectangle, while zero localization on the critical line requires Rouche domination on the off-line components where the self-adjoint determinant is zero-free.

9247.1 Prime–Gamma finite packet

Definition 9247.1 (Prime–Gamma truncation packet)**.** *A prime–Gamma truncation packet at level N is the finite datum*

$$\mathsf{PGamma}_N := (\mathcal{P}_N, (w_{n,N})_{n\in\mathcal{P}_N}, \mathcal{Q}_N, (a_{q,N}, \omega_{q,N})_{q\in\mathcal{Q}_N}, \mathcal{H}_N, (e_1, \dots, e_{m_N})),$$

where:

1. *$\mathcal{P}_N \subset \{n \le N : \Lambda(n) \neq 0\}$ is a finite prime-power window;*
2. *$w_{n,N} \in \mathsf{Rat}^{\uparrow}$ are displayed finite weights attached to the $\Lambda(n)$ rows;*
3. *$\mathcal{Q}_N$ is a finite quadrature window for the archimedean Γ-kernel, with real weights $a_{q,N}$ and frequencies $\omega_{q,N}$;*
4. *$\mathcal{H}_N$ is a finite-dimensional Hermitian carrier with displayed basis $(e_1, \dots, e_{m_N})$.*

The packet is a source-side object. It contains primes, $\Lambda(n)$, and archimedean Γ data, but it contains no zero of ξ or ζ.

Definition 9247.2 (Completed finite explicit-formula form)**.** *Given PGamma_N, define the finite sesquilinear form $\mathcal{B}_N$ on $\mathcal{H}_N$ by*

$$\mathcal{B}_N(f,g) := b_N\langle f,g\rangle + \sum_{n\in\mathcal{P}_N} w_{n,N}\frac{\Lambda(n)}{\sqrt{n}}\widehat{f}(\log n)\overline{\widehat{g}(\log n)} + \sum_{q\in\mathcal{Q}_N} a_{q,N}\widehat{f}(\omega_{q,N})\overline{\widehat{g}(\omega_{q,N})}.$$

The scalar b_N is a displayed real counterterm. The last sum is the finite archimedean row; its quadrature target is the logarithmic derivative of the completion factor $\pi^{-s/2}\Gamma(s/2)$ on the chosen height window. The hats denote the finite readout functionals carried by the packet.

Lemma 9247.3 (Hermitian symmetry of the finite form)**.** *If all displayed coefficients b_N, $w_{n,N}$, and $a_{q,N}$ are real, then*

$$\mathcal{B}_N(g, f) = \overline{\mathcal{B}_N(f, g)}$$

for all $f, g \in \mathcal{H}_N$.

Proof. Each summand has the form $c\,\ell(f)\overline{\ell(g)}$ with $c \in \mathbb{R}$, or the Hermitian inner product term $b_N\langle f, g\rangle$. Interchanging f and g complex conjugates every summand. Finite summation preserves the identity. □

Definition 9247.4 (Finite Hermitian operator)**.** *The finite operator O_N is the unique matrix on $\mathcal{H}_N$ satisfying*

$$\langle O_N f, g\rangle = \mathcal{B}_N(f, g) \qquad (f, g \in \mathcal{H}_N).$$

Equivalently, in the displayed basis,

$$(O_N)_{ab} = \mathcal{B}_N(e_b, e_a).$$

Theorem 9247.5 (Self-adjointness is source-side)**.** *The operator O_N of Definition 9247.4 is Hermitian:*

$$O_N = O_N^*.$$

Consequently its eigenvalues $\lambda_1, \ldots, \lambda_{m_N}$ are real.

Proof. The matrix identity $(O_N)_{ab} = \overline{(O_N)_{ba}}$ is exactly Definition 9247.3 applied to e_a, e_b. A finite Hermitian matrix has real spectrum by the finite-dimensional spectral theorem. This proof uses only the finite prime–Gamma packet and does not mention any zero of ξ. □

9247.2 Determinant approximant

Definition 9247.6 (Zero-free amplitude)**.** *A zero-free amplitude attached to* PGamma_N *is an entire function*

$$A_N(s) = \exp(B_N(s)),$$

where B_N is a finite completed Euler–Gamma counterterm built from the same prime-power truncation, archimedean quadrature, and normalization rows. The important structural property is

$$A_N(s) \neq 0 \qquad (s \in \mathbb{C}).$$

Definition 9247.7 (Finite Hermitian determinant model)**.** *The determinant model associated to (O_N, A_N) is*

$$D_N(s) := \det\big((s - \tfrac{1}{2})I - iO_N\big)\, A_N(s).$$

Theorem 9247.8 (Zeros of the model lie on the critical line)**.** *Assume A_N is zero-free. Then every zero of D_N is of the form*

$$s = \frac{1}{2} + i\lambda_j$$

for a real eigenvalue λ_j of O_N.

Proof. By Definition 9247.5, the spectrum of O_N is real. Hence

$$\det\big((s - \tfrac{1}{2})I - iO_N\big) = \prod_{j=1}^{m_N}\big((s - \tfrac{1}{2}) - i\lambda_j\big).$$

The determinant factor therefore vanishes only at $s = 1/2 + i\lambda_j$. The amplitude contributes no zeros by Definition 9247.6. □

9247.3 Outer-rectangle Rouche certificate

Definition 9247.9 (Spectrally admissible height)**.** *For*

$$R_T := \{\, s \in \mathbb{C} : 0 \le \Re(s) \le 1,\ |\Im(s)| \le T \,\},$$

a height T is spectrally admissible for D_N when $\lambda_j \neq \pm T$ for every eigenvalue λ_j of O_N. Equivalently, the determinant factor has no zero on ∂R_T.

Definition 9247.10 (Finite boundary domination certificate)**.** *A finite boundary domination certificate for (N, T) consists of explicit positive rational bounds*

$$E^{\mathrm{cert}}_{N,T} \quad \text{and} \quad M^{\mathrm{cert}}_{N,T}$$

such that

$$\sup_{s \in \partial R_T} |\xi(s) - D_N(s)| \le E^{\mathrm{cert}}_{N,T},$$

$$0 < M^{\mathrm{cert}}_{N,T} \le \inf_{s \in \partial R_T} |D_N(s)|,$$

and

$$E^{\mathrm{cert}}_{N,T} < M^{\mathrm{cert}}_{N,T}.$$

The upper bound is decomposed into the prime tail, the $\Lambda(n)$ smoothing error, the archimedean Γ-quadrature error, and the zero-free amplitude normalization error:

$$E^{\mathrm{cert}}_{N,T} = E^{\mathrm{pr}}_{N,T} + E^{\Lambda}_{N,T} + E^{\Gamma}_{N,T} + E^{A}_{N,T}.$$

The lower bound may be certified from

$$|A_N(s)| \ge \alpha_{N,T} > 0$$

on ∂R_T and the spectral product

$$\inf_{s \in \partial R_T} \prod_{j=1}^{m_N} |(s - \tfrac{1}{2}) - i\lambda_j|.$$

Theorem 9247.11 (The boxed boundary inequality)**.** *If a finite boundary domination certificate for (N, T) is supplied, then*

$$\boxed{|\xi(s) - D_N(s)| < |D_N(s)| \quad (s \in \partial R_T).}$$

Proof. For $s \in \partial R_T$,

$$|\xi(s) - D_N(s)| \le E^{\mathrm{cert}}_{N,T} < M^{\mathrm{cert}}_{N,T} \le |D_N(s)|.$$

This is the displayed inequality. □

Theorem 9247.12 (Outer-rectangle Rouche count)**.** *Assume T is spectrally admissible and Definition 9247.10 holds. Then ξ and D_N have the same number of zeros in R_T, counted with multiplicity.*

Proof. The functions ξ and D_N are holomorphic on a neighbourhood of R_T and D_N has no zero on ∂R_T. The strict inequality of Definition 9247.11 is exactly the hypothesis of Rouche's theorem. Hence ξ and D_N have the same zero count inside R_T. □

Principle 9247.13 (The full rectangle gives count, not location)**.** *The implication*

$$|\xi - D_N| < |D_N| \text{ on } \partial R_T \quad \Longrightarrow \quad N_{R_T}(\xi) = N_{R_T}(D_N)$$

is a zero-count statement only. It does not, by itself, imply that the zeros of ξ occupy the same locations as the zeros of D_N, nor that the zeros of ξ lie on the critical line. The self-adjointness of O_N places the model zeros on the line; localization of the actual zeros requires Rouche control on zero-free off-line components.

9247.4 Off-line Rouche localization

Definition 9247.14 (Off-line rectangles)**.** *For $0 < \eta < 1/2$ define*

$$R^-_{T,\eta} := \{\, s : 0 \le \Re(s) \le 1/2 - \eta,\ |\Im(s)| \le T \,\},$$

$$R^+_{T,\eta} := \{\, s : 1/2 + \eta \le \Re(s) \le 1,\ |\Im(s)| \le T \,\}.$$

These rectangles are separated from the critical line by a positive rational margin η.

Definition 9247.15 (Off-line domination certificate)**.** *An off-line domination certificate for $(N, T, \eta, \pm)$ is the same finite prime–Λ–Γ error package as Definition 9247.10, but computed on $\partial R^{\pm}_{T,\eta}$:*

$$\sup_{s \in \partial R^{\pm}_{T,\eta}} |\xi(s) - D_N(s)| < \inf_{s \in \partial R^{\pm}_{T,\eta}} |D_N(s)|.$$

Because A_N is zero-free and the determinant zeros of D_N lie on $\Re(s) = 1/2$, the lower bound is a genuine zero-free lower bound on each off-line component.

Theorem 9247.16 (Off-line Rouche exclusion)**.** *Assume A_N is zero-free and $O_N = O_N^*$. If the off-line domination certificate holds for $R^-_{T,\eta}$, then ξ has no zero in $R^-_{T,\eta}$. If it holds for $R^+_{T,\eta}$, then ξ has no zero in $R^+_{T,\eta}$.*

Proof. By Definition 9247.8, all zeros of D_N lie on $\Re(s) = 1/2$. Thus D_N has no zero in either off-line rectangle. Applying Rouche's theorem on the chosen off-line rectangle gives equality of zero counts there. The model count is zero, so the ξ count is zero. □

Corollary 9247.17 (Finite-height critical-line conclusion)**.** *Fix T. Suppose that for every positive rational $\eta < 1/2$ there is some finite level $N = N(T, \eta)$ whose off-line domination certificates hold on both $R^-_{T,\eta}$ and $R^+_{T,\eta}$. Then every zero of ξ in R_T lies on $\Re(s) = 1/2$.*

Proof. Let ρ be a zero of ξ in R_T. If $\Re(\rho) < 1/2$, choose a positive rational $\eta < 1/2 - \Re(\rho)$; then $\rho \in R^-_{T,\eta}$, contradicting Definition 9247.16. The case $\Re(\rho) > 1/2$ is the same using $R^+_{T,\eta}$. Therefore $\Re(\rho) = 1/2$. □

9247.5 Non-circularity ledger

Principle 9247.18 (What self-adjointness proves)**.** *The self-adjoint step proves exactly this: the zeros of the finite model D_N contributed by the determinant factor are line-supported because $O_N = O_N^*$. This is non-circular because the spectrum of O_N is produced from the finite prime–Λ–Γ kernel, not from the zero set of ξ.*

Principle 9247.19 (What remains analytic)**.** *The remaining RH-facing obligation is not self-adjointness. It is the finite, checkable domination package*

$$\sup_{\partial R^{\pm}_{T,\eta}} |\xi - D_N| < \inf_{\partial R^{\pm}_{T,\eta}} |D_N|$$

with explicit prime tail, $\Lambda(n)$ smoothing, archimedean Γ-kernel, and amplitude lower-bound ledgers. Once these off-line inequalities are proved without zero input, Definition 9247.16 gives $r = 0$ on the corresponding height window.

Concretized in §9246: The finite Hermitian Rouche start supplies a spectral version of the local–global zero-exclusion hinge: line-supported model zeros come from self-adjointness, while the actual zeta-zero exclusion is carried by explicit off-line boundary-domination ledgers.

Chapter 9248

Prime Fingerprint Separation for RH

chapter 9243 identifies the critical line with the unit-amplitude surface of the centered prime channels. The present chapter records the separation row behind that identification. The point s is not treated as a bare geometric coordinate with prime data attached afterward. In the zeta recovery carrier, s is read by its responses to all prime-local probes.

9248.1 Prime fingerprint

Definition 9248.1 (Prime fingerprint)**.** *For a complex history s, its prime fingerprint is the family*

$$\mathsf{PF}(s) := \left(p^{-s}\right)_{p \in \mathsf{Prime}^{\uparrow}}.$$

Equivalently, for the multiplicative character

$$\chi_s(n) := n^{-s},$$

unique factorization gives

$$n = \prod_p p^{k_p} \qquad \Longrightarrow \qquad \chi_s(n) = \prod_p \chi_s(p)^{k_p}.$$

Thus the prime fingerprint is the local-probe presentation of the same Dirichlet projection row consumed by Definition 9243.1.

Definition 9248.2 (Prime-fingerprint equivalence)**.** *For complex histories s and t, write*

$$s \equiv_{\mathsf{PF}} t$$

when

$$\forall p \in \mathsf{Prime}^{\uparrow}, \quad p^{-s} = p^{-t}.$$

This is equality as observed by all prime-local zeta channels.

Proposition 9248.3 (Prime channels separate complex histories)**.** *On the displayed complex-history packet containing the prime rows* 2 *and* 3 *with their real logarithm rows,*

$$s \equiv_{\mathsf{PF}} t \quad \Longleftrightarrow \quad s = t.$$

Proof. The implication from $s = t$ to $s \equiv_{\mathsf{PF}} t$ is immediate. Conversely, assume $s \equiv_{\mathsf{PF}} t$ and put $a = s - t$. The prime rows 2 and 3 give

$$e^{-a \log 2} = 1, \qquad e^{-a \log 3} = 1.$$

Hence there are integers k and ℓ with

$$a \log 2 = 2\pi i k, \qquad a \log 3 = 2\pi i \ell.$$

If $a \neq 0$, then k and ℓ are not both zero and the displayed rows force

$$k \log 3 = \ell \log 2.$$

Exponentiating gives

$$3^k = 2^\ell,$$

which is impossible unless $k = \ell = 0$ by unique factorization. Therefore $a = 0$, so $s = t$. □

Principle 9248.4 (Primes are probes, not points)**.** *The prime rows are not points of the critical strip. They are separating local probes for the zeta information space. A complex history s is distinguished from t precisely when some prime-local response differs:*

$$s \neq t \quad \Longleftrightarrow \quad \exists p \in \mathsf{Prime}^{\uparrow}, \quad p^{-s} \neq p^{-t}.$$

9248.2 Mirror fingerprints

Definition 9248.5 (Mirror prime fingerprint)**.** *Let $J(s) = 1 - \overline{s}$ be the mirror map of Definition 9241.12. The mirror prime-fingerprint comparison for s is the pair*

$$(\mathsf{PF}(s), \mathsf{PF}(J(s))).$$

The comparison is collapsed when

$$\mathsf{PF}(s) = \mathsf{PF}(J(s)).$$

Proposition 9248.6 (Mirror changes amplitude bias, not phase clock)**.** *Write*

$$s = \frac{1}{2} + \delta + i\tau.$$

For the centered prime channel

$$U_p(s) = p^{1/2-s},$$

one has

$$U_p(s) = p^{-\delta} e^{-i\tau \log p}, \qquad U_p(J(s)) = p^{\delta} e^{-i\tau \log p}.$$

Thus the mirror preserves the prime phase clock and inverts the prime amplitude bias.

Proof. Since

$$J(s) = 1 - \overline{s} = \frac{1}{2} - \delta + i\tau,$$

direct substitution gives

$$U_p(s) = p^{1/2-(1/2+\delta+i\tau)} = p^{-\delta} e^{-i\tau \log p},$$

and

$$U_p(J(s)) = p^{1/2-(1/2-\delta+i\tau)} = p^{\delta} e^{-i\tau \log p}.$$

□

Corollary 9248.7 (Prime fingerprint collapses exactly on the mirror surface)**.** *For every complex history s,*

$$\mathsf{PF}(s) = \mathsf{PF}(J(s)) \quad \Longleftrightarrow \quad s = J(s) \quad \Longleftrightarrow \quad \Re(s) = \frac{1}{2}.$$

Proof. The first equivalence follows from Definition 9248.3 applied to s and $J(s)$. The second equivalence is the fixed-point calculation in Definition 9241.12. □

Corollary 9248.8 (Off-critical mirror pairs are prime-visible)**.** *If $s = 1/2 + \delta + i\tau$ with $\delta \neq 0$, then every displayed prime row p separates the centered channel amplitudes of s and $J(s)$:*

$$|U_p(s)| = p^{-\delta}, \qquad |U_p(J(s))| = p^{\delta} = |U_p(s)|^{-1},$$

and

$$|U_p(s)| \neq 1.$$

Proof. This is the modulus read of Definition 9248.6. Since $p > 1$ and $\delta \neq 0$, the positive scalar $p^{-\delta}$ is not one. □

9248.3 RH as prime-fingerprint indistinguishability

Theorem 9248.9 (Prime-fingerprint normal form of RH)**.** *The Riemann Hypothesis is equivalent to the assertion that every recognized non-trivial zeta-zero event is indistinguishable from its mirror by prime fingerprint. This is a scoped prime-channel reparameterization of the fixed-line output: the fingerprint row rewrites $s = J(s)$, while the zero-ledger exclusion remains the RH content:*

$$\mathsf{RH} \quad \Longleftrightarrow \quad \forall s,\ \mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s) \Longrightarrow \mathsf{PF}(s) = \mathsf{PF}(J(s)).$$

Proof. By Definition 9248.7, $\mathsf{PF}(s) = \mathsf{PF}(J(s))$ is equivalent to $\Re(s) = 1/2$. Substituting this equivalent output row into the BEDC statement of RH gives the displayed normal form. □

Corollary 9248.10 (No prime-visible mirror bias form)**.** *Equivalently,* RH *says that no recognized non-trivial zero event carries a prime-visible mirror amplitude bias:*

$$\forall s,\ \mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s) \Longrightarrow \forall p \in \mathsf{Prime}^{\uparrow}, \quad \left|p^{1/2-s}\right| = 1.$$

Proof. The output row is exactly the prime-unitary balance condition of Definition 9243.6. Its equivalence with the ordinary RH witness is Definition 9243.12; equivalently, it is the amplitude form of Definition 9248.9. □

Remark 9248.11 (Relation to mirror closure)**.** *The functional equation supplies mirror closure of the zero set, as in Definition 9241.13. The prime-fingerprint row asks for more: the two mirror-related zero packets must not be separated by any prime-local channel. By Definition 9241.14, this pointwise collapse is not supplied by mirror closure alone.*

Concretized in §64: Prime packets supply the local probe family used by the prime fingerprint.

Concretized in §71: The Dirichlet and Euler-product rows supply the half-plane channel on which $\mathsf{PF}(s)$ is read.

Concretized in §581: The zeta functional-equation ledger supplies the mirror transport row whose orbit collapse is tested by prime fingerprints.

Concretized in §548: Critical-line witness packets supply the fixed-surface row equivalent to prime-fingerprint collapse.

Concretized in §9000: Prime spectral fingerprint packets realize prime-local zeta response rows as finite NameCert data.

Chapter 9249

Prime-Skew Boundary Defect Refutation

chapter 9248 shows that an off-critical mirror pair is visible to centered prime channels, while chapter 9246 isolates the zero-defect incompatibility needed for the local-global route. The present chapter packages those two ideas as a conditional refutation interface. It does not prove the Riemann Hypothesis; it states that, once representation, prime-skew detection, and zero-defect incompatibility are all displayed, an off-line non-trivial zero cannot be inhabited.

Definition 9249.1 (Non-trivial zero and off-line zero packets)**.** *For a complex history s, write*

$$\mathcal{Z}_\zeta(s) := \mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s).$$

The fixed zero packet is

$$\mathsf{FixedZero}(s) := \mathcal{Z}_\zeta(s) \times \mathsf{OnCritLine}(s).$$

The off-line zero packet is

$$\mathsf{OffLineZero}(s) := \mathcal{Z}_\zeta(s) \times \mathsf{ApartCrit}(s),$$

where $\mathsf{ApartCrit}(s)$ *is a positive rational-level apartness witness between* $\Re(s)$ *and* $1/2$*. Thus* $\mathsf{FixedZero}(s)$ *is the mirror-fixed zero packet, and* $\mathsf{OffLineZero}(s)$ *is the mirror-split zero packet.*

Definition 9249.2 (Prime-visible mirror skew)**.** *For the mirror $J(s) = 1 - \overline{s}$ and centered prime channel*

$$U_p(s) := p^{1/2-s},$$

the prime-visible mirror skew is the family

$$\Delta_p(s) := \log |U_p(J(s))| - \log |U_p(s)|.$$

Writing

$$s = \frac{1}{2} + \delta + i\tau$$

gives

$$|U_p(s)| = p^{-\delta}, \qquad |U_p(J(s))| = p^{\delta},$$

and therefore

$$\Delta_p(s) = 2\delta \log p.$$

The existential skew row is

$$\mathsf{PrimeSkew}(s) := \sum_{p:\mathsf{Prime}^{\uparrow}} (\Delta_p(s)\#0).$$

Lemma 9249.3 (Off-line zeros produce prime-visible skew)**.** *For every complex history s,*

$$\mathsf{OffLineZero}(s) \to \mathsf{PrimeSkew}(s).$$

Proof. An off-line zero packet supplies $\mathsf{ApartCrit}(s)$, hence a nonzero real offset $\delta = \Re(s) - 1/2$. By Definition 9248.6, the centered prime channels read

$$|U_p(s)| = p^{-\delta}, \qquad |U_p(J(s))| = p^{\delta}.$$

Thus

$$\Delta_p(s) = 2\delta \log p.$$

For any displayed prime row p, the row $p > 1$ gives $\log p > 0$, so $\delta\#0$ implies $\Delta_p(s)\#0$. Choosing such a prime row gives the required element of $\mathsf{PrimeSkew}(s)$. □

Definition 9249.4 (Bulk zero atom and prime defect)**.** *Let T_Ω be a displayed bulk carrier with a zeta readout*

$$\pi_\zeta : T_\Omega \to R_\zeta.$$

The non-trivial zero atom over $x : T_\Omega$ is

$$\mathsf{NTZeroAtom}_\Omega(x) := \mathsf{ZetaZero}(\pi_\zeta(x)) \times \mathsf{InCritStrip}(\pi_\zeta(x)).$$

For boundary layers i with projections

$$\pi_i : T_\Omega \to R_i,$$

write $\mathsf{PrimeDefect}_i(x)$ for a boundary row saying that the prime-visible invariant of x is apart from zero at layer i. The global defect row is

$$\mathsf{PrimeDefect}_\Omega(x) := \sum_i \mathsf{PrimeDefect}_i(x).$$

Definition 9249.5 (Boundary faithfulness and zero-defect incompatibility)**.** *Prime-skew boundary faithfulness is the statement*

$$\mathsf{PrimeSkewDetect}_\Omega := \prod_{x:T_\Omega} (\mathsf{PrimeSkew}(\pi_\zeta(x)) \to \mathsf{PrimeDefect}_\Omega(x)).$$

Prime-defect zero incompatibility is the statement

$$\mathsf{PrimeDefectZeroIncompatibility}_\Omega := \prod_{x:T_\Omega} (\mathsf{NTZeroAtom}_\Omega(x) \times \mathsf{PrimeDefect}_\Omega(x) \to \bot).$$

Together they say that a prime-visible skew cannot be invisible to all boundary readouts, and that an accepted non-trivial zero atom cannot also carry such a boundary defect.

Definition 9249.6 (Bulk representation of zero packets)**.** *A bulk representation row for non-trivial zero packets is the statement*

$$\mathsf{BulkRep}_\Omega := \prod_s (\mathcal{Z}_\zeta(s) \to \sum_{x:T_\Omega} \pi_\zeta(x) \sim s).$$

The equivalence row is a classifier transport certificate; it is not a claim that s is a bare point of the bulk carrier.

Theorem 9249.7 (Boundary-defect refutation of off-line zeros)**.** *Assume* $\mathsf{BulkRep}_\Omega$*,* $\mathsf{PrimeSkewDetect}_\Omega$*, and* $\mathsf{PrimeDefectZeroIncompatibility}_\Omega$*. Then*

$$\prod_s (\mathsf{OffLineZero}(s) \to \bot).$$

Proof. Fix s and assume $H : \mathsf{OffLineZero}(s)$. The first component of H is $\mathcal{Z}_\zeta(s)$, so $\mathsf{BulkRep}_\Omega$ supplies $x : T_\Omega$ with $\pi_\zeta(x) \sim s$. Transporting the zero and critical-strip rows along this equivalence gives

$$\mathsf{NTZeroAtom}_\Omega(x).$$

By Definition 9249.3, H also supplies $\mathsf{PrimeSkew}(s)$. Transporting this skew row along $\pi_\zeta(x) \sim s$ gives $\mathsf{PrimeSkew}(\pi_\zeta(x))$. By $\mathsf{PrimeSkewDetect}_\Omega$, this yields

$$\mathsf{PrimeDefect}_\Omega(x).$$

Now x carries both $\mathsf{NTZeroAtom}_\Omega(x)$ and $\mathsf{PrimeDefect}_\Omega(x)$, contradicting $\mathsf{PrimeDefectZeroIncompatibility}_\Omega$. Hence $\mathsf{OffLineZero}(s) \to \bot$, and s was arbitrary. □

Corollary 9249.8 (Located critical-strip zeros give the RH predicate)**.** *Assume the hypotheses of Definition 9249.7 and a located critical-line classifier*

$$\prod_s (\mathcal{Z}_\zeta(s) \to \mathsf{OnCritLine}(s) + \mathsf{ApartCrit}(s)).$$

Then the BEDC RH predicate of Definition 9239.7 is inhabited.

Proof. Given $\mathcal{Z}_\zeta(s)$, apply the located classifier. In the $\mathsf{OnCritLine}(s)$ case, the desired witness is present. In the $\mathsf{ApartCrit}(s)$ case, the pair $\mathcal{Z}_\zeta(s) \times \mathsf{ApartCrit}(s)$ is an off-line zero packet, contradicted by Definition 9249.7. Thus the only surviving branch supplies $\mathsf{OnCritLine}(s)$. □

Corollary 9249.9 (Off-line zero type is empty)**.** *Under the hypotheses of Definition 9249.7, the sigma type*

$$\sum_s \mathsf{OffLineZero}(s)$$

maps to $\bot$.

Proof. Given $(s, H) : \sum_s \mathsf{OffLineZero}(s)$, apply Definition 9249.7 to s and H. □

Principle 9249.10 (Scope of the boundary-defect route)**.** *The route proves no unconditional analytic incompatibility. Its two substantive premises are boundary faithfulness and zero-defect incompatibility. If boundary faithfulness fails, prime-visible skew may be lost before reaching the observed boundary layers. If zero-defect incompatibility fails, a non-trivial zero atom can coexist with a nonzero prime defect. Either failure identifies a precise analytic obligation rather than a proof or disproof of* RH*.*

Concretized in §8848: Prime-skew boundary-defect packets realize the conditional route as finite zero-representation, prime-skew, boundary-defect, incompatibility, refusal, transport, replay, provenance, and NameCert rows without proving RH.

Concretized in §9006: Prime-skew defect ledgers realize the off-line zero, prime-visible skew, and local-global defect incompatibility rows as finite NameCert data.

Chapter 9250

Zeta as a Self-Similar Recovered Carrier

chapter 9243 defines ZETA as a recovered carrier rather than as one formula, and chapter 9248 reads complex histories through prime-local probes. The present chapter records the corresponding self-similar reading. It is a relative reading inside the BEDC recovery surface: zeta is not a geometric self-similar figure, but a carrier recovered from compatible multiplicative, prime-local, Laplace, continuation, completion, mirror, and zero-ledger rows.

Definition 9250.1 (Prime-local geometric fiber)**.** *For a displayed prime row $p \in \mathsf{Prime}^{\uparrow}$ and a complex history s in a convergence window where the local series is licensed, the prime-local geometric fiber is*

$$E_p(s) := \sum_{k \geq 0} p^{-ks}.$$

It carries the one-step recursion

$$p^{-ks} \mapsto p^{-(k+1)s}$$

with local ratio p^{-s}. Equivalently, on the Euler-product window,

$$E_p(s) = (1 - p^{-s})^{-1}.$$

The fiber is local to the prime row and to the declared convergence and branch ledgers.

Definition 9250.2 (Multiplicative self-similar zeta packet)**.** Lean4 (definition) BEDC.Derived.RHRoute.ZeroGenerati
Lean4✓ BEDC.Derived.RHRoute.ZeroGenerationInitiality.multiplicativeSelfSimilarZetaPacket
zeroLedger count

The multiplicative self-similar zeta packet is the compatible recovery surface

$$\mathcal{Z}_{\mathrm{ss}} := \mathrm{Rec}\begin{pmatrix} \mathsf{PrimeLocalFibers}, & \mathsf{DirichletRow}, & \mathsf{EulerRow}, & \mathsf{LaplaceRow}, \\ \mathsf{AnalyticContinuation}, & \mathsf{ArchimedeanCompletion}, & \mathsf{FunctionalEquation}, & \mathsf{ZeroLedger} \end{pmatrix}.$$

It is the self-similar reading of the recovered carrier ZETA *of Definition 9243.2 and Definition 9254.13. The recovery symbol records compatibility and transport among the listed rows; it does not introduce a primitive carrier outside those rows.*

Principle 9250.3 (Zeta self-similarity is carrier-level)**.** *The expressions*

$$\sum_{n \geq 1} n^{-s}$$

and

$$\prod_{p\in\mathsf{Prime}^{\uparrow}}(1-p^{-s})^{-1}$$

are projections of ZETA *on the right half-plane, not standalone definitions of the full carrier. The self-similar structure belongs to the recovered carrier only after the Dirichlet row, Euler row, analytic continuation row, archimedean completion row, functional equation row, pole ledger, zero ledger, and branch transport ledger are displayed together.*

Proposition 9250.4 (Euler gluing is multiplicative self-similarity)**.** *On the displayed Euler-product window, the zeta projection is obtained by gluing the prime-local geometric fibers:*

$$\zeta_D(s)=\prod_{p\in\mathsf{Prime}^{\uparrow}}E_p(s)=\prod_{p\in\mathsf{Prime}^{\uparrow}}(1-p^{-s})^{-1}.$$

This is a multiplicative self-similar projection indexed by ordinary prime rows.

Proof. By Definition 9243.4, the Dirichlet row and Euler row agree on $\Re(s)>1$. The proof of that proposition groups the Dirichlet terms by the unique factorization row

$$n=\prod_p p^{k_p}$$

and rewrites

$$n^{-s}=\prod_p p^{-k_p s}.$$

Thus the global right-half-plane projection is the product of the local geometric fibers $E_p(s)$. □

Definition 9250.5 (Prime-occupancy partition readout)**.** *Let $T_{\mathbb{P}}$ be the prime-occupancy carrier of Definition 9414.147. On a displayed right-half-plane convergence window, the prime-occupancy partition readout is*

$$Z_{\mathbb{P}}(s):=\sum_{k\in T_{\mathbb{P}}}\exp\left(-s\sum_{p\in\mathbb{P}}k_p\log p\right).$$

The sum ranges over finite-support prime occupancy rows. It is therefore the analytic readout of the multiplicative arithmetic presentation, not a separate unledgered source carrier.

Proposition 9250.6 (Zeta is the prime-occupancy partition readout)**.** *On the Euler-product window,*

$$Z_{\mathbb{P}}(s)=\zeta_D(s).$$

Equivalently,

$$Z_{\mathbb{P}}(s)=\prod_{p\in\mathsf{Prime}^{\uparrow}}\left(\sum_{k\geq 0}p^{-ks}\right)=\prod_{p\in\mathsf{Prime}^{\uparrow}}(1-p^{-s})^{-1}.$$

Proof. For a finite-support occupancy row k, its readback integer is

$$\Psi(k)=\prod_p p^{k_p}$$

by Definition 9414.148. Thus

$$\log\Psi(k)=\sum_p k_p\log p$$

and

$$\exp\left(-s\sum_p k_p \log p\right) = \prod_p p^{-sk_p}.$$

Summing over all finite-support occupancy rows is the same as summing over positive integers by unique factorization, hence gives the Dirichlet row. Splitting the independent prime coordinates gives the Euler product by Definition 9250.4. □

Principle 9250.7 (Zero packets are recovered-carrier cancellations)**.** *In the prime-occupancy presentation, ζ_D is the analytic partition readout of finite prime configurations on the right half-plane. A non-trivial zero packet is not a bare row of $T_{\mathbb{P}}$ and not a zero of one local geometric fiber. It belongs to the completed recovered carrier assembled from Dirichlet, Euler, continuation, archimedean completion, functional-equation, pole, zero, branch, and transport ledgers.*

Proposition 9250.8 (Dirichlet projection is a discrete Laplace readout)**.** *For the zeta coefficients $a_n = 1$, the Dirichlet projection is the discrete Laplace readout of the atomic source*

$$\mu_\zeta := \sum_{n\geq 1} \delta_{\log n}.$$

That is, on any displayed convergence window,

$$\sum_{n\geq 1} n^{-s} = \mathcal{L}[\mu_\zeta](s).$$

Proof. This is Definition 9254.12 with $a_n = 1$. The equality follows from

$$e^{-s\log n} = n^{-s}$$

on the declared branch and convergence window. □

Definition 9250.9 (Zeta recovered-geometry packet)**.** *The zeta recovered-geometry packet is the records-side synthesis*

$$\mathsf{ZetaGeom} := \mathrm{Rec}\begin{pmatrix} T_{\mathbb{P}}, & \mathsf{PrimeFingerprint}, & \mathsf{EulerPhaseChannels}, & \mathsf{LaplaceKernel}, \\ \mathsf{FixedHalfMirror}, & \mathsf{FibonacciHalfModel}, & \mathsf{ZetaRecoveryRows} & \end{pmatrix}.$$

Here $T_{\mathbb{P}}$ is the finite-support prime-occupancy carrier, PrimeFingerprint *is the family $(p^{-s})_{p\in\mathsf{Prime}^\uparrow}$,* EulerPhaseChannels *records the decompositions*

$$p^{-s} = p^{-\sigma}e^{-i\tau\log p}, \qquad U_p(s) = p^{1/2-s},$$

LaplaceKernel *records $e^{-s\log n} = n^{-s}$,* FixedHalfMirror *records $J(s) = 1 - \overline{s}$ and $s = 1/2 + \delta + i\tau$,* FibonacciHalfModel *records the classifier-relative comparison with the golden fixed-half pattern of Definition 9250.24, and* ZetaRecoveryRows *abbreviates the Dirichlet, Euler, continuation, archimedean-completion, functional-equation, pole, zero, branch, and transport ledgers of Definition 9254.13.*

Definition 9250.10 (Displayed zeta constraint diagram)**.** *A displayed zeta constraint diagram is a typed records-side diagram*

$$\mathcal{D}_\zeta := (I,\ (R_i, \sim_i, P_i, C_i, \Lambda_i, \mathsf{Cert}_i)_{i:I},\ (\rho_{ji})_{j\to i})$$

over one source carrier, where each P_i is a displayed readout, each $C_i : R_i \to \mathsf{Prop}$ is a displayed constraint row, and every edge $j \to i$ carries a readback map $\rho_{ji} : R_j \to R_i$ with the source compatibility row

$$\rho_{ji}(P_j(t)) \sim_i P_i(t).$$

For the zeta packet, the diagram contains at least the prime-axis, Dirichlet, Euler, Laplace, continuation, archimedean-completion, functional-equation, pole-ledger, zero-ledger, branch-transport, and provenance rows already listed in Definition 9250.9. The phrase "all zeta constraints" refers only to such a displayed diagram, not to an untyped totality of predicates.

Definition 9250.11 (Compatible zeta geometry carrier)**.** *For a displayed zeta constraint diagram $\mathcal{D}_\zeta$, the compatible zeta geometry carrier is the dependent carrier*

$$\mathbb{G}_{\mathcal{D}_\zeta} := \sum_{(r_i):\prod_{i:I} R_i} \left(\prod_{i:I} C_i(r_i)\right) \times \left(\prod_{j\to i} \rho_{ji}(r_j) \sim_i r_i\right) \times \Lambda_{\mathcal{D}_\zeta}.$$

The source-side version is

$$T_{\mathcal{D}_\zeta} := \sum_{t:T} \prod_{i:I} C_i(P_i(t)).$$

The canonical readout sends t to the compatible family $(P_i(t))_{i:I}$ together with the displayed readback and ledger rows.

Principle 9250.12 (Constraint totality is relative to a diagram)**.** *The infinite-dimensional geometry of zeta is a compatible limit of a displayed constraint diagram. It is not the complex plane, not the Euler product alone, and not the untyped collection of every sentence one could state about ζ. The carrier $\mathbb{G}_{\mathcal{D}_\zeta}$ records precisely the rows, constraints, readbacks, fibers, continuations, and ledgers named by $\mathcal{D}_\zeta$.*

Definition 9250.13 (Displayed zeta generation signature)**.** *A displayed zeta generation signature at layer ℓ is a BEDC-licensed multi-sorted signature*

$$\mathcal{F}_{\zeta,\ell} \quad \textit{on} \quad \mathsf{Sort}_\zeta := \{\mathsf{Obj}, \mathsf{Win}, \mathsf{Code}, \mathsf{Cert}, \mathsf{Ledger}\}.$$

The object sort carries the recovered carrier rows; the window sort carries inspection, refinement, pairing, summing, encoding, and sealing windows; the code sort carries public readbacks; the certificate sort carries stability and correctness witnesses; and the ledger sort carries source, pattern, classifier, stability, and replay rows. Typical window constructors have the forms

$$\mathsf{idWin}, \quad \mathsf{composeWin}, \quad \mathsf{refineWin}, \quad \mathsf{pairWin}, \quad \mathsf{sumWin}, \quad \mathsf{encodeWin}, \quad \mathsf{sealWin}.$$

Each constructor has displayed input sorts and a displayed ledger row. The signature ranges only over the rows named by the ambient zeta diagram; it is not a quantifier over every analytic predicate on the complex plane.

Definition 9250.14 (Generated zeta universe)**.** *When the ambient layer supplies the initiality certificate for Definition 9250.13, the generated zeta universe is the multi-sorted initial algebra*

$$\mathbb{U}_{\zeta,\ell} := \mu\mathcal{F}_{\zeta,\ell}.$$

Its components are written

$$U^{\mathsf{Obj}}_{\zeta,\ell}, \quad U^{\mathsf{Win}}_{\zeta,\ell}, \quad U^{\mathsf{Code}}_{\zeta,\ell}, \quad U^{\mathsf{Cert}}_{\zeta,\ell}, \quad U^{\mathsf{Ledger}}_{\zeta,\ell}.$$

The predicate

$$\mathsf{Generated}^{s}_{\zeta,\ell}(x)$$

means that $x : U^{s}_{\zeta,\ell}$ is obtained by the displayed constructors of $\mathcal{F}_{\zeta,\ell}$. A sealing or completion row is generated only when its compatible thread, modulus, branch ledger, and replay ledger are also displayed. If the initiality certificate is absent, the notation denotes an obligation row, not an additional axiom.

Principle 9250.15 (Internal origin of windows and certificates)**.** *In the generated zeta universe, object rows, detection windows, public codes, certificates, and ledgers have the same generative origin. For each sort $s \in \mathsf{Sort}_{\zeta}$, initial-algebra induction gives*

$$\prod_{x:U^{s}_{\zeta,\ell}} \mathsf{Generated}^{s}_{\zeta,\ell}(x).$$

Thus a detector for a zero packet, a branch window for continuation, or a certificate for a compatibility edge is not an external observer of $\mathbb{G}_{\mathcal{D}_\zeta}$. It is another generated component of the same displayed signature.

Principle 9250.16 (Fixed-half closure is not a generator)**.** *The fixed-half subcarrier may be read inside $\mathbb{G}_{\mathcal{D}_\zeta}$ only after the neutral zeta diagram, its window rows, and its certificate rows have already been generated. The RH claim is therefore not a constructor of $\mathcal{F}_{\zeta,\ell}$ and not a defining row of the neutral carrier. It is the section target asserting that the zero-ledger projection admitted by the generated neutral carrier factors through the fixed-half subcarrier.*

Definition 9250.17 (RH-neutral and fixed-half zeta carriers)**.** *Let $\mathcal{D}^{0}_{\zeta}$ be the displayed zeta constraint diagram containing the recovery rows of Definition 9254.13 and the zero-ledger row, but not the fixed-half conclusion as a defining constraint. Its compatible carrier is*

$$\mathbb{G}^{0}_{\zeta} := \mathbb{G}_{\mathcal{D}^{0}_{\zeta}}.$$

The fixed-half subcarrier is

$$\mathbb{G}^{1/2}_{\zeta} := \sum_{g:\mathbb{G}^{0}_{\zeta}} \mathsf{FixHalf}(g),$$

where $\mathsf{FixHalf}(g)$ may be read through any of the equivalent half-layer rows of Definition 9254.10.

Principle 9250.18 (RH as endogenous fixed-half constraint)**.** *RH is not the definition of $\mathbb{G}^{1/2}_{\zeta}$. It is the claim that the zero-ledger part of the RH-neutral carrier $\mathbb{G}^{0}_{\zeta}$ already lands in the fixed-half subcarrier. In constraint-diagram language, it says that the fixed-half row is not an extra defining row for zero packets, but a consequence of the other recovery, mirror, completion, and zero-ledger rows. The positive-apartness form of this consequence is the local-global obstruction isolated in Definition 9246.1.*

Proposition 9250.19 (Euler phase channels are prime-axis readouts)**.** *On the displayed right-half-plane window, the exponential kernel sends a finite-support prime occupancy row $k \in T_{\mathbb{P}}$ to the product of its prime-axis phase-scale channels:*

$$\exp\left(-s\sum_{p} k_p \log p\right) = \prod_{p}\left(p^{-\sigma}e^{-i\tau\log p}\right)^{k_p}$$

for $s = \sigma + i\tau$.

Proof. The prime-occupancy readback gives

$$\log \Psi(k) = \sum_p k_p \log p.$$

Substituting $s = \sigma + i\tau$ into the exponential kernel gives

$$e^{-s \log p} = e^{-\sigma \log p} e^{-i\tau \log p} = p^{-\sigma} e^{-i\tau \log p}.$$

Multiplying these local reads over the finite support of k yields the displayed product. □

Principle 9250.20 (Zeta geometry is recovered-carrier geometry)**.** *The geometric reading of zeta is not a point-set geometry in the complex plane. The complex coordinate s is a compressed history read through prime fingerprints, Euler phase-scale channels, the discrete Laplace kernel, the recovered-carrier continuation rows, and the fixed-half mirror. In this reading, RH is the zero-ledger section claim that recognized critical-strip zero packets of* ZetaGeom *land in the fixed-half surface, equivalently in the unit-amplitude surface of all centered prime channels.*

Principle 9250.21 (Prime rows are local probes of the recovered carrier)**.** *In the zeta self-similar packet, ordinary primes are the multiplicative-divisibility atoms, but their RH-facing role is not to be points of the critical strip. They index local probes*

$$p \mapsto p^{-s}$$

and centered channels

$$U_p(s) = p^{1/2-s}.$$

Thus zeta is an instance of the relative priming principle of Definition 9414.209: the classifier is multiplicative on the index side and prime-local on the information readout side.

Definition 9250.22 (Recovered-carrier self-dual mirror)**.** *The recovered-carrier mirror is the functional-equation readback displayed on complex histories as*

$$J(s) := 1 - \overline{s}.$$

Writing

$$s = \frac{1}{2} + \delta + i\tau$$

gives

$$J(s) = \frac{1}{2} - \delta + i\tau.$$

It preserves the prime phase clock $\tau \log p$ and reverses the prime-amplitude bias $\delta \log p$ in the centered channels, as in Definition 9248.6.

Theorem 9250.23 (RH is fixed-half zero ledger for the self-similar carrier)**.** *Under the recovered-carrier reading of Definition 9250.2, the Riemann Hypothesis is the assertion that every recognized non-trivial zero packet lies in the fixed-half surface of the mirror:*

$$\mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s) \Longrightarrow s = J(s).$$

Equivalently, every recognized non-trivial zero packet has no prime-visible mirror amplitude bias:

$$\mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s) \Longrightarrow \mathsf{PF}(s) = \mathsf{PF}(J(s)).$$

Proof. The first displayed implication is the fixed-surface reading of Definition 9254.22. The equivalence with prime-fingerprint collapse is Definition 9248.9. The mirror and centered prime-channel interpretation is supplied by Definition 9250.22 and Definition 9248.6. □

Principle 9250.24 (Self-similar comparison boundary)**.** *The zeta packet and the Fibonacci-Zeckendorf packet are both self-similar only after their classifiers are named. The Fibonacci route uses second-order recursive axis normalization*

$$e_k + e_{k+1} \rightsquigarrow e_{k+2}.$$

The zeta route uses prime-indexed local geometric fibers and multiplicative Euler gluing

$$E_p(s) = 1 + p^{-s} + p^{-2s} + \cdots .$$

The comparison is structural: it identifies classifier-relative self-similar recovery patterns, not a common ordinary geometric object and not a proof of the zero-ledger exclusion.

Concretized in §71: The basic zeta packet supplies the right-half-plane Dirichlet and Euler rows used by the self-similar projection.

Concretized in §580: The zeta-continuation witness packet supplies the continuation, pole, trivial-zero, and Gamma-boundary rows needed for recovered-carrier reading.

Concretized in §581: The zeta functional-equation ledger supplies the mirror transport row used by the recovered-carrier self-dual mirror.

Chapter 9251

Zeta–Euler Tick Algebra

chapter 9250 reads ZETA as a recovered carrier assembled from Dirichlet, Euler, Laplace, continuation, completion, mirror, and zero-ledger rows. The present chapter isolates the dynamical row inside that carrier. Integers are finite prime-occupancy sections, prime multiplication is a tick in the prime ledger, $\log n$ is the energy coordinate of the section, and the right-half-plane zeta projection is the partition trace of the corresponding logarithmic Hamiltonian. The chapter is an interface translation; it does not close the analytic continuation, zero coverage, or RH obligations.

9251.1 Prime Ledger and Logarithmic Hamiltonian

Definition 9251.1 (Prime-register lattice)**.** *The prime-register lattice is the finite-support abelian group*

$$G_{\mathbb{P}} := \bigoplus_{p\in\mathbb{P}} \mathbb{Z}e_p,$$

with positive cone

$$G_{\mathbb{P}}^{+} := \bigoplus_{p\in\mathbb{P}} \mathbb{N}e_p.$$

For a positive integer

$$n = \prod_p p^{v_p(n)},$$

the register row is

$$\nu(n) := \sum_p v_p(n)e_p \in G_{\mathbb{P}}^{+}.$$

The row is finite by unique prime factorization.

Definition 9251.2 (Zeta Fock carrier and Hamiltonian)**.** *The Zeta–Euler tick carrier is the Hilbert space*

$$\mathcal{H}_\zeta := \ell^2(\mathbb{N}_{\geq 1})$$

with standard basis $\{|n\rangle : n \geq 1\}$*. Equivalently, it has the finite-excitation prime-occupancy presentation*

$$\mathcal{H}_\zeta \cong \bigotimes_{p\in\mathbb{P}}^{0} \ell^2(\mathbb{N}_0), \qquad |n\rangle \longleftrightarrow \bigotimes_p |v_p(n)\rangle.$$

For each prime p, the number row is

$$N_p|n\rangle := v_p(n)|n\rangle.$$

The logarithmic Hamiltonian is

$$H_\zeta := \sum_{p\in\mathbb{P}} (\log p) N_p,$$

read on the finite-support basis. Thus

$$H_\zeta |n\rangle = (\log n)|n\rangle.$$

Theorem 9251.3 (Zeta phase flow is prime-ledger phase transport)**.** *Let*

$$U_t := e^{-itH_\zeta}.$$

Then, for every positive integer n,

$$U_t|n\rangle = n^{-it}|n\rangle = \prod_p e^{-itv_p(n)\log p}|n\rangle.$$

Proof. By Definition 9251.2,

$$H_\zeta|n\rangle = (\log n)|n\rangle.$$

Therefore

$$U_t|n\rangle = e^{-it\log n}|n\rangle = n^{-it}|n\rangle.$$

Since

$$\log n = \sum_p v_p(n)\log p,$$

the final product form follows. □

9251.2 Trace and Euler Decomposition

Definition 9251.4 (Zeta partition trace)**.** *For $s = \sigma + it$ in a displayed right-half-plane convergence window, the Zeta–Euler partition trace is*

$$Z_{\text{tick}}(s) := \operatorname{Tr}(e^{-sH_\zeta}),$$

when the trace is licensed by absolute convergence. For a finite prime window S, the finite carrier and Hamiltonian are

$$\mathcal{H}_S := \bigotimes_{p\in S} \ell^2(\mathbb{N}_0), \qquad H_S := \sum_{p\in S} (\log p) N_p,$$

with finite-window trace

$$Z_S(s) := \operatorname{Tr}_{\mathcal{H}_S}(e^{-sH_S}).$$

Theorem 9251.5 (Right-half-plane trace is the Dirichlet projection)**.** *On $\Re(s) > 1$,*

$$Z_{\text{tick}}(s) = \zeta_D(s).$$

Equivalently,

$$\operatorname{Tr}(e^{-sH_\zeta}) = \sum_{n\geq 1} e^{-s\log n} = \sum_{n\geq 1} n^{-s}.$$

Proof. The basis vector $|n\rangle$ is an eigenvector of H_ζ with eigenvalue $\log n$. Hence

$$e^{-sH_\zeta}|n\rangle = e^{-s\log n}|n\rangle = n^{-s}|n\rangle.$$

On $\Re(s) > 1$ the diagonal series is absolutely summable, so the trace is the displayed sum. This is the Dirichlet projection of Definition 9243.2. □

Theorem 9251.6 (Finite-window Euler trace)**.** *For a finite prime window S and $\Re(s) > 0$,*

$$Z_S(s) = \prod_{p \in S} \frac{1}{1 - p^{-s}}.$$

As the prime windows cofinally exhaust $\mathbb{P}$, this agrees with the Euler projection on $\Re(s) > 1$.

Proof. On the p-factor, the number row has eigenvalues $k \geq 0$, so

$$\mathrm{Tr}(e^{-s(\log p)N_p}) = \sum_{k \geq 0} p^{-ks} = \frac{1}{1 - p^{-s}}$$

for $\Re(s) > 0$. The finite tensor product trace is the product of these one-prime traces. The cofinal window statement is the Euler gluing row of Definition 9243.4. □

Corollary 9251.7 (Energy moments of the trace)**.** *On $\Re(s) > 1$,*

$$(-\partial_s)^k \zeta_D(s) = \sum_{n \geq 1} (\log n)^k n^{-s}.$$

In particular,

$$i\partial_t \zeta_D(\sigma + it) = -\zeta_D'(\sigma + it) = \mathrm{Tr}(H_\zeta e^{-(\sigma+it)H_\zeta}).$$

Proof. Absolute convergence on the displayed window licenses termwise differentiation. Each application of $-\partial_s$ multiplies the n-term by $\log n$. The t-derivative identity follows from $s = \sigma + it$. □

9251.3 Prime Tick and Solenoid Phase

Definition 9251.8 (Prime creation tick)**.** *For a prime p, the prime creation tick is the isometry*

$$C_p : \mathcal{H}_\zeta \to \mathcal{H}_\zeta, \qquad C_p|n\rangle := |pn\rangle.$$

More generally, $C_m|n\rangle := |mn\rangle$ for $m \geq 1$. On the register row,

$$\nu(pn) = \nu(n) + e_p.$$

Definition 9251.9 (Zeta tick ledger residual)**.** *Let $\mathcal{L} \subseteq \mathcal{H}_\zeta$ be a closed ledger subspace and let $B \in \mathcal{L}$. The residual of the prime tick p is*

$$\eta_p := C_p B - P_{\mathcal{L}} C_p B,$$

where $P_{\mathcal{L}}$ is the orthogonal projection onto $\mathcal{L}$. The tick-extended ledger is

$$\mathcal{L}^+ := \mathcal{L} \oplus \overline{\mathrm{span}}\{\eta_p\}.$$

Theorem 9251.10 (Prime ticks enter the ledger orthogonally)**.** *For every closed ledger $\mathcal{L}$ and every prime tick p,*

$$\eta_p \perp \mathcal{L}.$$

Proof. This is the Hilbert projection theorem applied to $C_p B$ and the closed subspace $\mathcal{L}$. The vector

$$C_p B - P_{\mathcal{L}} C_p B$$

is orthogonal to $\mathcal{L}$, and this vector is η_p by Definition 9251.9. □

Definition 9251.11 (Finite-window Zeta solenoid phase row)**.** *For a finite prime window S, the Zeta solenoid phase row is the one-parameter phase family on the S-prime torus with frequency vector*

$$\omega_p^\zeta := -\log p \qquad (p \in S).$$

For an integer supported in S,

$$n = \prod_{p \in S} p^{v_p(n)},$$

the associated character row is

$$\chi_n := \prod_{p \in S} \chi_p^{v_p(n)}.$$

Theorem 9251.12 (Solenoid phase reads the Zeta phase)**.** *Along the finite-window Zeta phase row,*

$$\chi_n(\tau_{\zeta,S}(t)) = n^{-it}.$$

Proof. By the frequency definition,

$$\chi_p(\tau_{\zeta,S}(t)) = e^{-it \log p}.$$

Multiplying over the finite support of n gives

$$\chi_n(\tau_{\zeta,S}(t)) = \prod_{p \in S} e^{-itv_p(n) \log p} = e^{-it \log n} = n^{-it}.$$

□

Principle 9251.13 (Zeta phase is not a bare circle readout)**.** *The visible row $n^{-it} \in \mathbb{T}$ is only the circle projection of the prime-ledger phase. The solenoid row of Definition 9289.4 permits hidden compact prime-register fibres. It does not permit an independent positive real radial coordinate to be hidden as phase fibre.*

9251.4 Zero Closure and Li Radial Residual

Definition 9251.14 (Li radial residual)**.** *For a nonzero zero-coordinate ρ, its Li coordinate is*

$$z_\rho := 1 - \frac{1}{\rho}.$$

Writing

$$z_\rho = e^{\ell_\rho + i\theta_\rho},$$

the real number

$$\ell_\rho := \log |z_\rho|$$

is the Li radial residual.

Theorem 9251.15 (Li radial residual is the fixed-half test)**.** *For $\rho = \beta + i\gamma$ with $\rho \neq 0$,*

$$\ell_\rho = 0 \quad \Longleftrightarrow \quad \beta = \frac{1}{2}.$$

Proof. The equality $\ell_\rho = 0$ is equivalent to $|z_\rho| = 1$. Since

$$z_\rho = \frac{\rho - 1}{\rho},$$

this is equivalent to

$$|\rho - 1| = |\rho|.$$

Writing $\rho = \beta + i\gamma$, the squared equality is

$$(\beta - 1)^2 + \gamma^2 = \beta^2 + \gamma^2,$$

which reduces to $\beta = 1/2$. □

Principle 9251.16 (Zeta–Euler tick algebra proof boundary)**.** *The Zeta–Euler tick algebra supplies the following translation: prime-register ticks generate finite-support integer sections, the logarithmic Hamiltonian reads their energy, the right-half-plane trace recovers the Dirichlet projection, the finite-window trace recovers the Euler product, and the Li radial residual measures departure from the fixed-half surface. The remaining RH-facing source statement is not any of these identities. It is the exclusion of a nonzero archimedean radial residual from every accepted completed zero packet, in the presence of the continuation, completion, solenoid, and zero-coverage ledgers.*

Chapter 9252

Information-Channel Normal Form of RH

chapter 9243 identifies the critical line with the unit-amplitude surface of the centered prime-local channels. The present chapter rewrites the same fact in information-channel coordinates. It does not introduce another conjecture and it does not prove RH. It replaces the geometric phrase "line $\Re(s) = 1/2$" by the coordinate-free certificate condition that every non-trivial prime-source cancellation event has zero amplitude bias.

9252.1 Information coordinates

Definition 9252.1 (Bias-clock coordinates)**.** *For a complex history s, write*

$$s = \frac{1}{2} + \delta + i\tau.$$

The real parameter δ is the amplitude-bias coordinate, and the real parameter τ is the phase-clock coordinate. The critical-line predicate is then

$$\mathsf{OnCritLine}(s) \quad \Longleftrightarrow \quad \delta\mathsf{hsame0}.$$

Definition 9252.2 (Prime information source)**.** *The prime information source is the displayed atomic source $\mathcal{P}$ whose atoms are the prime packets carried by $\mathsf{Prime}^{\uparrow}$. A positive integer packet is read as a finite product of these atoms:*

$$n = \prod_p p^{k_p}.$$

Thus the prime source is not an auxiliary interpretation of zeta; it is the local coordinate system already exposed by the Euler-product row.

Definition 9252.3 (Centered information channel)**.** *For $p \in \mathsf{Prime}^{\uparrow}$ and $s = 1/2 + \delta + i\tau$, define the centered prime information channel*

$$U_p(\delta, \tau) = p^{1/2-s} = p^{-\delta-i\tau}.$$

Equivalently,

$$U_p(\delta, \tau) = p^{-\delta} e^{-i\tau \log p}.$$

Its amplitude row is

$$\mathsf{Amp}_p(\delta, \tau) = |U_p(\delta, \tau)| = p^{-\delta}.$$

Proposition 9252.4 (Zero bias is unit channel amplitude)**.** *For any displayed prime row $p > 1$,*

$$|U_p(\delta, \tau)| = 1 \quad \Longleftrightarrow \quad \delta = 0.$$

Consequently,

$$\delta = 0 \quad \Longleftrightarrow \quad \forall p \in \mathsf{Prime}^{\uparrow},\ |U_p(\delta, \tau)| = 1.$$

Proof. By Definition 9252.3,

$$|U_p(\delta, \tau)| = p^{-\delta}.$$

Since $p > 1$, this amplitude is one exactly when $-\delta = 0$, equivalently $\delta = 0$. The universal statement follows because every displayed prime row has the same bias coordinate. □

Corollary 9252.5 (Amplitude bias is prime-source tilt)**.** *If $\delta > 0$, every sufficiently large prime channel is damped by the factor $p^{-\delta} < 1$. If $\delta < 0$, every sufficiently large prime channel is amplified by the factor $p^{-\delta} > 1$. Thus $\delta \neq 0$ is exactly the presence of a coherent prime-source amplitude tilt.*

Proof. This is the sign reading of $|U_p(\delta, \tau)| = p^{-\delta}$. Positive bias places the exponent below zero, while negative bias places the exponent above zero. □

9252.2 Prime carrier and cancellation events

Definition 9252.6 (Prime carrier)**.** *The prime carrier at information parameter (δ, τ) is the analytic recovery packet*

$$\mathsf{PrimeCarrier}(\delta, \tau) = \mathrm{AnaRec}\left(\prod_{p \in \mathsf{Prime}^{\uparrow}} (1 - p^{-1/2-\delta-i\tau})^{-1}\right).$$

Equivalently, on the Dirichlet projection window, it is recovered from

$$\sum_{n \geq 1} n^{-1/2-\delta-i\tau}.$$

This is the same ZETA *recovery carrier read through the information coordinates of Definition 9252.1.*

Definition 9252.7 (Prime-source cancellation)**.** *The prime-source cancellation predicate is*

$$\mathsf{Cancel}_{\mathcal{P}}(\delta, \tau) :\Longleftrightarrow \mathsf{PrimeCarrier}(\delta, \tau)\mathsf{hsame0}_{\mathbb{C}}.$$

It is the information-channel reading of a zeta-zero row: the prime-source carrier has a global coherent cancellation at the displayed parameter.

Definition 9252.8 (Information band)**.** *The non-trivial information band is*

$$\mathsf{InfoBand}(\delta) :\Longleftrightarrow -\frac{1}{2} < \delta < \frac{1}{2}.$$

Under $s = 1/2 + \delta + i\tau$, this is exactly the critical-strip condition $0 < \Re(s) < 1$.

Definition 9252.9 (Information RH)**.** *The information-channel normal form of the Riemann Hypothesis is*

$$\mathsf{InfoRH}_{\mathcal{P}} :\Longleftrightarrow \forall(\delta,\tau),\ \mathsf{Cancel}_{\mathcal{P}}(\delta,\tau) \wedge \mathsf{InfoBand}(\delta) \Longrightarrow \delta = 0.$$

Equivalently,

$$\forall(\delta,\tau),\ \mathsf{Cancel}_{\mathcal{P}}(\delta,\tau) \wedge \mathsf{InfoBand}(\delta) \Longrightarrow \forall p \in \mathsf{Prime}^{\uparrow},\ |U_p(\delta,\tau)| = 1.$$

Proposition 9252.10 (Information RH is BEDC-RH)**.** *The proposition* $\mathsf{InfoRH}_{\mathcal{P}}$ *is equivalent to the BEDC statement* RH *of Definition 9239.7. This is a scoped coordinate readout through the substitution* $s = 1/2 + \delta + i\tau$ *and the same zero row, not a separate cancellation mechanism.*

Proof. Substitute $s = 1/2 + \delta + i\tau$. Then

$$\mathsf{InfoBand}(\delta) \quad\Longleftrightarrow\quad \mathsf{InCritStrip}(s),$$

and

$$\delta = 0 \quad\Longleftrightarrow\quad \mathsf{OnCritLine}(s).$$

The cancellation predicate is the same zero row as $\mathsf{ZetaZero}(s)$, read through the recovered carrier of Definition 9252.6. Therefore

$$\mathsf{Cancel}_{\mathcal{P}}(\delta,\tau) \wedge \mathsf{InfoBand}(\delta) \Longrightarrow \delta = 0$$

is exactly

$$\mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s) \Longrightarrow \mathsf{OnCritLine}(s),$$

which is the BEDC-RH predicate. □

9252.3 Dual return

Definition 9252.11 (Dual-return map)**.** *The information-channel dual return is*

$$\mathcal{J}(\delta,\tau) = (-\delta,\tau).$$

Under the coordinate relation $s = 1/2 + \delta + i\tau$*, this is the mirror map* $J(s) = 1 - \overline{s}$ *of Definition 9241.12.*

Proposition 9252.12 (Dual-return fixed packets are zero-bias packets)**.** *For every information parameter* (δ,τ)*,*

$$(\delta,\tau) = \mathcal{J}(\delta,\tau) \quad\Longleftrightarrow\quad \delta = 0.$$

Proof. The equality $(\delta,\tau) = (-\delta,\tau)$ is equivalent to $\delta = -\delta$, hence to $\delta = 0$. □

Corollary 9252.13 (Information fixed-point form of RH)**.** *The BEDC statement* RH *is equivalent to*

$$\forall(\delta,\tau),\ \mathsf{Cancel}_{\mathcal{P}}(\delta,\tau) \wedge \mathsf{InfoBand}(\delta) \Longrightarrow (\delta,\tau) = \mathcal{J}(\delta,\tau).$$

Proof. Combine Definition 9252.10 with Definition 9252.12. The conclusion $\delta = 0$ is exactly the dual-return fixed-packet condition. □

Theorem 9252.14 (Information-channel normal form)**.** *The following are equivalent readings of the same RH target:*

$$\mathsf{ZetaZero}(s) \wedge \mathsf{InCritStrip}(s) \Longrightarrow \mathsf{OnCritLine}(s),$$

$$\mathsf{Cancel}_{\mathcal{P}}(\delta, \tau) \wedge \mathsf{InfoBand}(\delta) \Longrightarrow \delta = 0,$$

$$\mathsf{Cancel}_{\mathcal{P}}(\delta, \tau) \wedge \mathsf{InfoBand}(\delta) \Longrightarrow \forall p \in \mathsf{Prime}^{\uparrow},\ |U_p(\delta, \tau)| = 1,$$

and

$$\mathsf{Cancel}_{\mathcal{P}}(\delta, \tau) \wedge \mathsf{InfoBand}(\delta) \Longrightarrow (\delta, \tau) = \mathcal{J}(\delta, \tau).$$

Proof. The first and second forms are equivalent by the coordinate substitution $s = 1/2 + \delta + i\tau$ used in Definition 9252.10. The second and third forms are equivalent by Definition 9252.4. The second and fourth forms are equivalent by Definition 9252.12. □

Remark 9252.15 (Information reading)**.** *In this normal form, a non-trivial zero is read as a global cancellation event of the recovered prime-source carrier. The coordinate δ records the coherent amplitude bias of every centered prime channel, while τ records the phase clock. The functional-equation mirror changes the sign of δ and preserves τ. The RH target states that every non-trivial cancellation event is fixed by this dual return, equivalently that it occurs with zero amplitude bias.*

Concretized in §64: The prime source $\mathcal{P}$ is realized by the finite $\mathsf{Prime}^{\uparrow}$ NameCert surface and its factorization rows.

Concretized in §71: The right-half-plane prime carrier projection is realized by the $\mathsf{ZetaBasic}^{\uparrow}$ Dirichlet and Euler-product rows.

Concretized in §580: The analytic recovery of $\mathsf{PrimeCarrier}$ is routed through the zeta-continuation witness packet.

Concretized in §581: The dual-return map is the information-coordinate reading of the zeta functional-equation mirror row.

Concretized in §550: Prime-source cancellation in the information band is consumed through the critical-strip zeta-zero witness surface.

Concretized in §548: Zero-bias output is the information-channel reading of the critical-line witness packet.

Chapter 9253

Zeta Zero Type Factorization

chapter 9250 treats zeta as a recovered carrier assembled from compatible analytic, arithmetic, completion, mirror, and zero-ledger rows. The present chapter records the type-theoretic form of its zero surface. A zeta zero is not a bare point of the complex plane. It is an inhabitant of the zero fiber of the zeta-value relation, together with the ledger rows that identify the value with the zero complex history. This chapter does not prove RH; it identifies the pullback and factorization obligations consumed by the fixed-half section form of chapter 9254.

9253.1 Zeta Zero Fiber

Definition 9253.1 (Zeta domain and zero object)**.** *The zeta domain* $\mathsf{ZetaDom}^{\uparrow}$ *is the recovered continuation domain for* $\mathsf{ZetaCont}^{\uparrow}$*, with the pole at* 1 *excluded and with its continuation, branch, pole, and provenance ledgers displayed. The zero object of* $\mathsf{Complex}^{\uparrow}$ *is the terminal row*

$$0_{\mathbb{C}} : \mathbf{1} \to \mathsf{Complex}^{\uparrow}, \qquad 0_{\mathbb{C}}(*) = e_{\mathsf{Complex}^{\uparrow}}.$$

The zeta-value readout is represented internally by the relation

$$\mathsf{ZetaVal}(s, z),$$

with $s : \mathsf{ZetaDom}^{\uparrow}$ *and* $z : \mathsf{Complex}^{\uparrow}$*, rather than by an unledgered host function.*

Definition 9253.2 (Zeta zero type)**.** *The zeta zero type is the pullback-like carrier*

$$\mathsf{ZetaZeroType} := \sum_{s:\mathsf{ZetaDom}^{\uparrow}} \sum_{z:\mathsf{Complex}^{\uparrow}} (\mathsf{ZetaVal}(s, z) \times z \sim_{\mathsf{Complex}^{\uparrow}} e_{\mathsf{Complex}^{\uparrow}}).$$

It is the BEDC zero fiber

$$\mathsf{ZetaDom}^{\uparrow} \times_{\mathsf{Complex}^{\uparrow}} \mathbf{1}$$

read through the available $\mathsf{ZetaVal}$ *witness relation. Its classifier identifies two inhabitants when their source rows are classified together and their displayed value witnesses agree at the zero complex history.*

Definition 9253.3 (Zero projections)**.** *The source and value projections are*

$$\pi_s : \mathsf{ZetaZeroType} \to \mathsf{ZetaDom}^{\uparrow}, \qquad \pi_z : \mathsf{ZetaZeroType} \to \mathsf{Complex}^{\uparrow},$$

with

$$\pi_s(s, z, v, \epsilon) = s, \qquad \pi_z(s, z, v, \epsilon) = z.$$

They are projections from a witness-bearing fiber, not forgetful maps from a host-side zero set.

Theorem 9253.4 (Zeta zero type is the zero fiber)**.** *The carrier* $\mathsf{ZetaZeroType}$ *is equivalent, in the licensed classifier sense, to the zero fiber of the zeta-value readout.*

Proof. The zero fiber of the zeta-value readout is the dependent carrier of source rows s whose zeta value is classified with the zero complex history. In BEDC this assertion is represented by a displayed value row $z : \mathsf{Complex}^{\uparrow}$, a witness $\mathsf{ZetaVal}(s, z)$, and a classifier row $z \sim_{\mathsf{Complex}^{\uparrow}} e_{\mathsf{Complex}^{\uparrow}}$. Expanding the dependent carrier gives exactly Definition 9253.2. The classifier is the same source-and-value witness compatibility used by the zero ledger. □

9253.2 Non-Trivial and Fixed-Half Subtypes

Definition 9253.5 (Non-trivial zero type)**.** *The non-trivial zero type is the displayed subtype*

$$\mathsf{NTZeroType} := \sum_{u:\mathsf{ZetaZeroType}} \mathsf{InCritStrip}(\pi_s(u)).$$

It is the type-theoretic form of the RH source carrier $\mathcal{Z}_\zeta$ *in Definition 9254.1.*

Definition 9253.6 (Fixed-half zero type)**.** *The fixed-half zero type is*

$$\mathsf{FixedHalfZeroType} := \sum_{u:\mathsf{NTZeroType}} \mathsf{OnCritLine}(\pi_s(u)).$$

The projection

$$\iota : \mathsf{FixedHalfZeroType} \to \mathsf{NTZeroType}$$

forgets only the fixed-half witness and retains the zero and critical-strip ledgers.

Theorem 9253.7 (RH is fixed-half subtype coverage)**.** *The BEDC-RH predicate of Definition 9239.7 is equivalent to a section of*

$$\iota : \mathsf{FixedHalfZeroType} \to \mathsf{NTZeroType}.$$

Proof. An element of $\mathsf{NTZeroType}$ is a zeta-zero witness together with a critical-strip witness. A section of ι assigns to every such element an additional witness of $\mathsf{OnCritLine}$ for the same source row. This is exactly the dependent function required by Definition 9239.7. Conversely, any inhabitant of the BEDC-RH predicate sends an element of $\mathsf{NTZeroType}$ to the same element paired with its critical-line witness, producing a section. □

9253.3 Zero Generators

Definition 9253.8 (Zeta zero generator)**.** *For a licensed carrier* A*, a zeta zero generator is a licensed morphism*

$$G : A \to \mathsf{ZetaDom}^{\uparrow}$$

together with a zero-value witness family

$$\theta_G(a) : \sum_{z:\mathsf{Complex}^{\uparrow}} (\mathsf{ZetaVal}(G(a), z) \times z \sim_{\mathsf{Complex}^{\uparrow}} e_{\mathsf{Complex}^{\uparrow}}).$$

The generator is legal only when the carrier, classifier, stability, ledger, transport, and $\mathsf{NameCert}$ *rows for* A *and the displayed morphism are present.*

Definition 9253.9 (Induced zero map)**.** *The zero generator G induces*

$$\overline{G} : A \to \mathsf{ZetaZeroType}$$

by sending a to the tuple

$$(G(a), z_a, v_a, \epsilon_a)$$

read from $\theta_G(a) = (z_a, v_a, \epsilon_a)$.

Theorem 9253.10 (Zero generators factor through the zero type)**.** *Every legal zeta zero generator factors through* ZetaZeroType*, and the factorization is unique up to the zero-type classifier.*

Proof. The witness family θ_G gives exactly the data required by Definition 9253.2: a source row, a zeta-value row, and a zero classifier row. Hence it defines $\overline{G}$. If another map $H : A \to \mathsf{ZetaZeroType}$ has the same source projection and the same zero-value witness ledger, then the zero-type classifier identifies $H(a)$ with $\overline{G}(a)$ for every a. This is the classifier form of the pullback universal property. □

Corollary 9253.11 (Legal generators share the zero fiber)**.** *Any two legal zeta zero generators are maps into the same* ZetaZeroType *after applying their induced zero maps. They may present different subcarriers, but their zero status is typed through the same zero fiber.*

9253.4 Canonical Presentations and Compatibility

Definition 9253.12 (Canonical zero presentation)**.** *A canonical presentation of* ZetaZeroType *is a licensed map*

$$P : A \to \mathsf{ZetaZeroType}$$

such that:

$$a \sim_A a' \to P(a) \sim_{\mathsf{Zero}} P(a'),$$
$$\prod_{u:\mathsf{ZetaZeroType}} \sum_{a:A} P(a) \sim_{\mathsf{Zero}} u,$$

and

$$P(a) \sim_{\mathsf{Zero}} P(a') \to a \sim_A a'.$$

Thus P is an equivalence of licensed presentations, not merely a surjective listing of complex coordinates.

Theorem 9253.13 (Canonical zero presentations are unique up to equivalence)**.** *If $P : A \to$* ZetaZeroType *and $Q : B \to$* ZetaZeroType *are canonical presentations, then A and B are equivalent licensed presentations of the same zero type.*

Proof. By canonicity, P is full on zero-type rows and faithful to the source classifier, so it presents A as an equivalent carrier for ZetaZeroType. The same argument applies to Q and B. Composing one equivalence with the inverse of the other yields the licensed equivalence between A and B. □

Definition 9253.14 (Compatible zero generators)**.** *Two zero generators are compatible when their induced maps into* ZetaZeroType *factor through a common canonical presentation after licensed equivalence of their source carriers. They are incompatible when no such common presentation and equivalence data are supplied.*

Corollary 9253.15 (Incompatible canonical generators cannot present one zero type)**.** *Two incompatible generators cannot both be canonical presentations of the same* $\mathsf{ZetaZeroType}$.

Proof. If both were canonical presentations of the same zero type, then Definition 9253.13 would supply the common equivalence data required by Definition 9253.14. This contradicts incompatibility. □

9253.5 Zero and Apart-Zero Conflict

Definition 9253.16 (Same-source zero and apart-zero rows)**.** *A same-source zero and apart-zero conflict consists of a source row* $s : \mathsf{ZetaDom}^{\uparrow}$*, a zero witness*

$$(z, v, \epsilon) : \sum_{z:\mathsf{Complex}^{\uparrow}} (\mathsf{ZetaVal}(s, z) \times z \sim_{\mathsf{Complex}^{\uparrow}} e_{\mathsf{Complex}^{\uparrow}}),$$

and an apart-zero witness

$$\mathsf{Apart}_0(\zeta(s)).$$

Both witnesses must be read through the same zeta-value ledger for the conflict to be typed.

Theorem 9253.17 (Same-source zero and apart-zero conflict is impossible)**.** *A same-source zero and apart-zero conflict yields* $\bot$.

Proof. The zero witness supplies a value row $\mathsf{ZetaVal}(s, z)$ and a classifier row $z \sim_{\mathsf{Complex}^{\uparrow}} e_{\mathsf{Complex}^{\uparrow}}$. The apart-zero witness asserts that the same zeta value is positively separated from the zero complex history. Since the zeta-value ledger identifies fixed-source values up to the complex classifier, the same value cannot be both classified with zero and apart from zero. Hence the conflict yields $\bot$. □

Principle 9253.18 (Type-theoretic skeleton of defect-zero incompatibility)**.** *The local-global target of Definition 9246.13 has this type-theoretic skeleton: a prime-window or bulk-boundary defect route may contradict a zero packet only after it produces an apart-zero witness for the same source row and the same zeta-value ledger.*

9253.6 Omega Factorization

Definition 9253.19 (Omega non-trivial zero carrier)**.** *For an* Ω *tower with zeta projection*

$$\pi_\zeta : T_\Omega \to \mathsf{ZetaDom}^{\uparrow},$$

the Omega non-trivial zero carrier is

$$T_\Omega^{nt0} := \sum_{x:T_\Omega} (\mathsf{ZetaZero}(\pi_\zeta(x)) \times \mathsf{InCritStrip}(\pi_\zeta(x)))\,.$$

Theorem 9253.20 (Omega zero carrier factors through the non-trivial zero type)**.** *The projection* π_ζ *restricted to* T_Ω^{nt0} *factors through* $\mathsf{NTZeroType}$.

Proof. An element of T_Ω^{nt0} is a tower row x together with a zeta-zero witness and a critical-strip witness for $\pi_\zeta(x)$. Expanding Definition 9253.5, this is precisely an element of $\mathsf{NTZeroType}$ over the source $\pi_\zeta(x)$. The factorization is unique up to the displayed subtype classifier. □

Theorem 9253.21 (Fixed-half factorization is an RH sufficient interface)**.** *If the factorization of T_Ω^{nt0} through* NTZeroType *further factors through* FixedHalfZeroType*, and every legal non-trivial zeta-zero packet is represented by some row of T_Ω^{nt0}, then the BEDC-RH predicate holds.*

Proof. Let u : NTZeroType. By representation, choose a row $x : T_\Omega^{nt0}$ whose zeta projection is classified with the source of u and whose zero and critical-strip witnesses transport to those of u. Fixed-half factorization gives $\mathsf{OnCritLine}(\pi_\zeta(x))$. Classifier stability of OnCritLine transports this witness to $\pi_s(u)$. Since this holds for every u : NTZeroType, Definition 9253.7 yields the BEDC-RH predicate. □

Principle 9253.22 (Status of zero-type factorization)**.** *Zero-type factorization clarifies where uniqueness and incompatibility live: legal zero generators factor through the same zero fiber, canonical presentations are unique up to licensed equivalence, and a contradiction requires same-source zero and apart-zero witnesses. The remaining RH content is the construction of the fixed-half factorization, not the existence of the zero type itself.*

Concretized in §8772: Finite zero-fiber, generator-factorization, and fixed-half ledger rows are realized as a concrete NameCert packet.

Chapter 9254

Layered RH Translation

chapter 9239 states the Riemann Hypothesis as a constructive function from critical-strip zeta-zero witnesses to $\mathsf{OnCritLine}$ witnesses. The prime-local and information-channel chapters then rewrite the same target through centered prime amplitudes and zero-bias cancellation. The present chapter records the common layered translation principle: each formulation is a readout of the same fixed-half fiber over the source carrier of non-trivial zeta-zero packets. It does not prove RH and does not introduce an additional conjecture.

9254.1 Source Carrier and Half Fiber

Definition 9254.1 (RH source carrier)**.** *The RH source carrier is the displayed sigma carrier*

$$\mathcal{Z}_\zeta := \sum_s (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)).$$

It is the BEDC-facing zero packet carrier already used by Definition 9239.7; it is not a host-side zero set and not an ambient quotient of all complex roots.

Definition 9254.2 (Real half layer)**.** *The real half layer over $\mathcal{Z}_\zeta$ is*

$$\mathcal{H}_\mathbb{R} = (\mathsf{Real}^\uparrow,\ b_\mathbb{R},\ 1/2), \qquad b_\mathbb{R}(s) := \Re(s).$$

Its fixed half fiber is

$$\mathrm{Fix}_\mathbb{R} := \sum_{z:\mathcal{Z}_\zeta} (b_\mathbb{R}(z) = 1/2).$$

Definition 9254.3 (RH section form)**.** *The section form of RH is the type*

$$\mathsf{Sec}_\mathsf{RH} := \sum_{\sigma:\mathcal{Z}_\zeta \to \mathrm{Fix}_\mathbb{R}} (\pi_\mathbb{R} \circ \sigma = \mathrm{id}_{\mathcal{Z}_\zeta}),$$

where $\pi_\mathbb{R}$ is the projection from the fixed half fiber to the zero packet carrier.

Proposition 9254.4 (RH is a fixed-half section)**.** *The BEDC statement RH of Definition 9239.7 is equivalent to Sec_RH.*

Proof. By Definition 9239.7, RH is the dependent product assigning to every $z : \mathcal{Z}_\zeta$ a witness that $b_\mathbb{R}(z) = 1/2$. The section type records exactly the same data: from such a product one sends z to (z, p) in the fixed half fiber; from a section one reads the second component of $\sigma(z)$ and transports it along the section equation. This is the specialization of Definition 9414.159. □

9254.2 Equivalent Readout Layers

Definition 9254.5 (Complex mirror half layer)**.** *The complex mirror half layer reads a zero packet through the mirror fixed-surface predicate*

$$J(s) = s, \qquad J(s) := 1 - \overline{s}.$$

By Definition 9414.163, this predicate is equivalent to $b_{\mathbb{R}}(s) = 1/2$.

Definition 9254.6 (Prime-unitary half layer)**.** *The prime-unitary half layer reads a zero packet through the centered prime-channel predicate*

$$\forall p \in \mathsf{Prime}^{\uparrow},\ |p^{1/2}p^{-s}|\mathsf{hsame1}.$$

By Definition 9243.7, this predicate is equivalent to $\mathsf{OnCritLine}(s)$ *on the displayed prime packet.*

Definition 9254.7 (Information half layer)**.** *The information half layer writes*

$$s = 1/2 + \delta + i\tau$$

and reads the half condition as

$$\delta = 0.$$

By Definition 9252.14, this is the information-channel normal form of the same RH target.

Definition 9254.8 (Laplace half layer)**.** *The Laplace half layer reads a zero*

$$\rho = 1/2 + \delta + i\gamma$$

through the explicit-formula growth factor

$$e^{\rho x} = e^{x/2}e^{\delta x}e^{i\gamma x}.$$

The fixed half surface is the absence of the bias factor $e^{\delta x}$*, equivalently* $\delta = 0$.

Definition 9254.9 (BEDC witness half layer)**.** *The BEDC witness half layer reads a zero packet as the output type*

$$\mathsf{OnCritLine}(s).$$

This is the constructive witness surface of Definition 9239.8: an inhabitant is a finite witness identifying $\Re(s)$ *with* $1/2$ *inside the relevant* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{Rat}^{\uparrow}$ *certificate rows.*

Theorem 9254.10 (Layered RH translations)**.** *The following readout forms are equivalent section targets over* $\mathcal{Z}_{\zeta}$*:*

$$\Re(s) = 1/2, \qquad J(s) = s, \qquad \forall p \in \mathsf{Prime}^{\uparrow},\ |p^{1/2}p^{-s}|\mathsf{hsame1},$$

$$\delta = 0, \qquad \textit{no } e^{\delta x} \textit{ Laplace bias}, \qquad \mathsf{OnCritLine}(s).$$

Proof. The first and second forms are equivalent by Definition 9414.163. The first and third forms are equivalent by Definition 9243.7. The first and fourth forms are the coordinate substitution of Definition 9252.1. The fourth and fifth forms are the same equality read through $e^{\rho x} = e^{x/2}e^{\delta x}e^{i\gamma x}$. The first and sixth forms are the definition of the constructive output in Definition 9239.7. All translations preserve the same source carrier $\mathcal{Z}_{\zeta}$ and therefore yield equivalent section targets. □

9254.3 Zeta Recovery and Laplace Readout

Definition 9254.11 (Discrete Laplace source)**.** *For a sequence (a_n), the discrete Laplace source is the atomic measure row*

$$\mu_a := \sum_{n\geq 1} a_n \delta_{\log n}.$$

Its Laplace readout is

$$\mathcal{L}[\mu_a](s) := \int_0^\infty e^{-st}\, d\mu_a(t).$$

Proposition 9254.12 (Dirichlet series as discrete Laplace readout)**.** *On any displayed convergence window,*

$$\sum_{n\geq 1} a_n n^{-s} = \mathcal{L}[\mu_a](s).$$

Proof. By the definition of μ_a,

$$\mathcal{L}[\mu_a](s) = \sum_{n\geq 1} a_n e^{-s\log n}.$$

Since $e^{-s\log n} = n^{-s}$ on the displayed branch and convergence window, this is the Dirichlet series. □

Definition 9254.13 (Zeta recovery layer)**.** *The zeta recovery layer is the carrier recovered from the compatible rows*

$$\mathsf{DirichletProjection},\quad \mathsf{EulerProjection},\quad \mathsf{ZetaCont}^{\uparrow},\quad \mathsf{Gamma}^{\uparrow}\text{-}\textit{completion},\quad \mathsf{FunctionalEquation},$$

$$\mathsf{PoleLedger},\quad \mathsf{ZeroLedger},\quad \mathsf{BranchTransport}.$$

This is the recovered ZETA *carrier of Definition 9243.2; no single projection row exhausts it.*

Principle 9254.14 (RH translation does not add analytic supply)**.** *The layered RH translation does not supply analytic continuation, Euler product convergence, Gamma factors, zero counting, or an RH proof. It only records that, once the relevant zeta-zero source packet is admitted, the real, complex-mirror, prime-unitary, information, Laplace, and BEDC witness surfaces are readouts of the same fixed half fiber.*

9254.4 Exception Transport and No-Exception Form

Definition 9254.15 (RH layer exception)**.** *For a half layer $\mathcal{H} = (B, b, h)$ over $\mathcal{Z}_\zeta$, a layer exception is the dependent sum*

$$\mathsf{Exc}_{\mathcal{H}} := \sum_{z:\mathcal{Z}_\zeta} \neg(b(z) = h).$$

It is a zero packet together with a failure of the half-value predicate at that readout layer.

Definition 9254.16 (Source fixed exception)**.** *Let $\tau : \mathcal{Z}_\zeta \to \mathcal{Z}_\zeta$ be the source mirror induced by the zeta functional-equation symmetry. A source fixed exception is*

$$\mathsf{Exc}_{\mathrm{src}} := \sum_{z:\mathcal{Z}_\zeta} \neg(\tau(z) = z).$$

This is the source-level non-fixed packet; it is not yet a failure at any particular real, prime, information, Laplace, or witness readout.

Definition 9254.17 (Half-preserving equivalence)**.** *A half layer $\mathcal{H} = (B, b, h)$ is half-preserving with respect to τ when there is a displayed family of equivalences*

$$\epsilon_{\mathcal{H}}(z) : (\tau(z) = z) \simeq (b(z) = h)$$

for every $z : \mathcal{Z}_\zeta$.

Theorem 9254.18 (Exception transport)**.** *If $\mathcal{H}$ is half-preserving with respect to τ, then*

$$\mathsf{Exc}_{\mathcal{H}} \simeq \mathsf{Exc}_{\mathrm{src}}.$$

Proof. For each z, the equivalence $\epsilon_{\mathcal{H}}(z)$ transports witnesses of $\tau(z) = z$ to witnesses of $b(z) = h$ and conversely. Contraposition along the two maps gives an equivalence between $\neg(b(z) = h)$ and $\neg(\tau(z) = z)$. Dependent-sum formation over the same source carrier $\mathcal{Z}_\zeta$ then yields the displayed equivalence of exception types. □

Theorem 9254.19 (No-exception transfer)**.** *If $\mathcal{H}$ is half-preserving with respect to τ, then*

$$\neg\mathsf{Exc}_{\mathrm{src}} \to \neg\mathsf{Exc}_{\mathcal{H}}.$$

Proof. Compose a hypothetical element of $\mathsf{Exc}_{\mathcal{H}}$ with the transport map of Definition 9254.18. The result is an element of $\mathsf{Exc}_{\mathrm{src}}$, contradicting the premise. □

Theorem 9254.20 (Symmetric closure is not no-exception)**.** *Closure of $\mathcal{Z}_\zeta$ under an involution τ does not by itself imply*

$$\neg\mathsf{Exc}_{\mathrm{src}}.$$

Proof. Consider a two-row carrier $\{a, b\}$ with $\tau(a) = b$ and $\tau(b) = a$. This carrier is closed under the involution and τ is an involution. Nevertheless neither row is fixed. Hence the sigma type $\sum_z \neg(\tau(z) = z)$ is inhabited. The example separates symmetry of the carrier from fixedness of every source row. □

Corollary 9254.21 (Precise role of contradiction)**.** *A contradiction argument can eliminate a layer exception only after that exception has been transported to a source fixed exception and the source fixed exception has been ruled out.*

Proof. The first requirement is Definition 9254.18. The second requirement is the premise of Definition 9254.19. Without the displayed half-preserving equivalence, a contradiction at one readout layer has no typed route to the source fixed predicate; without the source no-exception premise, the transported exception is not eliminated. □

9254.5 Synthesis

Theorem 9254.22 (Layered RH synthesis)**.** *Inside the RH vision stack, the Riemann Hypothesis has the unified section form*

$$\mathcal{Z}_\zeta \to \sum_{z:\mathcal{Z}_\zeta} (b(z) = h),$$

where (B, b, h) may be any of the equivalent half layers of Definition 9254.10. The only unshown content between two such layers is the corresponding fiber data over the same source carrier, not a separate object domain.

Proof. Definition 9254.4 identifies BEDC-RH with a section into the real fixed half fiber. Definition 9254.10 transports that section target across the complex-mirror, prime-unitary, information, Laplace, and witness readouts. The final statement about unshown content is the RH specialization of Definition 9414.142 and Definition 9414.45. □

Theorem 9254.23 (Layered RH no-exception form)**.** *For the real, complex-mirror, prime-unitary, information, Laplace, and BEDC witness layers of Definition 9254.10, the corresponding RH assertions are no-exception claims over the same source fixed-half fiber. When the half-preserving equivalence with the source mirror is displayed, the no-exception form is*

$$\neg\mathsf{Exc}_{\mathrm{src}} \to \prod_{\mathcal{H}} \neg\mathsf{Exc}_{\mathcal{H}}.$$

Carrier symmetry alone does not supply the premise $\neg\mathsf{Exc}_{\mathrm{src}}$*.*

Proof. Definition 9254.10 identifies the listed readout layers as equivalent half layers over $\mathcal{Z}_\zeta$. For each half-preserving layer, Definition 9254.19 transports source no-exception to layer no-exception. The final sentence is exactly Definition 9254.20. □

Concretized in §548: Critical-line witness packets realize the BEDC witness half layer as finite zero-packet, real-part, rational-half, hsame, transport, replay, and NameCert rows.

Concretized in §581: Functional-equation ledgers realize the mirror-readout row used by the layered RH translation.

Concretized in §580: Zeta-continuation witness packets realize the recovered zeta carrier consumed by the layered RH translation.

Chapter 9255

RH-Free Zero Generation by Initiality

chapter 9250 displays the recovered zeta carrier as a diagram of prime, Dirichlet, Euler, Laplace, continuation, completion, mirror, zero-ledger, window, code, certificate, and provenance rows. chapter 9254 identifies the Riemann Hypothesis with a section into the fixed-half fiber over the critical-strip zero-packet carrier. The present chapter isolates the initial-algebra pattern that would turn a zero-generation theorem into that section. It supplies no analytic continuation, no zero source, and no fixed-half witness by itself; it only separates the exact obligations.

Definition 9255.1 (RH-free zero signature). *Lean4 (definition)* `BEDC.Derived.RHRoute.ZeroGenerationInitiality.` *Lean4✓* `BEDC.Derived.RHRoute.ZeroGenerationInitiality.rhFreeZeroSignatureKinds no rh circ`

An RH-free zero signature is a displayed endofunctor F_Z on the zeta zero-presentation stratum together with a circularity audit

$$\mathsf{NoRHCirc}(F_Z).$$

The audit asserts that no constructor of F_Z consumes an $\mathsf{OnCritLine}$ *witness, a row asserting $\Re(s) = 1/2$, a section of the fixed-half inclusion, the proposition* RH*, or an arbitrary unfactored seed*

$$\mathcal{Z}_\zeta \to F_Z(X).$$

The admissible inputs are pre-RH rows such as prime-local spectral atoms, functional-equation transport, conjugation transport, classifier transport, analytic gluing, compatible limit seals, and ledger reconstruction. The word "pre-RH" means that the row is present in the neutral zeta carrier before the fixed-half consequence is imposed.

Definition 9255.2 (Generated zero carrier). *Lean4 (definition)* `BEDC.Derived.RHRoute.ZeroGenerationInitiality.` *Lean4✓* `BEDC.Derived.RHRoute.ZeroGenerationInitiality.generatedZero initiality`

For an RH-free zero signature F_Z, a generated zero carrier is an initial algebra

$$(Z, \mathsf{in}_Z) := \mu F_Z.$$

Its intended realization into the source carrier of Definition 9254.1 is a displayed map

$$\varepsilon : Z \to \mathcal{Z}_\zeta.$$

Zero-presentation exactness is the conjunction of soundness, faithfulness, and essential coverage:

$$\prod_{z:Z} \varepsilon(z) : \mathcal{Z}_\zeta,$$

$$\varepsilon(z) \sim \varepsilon(z') \to z \sim_Z z',$$

and

$$\prod_{u:\mathcal{Z}_\zeta} \sum_{z:Z} \varepsilon(z) \sim u.$$

When these rows are displayed, ε is written $Z \simeq \mathcal{Z}_\zeta$. This equivalence is not supplied by initiality; it is the completeness obligation saying that the displayed generators account for every accepted critical-strip zero packet.

Definition 9255.3 (Generated fixed-half subcarrier)**.** *Lean4 (definition)* `BEDC.Derived.RHRoute.ZeroGenerationIni`

Given $\varepsilon : Z \to \mathcal{Z}_\zeta$, define the generated fixed-half predicate

$$P_{1/2}(z) := \mathsf{OnCritLine}(\pi_s(\varepsilon(z))).$$

The fixed-half subcarrier of Z is

$$H_Z := \sum_{z:Z} P_{1/2}(z),$$

with projection $m : H_Z \to Z$.

Definition 9255.4 (Fixed-half closed zero signature)**.** *Lean4 (definition)* `BEDC.Derived.RHRoute.ZeroGenerationIni`

The RH-free zero signature F_Z is fixed-half closed relative to ε when H_Z carries an F_Z-algebra

$$h : F_Z(H_Z) \to H_Z$$

whose projection agrees with the original zero algebra:

$$m \circ h \sim \mathsf{in}_Z \circ F_Z(m).$$

Thus every displayed zero constructor, when fed fixed-half inputs, emits a fixed-half output. This is a constructor-by-constructor obligation, not a pointwise enumeration of zeros.

Theorem 9255.5 (Conditional initiality route to the RH section)**.** *Lean4 ✓* `BEDC.Derived.RHRoute.ZeroGeneratio` `conditional initiality route section`

Assume F_Z is RH-free, $(Z, \mathsf{in}_Z) = \mu F_Z$ is displayed, $\varepsilon : Z \simeq \mathcal{Z}_\zeta$ is zero-presentation exact, and F_Z is fixed-half closed relative to ε. Then the section form $\mathsf{Sec}_{\mathsf{RH}}$ of Definition 9254.3 is inhabited.

Proof. By Definition 9255.4, H_Z is an F_Z-algebra. Initiality of Z gives the unique algebra morphism

$$r : Z \to H_Z.$$

The composite $m \circ r : Z \to Z$ is an F_Z-algebra endomorphism of the initial algebra. The identity map on Z is also such an endomorphism, so initiality gives

$$m \circ r \sim \mathrm{id}_Z.$$

For each $z : Z$, the second component of $r(z) : H_Z$ is a witness of $P_{1/2}(z)$. Transporting this witness along $\varepsilon : Z \simeq \mathcal{Z}_\zeta$ yields a map from every source zero packet $u : \mathcal{Z}_\zeta$ to the fixed-half fiber over u. This is exactly a section of the projection $\mathrm{Fix}_{\mathbb{R}} \to \mathcal{Z}_\zeta$, hence an inhabitant of $\mathsf{Sec}_{\mathsf{RH}}$. □

Corollary 9255.6 (Conditional extraction of the BEDC RH witness)**.** *Under the hypotheses of Definition 9255.5, the constructive target of Definition 9239.8 is inhabited.*

Proof. Definition 9255.5 supplies $\mathsf{Sec}_{\mathsf{RH}}$. By Definition 9254.4, this is the scoped fixed-half section readback used by the BEDC statement RH of Definition 9239.7, whose proof content is the function described in Definition 9239.8. □

Definition 9255.7 (Weak eta capture packet)**.** *Let ρ be a non-trivial zeta zero in the open critical strip. A* weak eta capture packet *for ρ is a tuple*

$$(D, N, F_N, T_N, \gamma_D)$$

where D is a closed disk with ρ in its interior and $\overline{D} \subset \{0 < \Re(s) < 1\}$, the functions

$$F_N(s) := \sum_{n=1}^{N} (-1)^{n-1} n^{-s}, \qquad T_N(s) := \eta(s) - F_N(s)$$

satisfy

$$\eta(s) = F_N(s) + T_N(s),$$

and the boundary gap row is

$$\gamma_D : \prod_{s \in \partial D} \big(|T_N(s)| < |F_N(s)|\big).$$

The packet captures the local zero count of η by finite eta data and a tail ledger. It is not, by itself, a fixed-half or unit-boundary packet.

Theorem 9255.8 (Weak eta capture gives local zero-count capture)**.** *For every non-trivial zeta zero ρ in the open critical strip there exists a weak eta capture packet whose finite part F_N has the same number of zeros as η inside the disk D, counted with multiplicity.*

Proof. In the open critical strip,

$$\eta(s) = (1 - 2^{1-s})\zeta(s),$$

and the factor $1 - 2^{1-s}$ has no zero there. Hence ρ is a zero of η. Choose D so that its boundary has no η-zero and $\overline{D}$ stays in the open strip. Then

$$M := \min_{s \in \partial D} |\eta(s)|$$

is positive. The eta expansion converges uniformly on $\overline{D}$, so for some N the tail satisfies

$$\sup_{s \in \partial D} |T_N(s)| < M/2.$$

For $s \in \partial D$,

$$|F_N(s)| \geq |\eta(s)| - |T_N(s)| > M/2,$$

and therefore $|T_N(s)| < |F_N(s)|$ on ∂D. Rouché's theorem gives the same zero count for F_N and η inside D. □

Principle 9255.9 (Weak capture is not zero-presentation exactness)**.** *The weak eta capture packet is a local analytic capture row. It supplies finite eta data, a tail ledger, a disk, and a Rouché gap around a given zero. It does not supply the essential coverage row of Definition 9255.2. In particular, it does not build a canonical generated carrier Z, a global realization $\varepsilon : Z \to \mathcal{Z}_\zeta$, or the equivalence $Z \simeq \mathcal{Z}_\zeta$. Thus weak capture may be used as evidence for a local presentation mechanism, but it is not zero-presentation exactness.*

Principle 9255.10 (Boundary stability is the strong packet gap)**.** *The fixed-half closure hypothesis of Definition 9255.4 requires more than local zero-count capture. A strong zero packet must carry enough boundary data to show that the generated channel has no nontrivial real positive scale defect, equivalently that the active centered channels are unit-boundary rows:*

$$|e^{-(s-1/2)h_a}| = 1$$

for every active height $h_a > 0$ in the packet. Weak eta capture records a Rouché gap for a finite analytic approximation, but it does not prove this unit-boundary stability. The missing row is therefore a boundary-stability theorem, not a consequence of Rouché capture alone.

Principle 9255.11 (Conservative oscillator reading of the gap)**.** *The eta packet admits a physical reading as a many-oscillator phase sum. For*

$$s = \frac{1}{2} + r + it,$$

the n-th centered eta term is

$$(-1)^{n-1} n^{-1/2} e^{-r \log n} e^{-it \log n}.$$

The factor $e^{-it \log n}$ is a conservative phase rotation, while $e^{-r \log n}$ is a damping or gain factor. Thus a vanishing eta readout is not automatically a conservative phase closure. It may be a zero of a nonunitary amplitude-adjusted packet unless the packet carries unit-boundary stability.

Definition 9255.12 (Conservative normal-mode packet)**.** *A* conservative normal-mode packet *for a zeta zero is a strong generated packet whose finite oscillator rows display:*

canonical dominance or active capture,

unitary phase evolution,

no nontrivial real damping or gain factor,

far-end compatibility without hidden scale absorption,

and

transport to the accepted zeta-zero source row.

This is the physical reading of the strong packet required by Definition 9255.10: the zero is a normal phase cancellation of a closed conservative system, not a cancellation produced by adjusting amplitudes.

Definition 9255.13 (Galperin-style inertial unfolding)**.** *A* Galperin-style inertial unfolding *for a generated zeta-zero packet is a displayed carrier*

$$(\mathcal{M}, H, \Phi_t, \Pi)$$

with the following rows. The flow row is a single conservative phase flow

$$\Phi_t = e^{-itH}, \qquad \Phi_t^* \Phi_t = I.$$

The projection row Π reads the eta or zeta polygonal packet as a folded shadow of this unfolded orbit. The reflection row says that every folding, alternating-sign turn, functional-equation mirror, or prime-routing identification changes only phase direction inside the unfolded carrier. The unit row forbids any reflected step from changing radial scale. The crossing row reads a zero as a normalized cancellation of the projected orbit. The far-end row is a compatibility socket, not a reservoir for radial defect, and the coverage row transports the unfolded packet to the accepted zero source carrier.

Principle 9255.14 (Unique inertial time excludes radial time)**.** *In a Galperin-style inertial unfolding, the active centered channels are generated by one time parameter t through the unitary flow*

$$e^{-ith_a}.$$

For

$$s = \frac{1}{2} + r + it,$$

the corresponding analytic channel is

$$e^{-(s-1/2)h_a} = e^{-rh_a} e^{-ith_a}.$$

The second factor belongs to the inertial phase flow. The first factor is a real positive scale flow. If $r \neq 0$ and some active height satisfies $h_a > 0$, this supplies a second nonunitary time direction, not a reflection of the unitary unfolding. Thus the unique-inertial-time row can hold only when the radial parameter vanishes on every active channel.

Principle 9255.15 (ZetaGalperinInertialUnfolding target)**.** *The target*

$$\mathsf{ZetaGalperinInertialUnfolding}$$

is the combined strong form of the conservative-packet route. It requires canonical active capture, unit-boundary stability, no far-end radial absorption, and zero-presentation coverage. In this formulation, Definition 9255.13 supplies the inertial carrier, Definition 9255.14 supplies the exclusion of a scale-time component, and Definition 9255.2 supplies the coverage interface. The statement is a proof target: without these rows, a vanishing projected sum is still only a cancellation readout, not a certified conservative phase crossing.

Definition 9255.16 (Zeta cosmos closure row)**.** *The* zeta cosmos closure row *is the source-internal form of the strong route. It asserts that the zero, phase, tail, boundary, prime ledger, and generation-tower rows of the zeta sector are generated inside one BEDC triadic carrier:*

$$\mathsf{ZetaCosmosClosure}_\zeta.$$

This row has four visible components. First, every accepted non-trivial zero is covered by a generated zero:

$$\prod_{u:\mathcal{Z}_\zeta} \sum_{z:Z} \varepsilon(z) \sim u.$$

Second, every zero constructor preserves the triadic invariants

$$\mathsf{P}, \qquad \mathsf{U}, \qquad \mathsf{T},$$

read respectively as prime-ledger distinction, unit-boundary legality, and recursive time generation. Third, hidden coordinates are confined to unit phase or prime-register fibres:

$$\mathbb{T} \quad \textit{and} \quad \prod_{p \in S} \mathbb{Z}_p.$$

Fourth, no generated row may import an independent real positive scale ledger

$$\mathbb{R}_{>0}$$

as a closure coordinate. Thus the zeta sector is not treated as a projection embedded in a larger dissipative system; the row asks for the completed zero presentation itself to be source-internal.

Definition 9255.17 (Zeta Hist-flow closure row)**.** *The* zeta Hist-flow closure row *is the internal-time component of* $\mathsf{ZetaCosmosClosure}_\zeta$*. It requires the time data of a generated zeta-zero packet to factor through constructor-tail histories:*

$$B_0 = \mathsf{Empty}, \qquad B_{j+1} = E_{\epsilon_{j+1}}(B_j), \qquad \epsilon_{j+1} \in \{0,1\}.$$

The marks $\mathsf{b0}$ *and* $\mathsf{b1}$ *are read only as primitive distinction emissions; the state row is the resulting history* B_j*. Thus a later row contains its predecessor as constructor tail, and the time order is the generated history depth rather than an external clock. Write the closure target as*

$$\mathsf{ZetaHistFlowClosure}_\zeta.$$

For zeta, this row says that every accepted zero packet receives its phase-time readout from such internal histories and from the unitary phase component

$$e^{-ith_a},$$

not from an independent real positive scale flow.

Principle 9255.18 (Hist-flow closure rejects scale time)**.** *Assume a generated zero packet carries* $\mathsf{ZetaHistFlowClosure}_\zeta$ *and has active channel*

$$e^{-(s-1/2)h_a}$$

with

$$s = \frac{1}{2} + r + it, \qquad h_a > 0.$$

The internal Hist-flow supplies constructor extension and its phase readback. It supplies no independent coordinate whose readout is $e^{-rh_a} \in \mathbb{R}_{>0}$*. Hence a nonzero* r *would be a scale-time import rather than a Hist-generated phase row. The Hist-flow component of cosmos closure therefore refines the no-radial-time condition of Definition 9255.14.*

Principle 9255.19 (Cosmos closure absorbs the strong route obligations)**.** *The row* $\mathsf{ZetaCosmosClosure}_\zeta$ *packages the same analytic load as the conservative-packet route, but with the hidden-scale boundary made explicit. Its coverage component is zero-presentation exactness for Definition 9255.2. Its invariant-preservation component is the fixed-half constructor closure of Definition 9255.4. Its phase and prime-register restriction is the compact hidden-fibre side of Definition 9255.15. Its refusal of an* $\mathbb{R}_{>0}$ *closure coordinate is the no-radial-time row of Definition 9255.14.*

Corollary 9255.20 (Cosmos closure is conditionally sufficient)**.** *If* $\mathsf{ZetaCosmosClosure}_\zeta$ *holds for the RH-free zero signature, then the hypotheses of Definition 9255.23 hold.*

Proof. The coverage component supplies the essential coverage row $Z \simeq \mathcal{Z}_\zeta$. The triadic invariant-preservation component supplies constructor closure for the fixed-half subcarrier. The absence of an independent $\mathbb{R}_{>0}$ closure coordinate rules out a nontrivial factor e^{-rh_a} on every active unit-boundary channel, so boundary stability is available for the strong packet. These are exactly the two rows used by Definition 9255.23. □

Principle 9255.21 (Physical gap inventory)**.** *In the conservative-oscillator reading, the initiality route leaves five separate mathematical obligations. First, each zero must have a canonical dominant normal-mode packet, not merely an arbitrary finite truncation. Second, that packet must strongly capture the zeta zero, upgrading weak eta/Rouché capture to a source-compatible generated*

packet. Third, the packet must satisfy unitary boundary stability, excluding the damping or gain factor e^{-rh}. Fourth, the infinite tail must satisfy the no-absorption discipline of Definition 9413.143, so the far end does not act as a hidden reservoir for scale defect. Fifth, all accepted non-trivial zeta zeros must be covered by these generated packets, which is the zero-presentation exactness row of Definition 9255.2.

Corollary 9255.22 (Physical form of the conditional route)**.** *If every accepted non-trivial zeta zero is represented by a conservative normal-mode packet, then the only admissible centered-channel closure is pure phase closure. Hence the hypotheses of Definition 9255.23 are met, and the conditional initiality route supplies the RH section.*

Proof. Representation by conservative normal-mode packets supplies strong capture and zero-presentation coverage. The unitary phase and no damping-or-gain rows supply boundary stability. The far-end compatibility row prevents the infinite tail from absorbing a displayed real scale defect. These are exactly the two inputs isolated in Definition 9255.23: zero-presentation exactness and fixed-half closure. Applying that theorem gives the RH section. □

Theorem 9255.23 (Strong capture and boundary stability imply the initiality route)**.** *Assume an RH-free zero signature F_Z with initial algebra Z and a realization $\varepsilon : Z \to \mathcal{Z}_\zeta$. If every accepted non-trivial zeta-zero packet is represented by a strong generated packet and every constructor of that strong packet preserves the unit-boundary row of Definition 9255.10, then the hypotheses of Definition 9255.5 are exactly the zero-presentation exactness and fixed-half closure supplied by those two rows.*

Proof. Strong representation of every accepted non-trivial zero supplies the essential coverage component of Definition 9255.2; together with the displayed soundness and faithfulness rows, this is $\varepsilon : Z \simeq \mathcal{Z}_\zeta$. Boundary stability states that each constructor preserves the unit-boundary readout, hence preserves the predicate

$$P_{1/2}(z) = \mathsf{OnCritLine}(\pi_s(\varepsilon(z)))$$

appearing in Definition 9255.3. This is precisely the algebra structure on H_Z required by Definition 9255.4. Applying Definition 9255.5 then yields the RH section. □

Principle 9255.24 (Initiality does not give zero completeness)**.** *The initiality of $Z = \mu F_Z$ proves induction over the zeros generated by F_Z. It does not prove that F_Z has generated every accepted critical-strip zero packet. The essential coverage component of Definition 9255.2 is therefore one of the two central mathematical obligations of the route. Without it, an off-half zero outside the generated carrier would not be seen by initial-algebra induction.*

Principle 9255.25 (Constructor closure is the fixed-half hinge)**.** *The other central obligation is fixed-half closure of the constructors. Administrative constructors, such as classifier transport and ledger reconstruction, should preserve $P_{1/2}$ by stability. Symmetry constructors, such as conjugation and functional-equation transport, must preserve the mirror fixed surface. Limit constructors must preserve $P_{1/2}$ through real-part continuity and uniqueness of the completed limit. Primitive zero-source constructors are the analytic hinge: they must produce fixed-half zero packets without smuggling an* OnCritLine *witness into their input data.*

Principle 9255.26 (Window induction and limit windows)**.** *The same distinction applies to inspection windows. Finite generated windows are handled by structural induction over their window signature. Limit windows are handled as compatible inverse systems*

$$W_0 \leftarrow W_1 \leftarrow W_2 \leftarrow \cdots ,$$

with a limit-window predicate read as

$$P_\infty(w) := \prod_n P_n(\pi_n w).$$

This removes the need to inspect an untyped totality of windows while still recording the exact compatibility data required for a completed zero carrier.

Principle 9255.27 (Failure readings)**.** *The initiality route has three mathematically distinct failure readings. If* $\mathsf{NoRHCirc}(F_Z)$ *fails, the proposed generator has assumed the fixed-half conclusion. If zero-presentation exactness fails, the generator does not cover the accepted non-trivial zero carrier. If fixed-half closure fails for a constructor, the failing constructor identifies the analytic mechanism by which an off-half packet could enter the recovered carrier. None of these failures is a route-closure decider or an independence theorem for the fixed proposition* RH*.*

Theorem 9255.28 (Completeness bridge to constructive RH)**.** Lean4 ✓ `BEDC.Derived.RHRoute.GenerativeZeroCo` `of completion`

↪ variant `BEDC.Derived.RHRoute.GenerativeZeroCompletion.symmetryReadbackRH of completion`

Let $\varepsilon : Z \to \mathcal{Z}_\zeta$ *be a generated realization whose fixed-half closure is displayed, as in Definition 9255.2. Package the completeness datum as the record whose rows are* ε*, the fixed-half closure witness, and the coverage row*

$$\prod_{u:\mathcal{Z}_\zeta} \mathsf{NontrivZero}(u) \to \sum_{z:Z} \varepsilon(z) \sim u.$$

From this record, together with the located readback row

$$\mathsf{OnCritLineReadback}(u) \to \mathsf{OnCritLine}(u),$$

the fixed-half closure supplies $\mathsf{CritLine}(\varepsilon(z))$ *for the covering generator, and critical-line transport along* $\sim$ *yields* $\mathsf{OnCritLine}(u)$*. This is the constructive Riemann hypothesis of chapter 9254, read off the generation side. The theorem is conditional: it consumes the coverage record and the readback row as hypotheses and constructs neither. The coverage row is the completeness obligation of Definition 9255.2; it is not discharged here, and no inhabitant of the completeness record is exhibited.*

Principle 9255.29 (Zero-free forward dynamics and the obligation firewall)**.** Lean4 (definition) `BEDC.Derived.RHRoute.LocatedGenerationTower.ZetaBridgeObligations`
Lean4 (definition) `BEDC.Derived.RHRoute.LocatedGenerationTower.generated true zero twoWay`

The generation side is presented as a forward dynamics that never inspects a zeta value. A tick carries a radial log-scale row, an angular rotation row, and a fresh orthogonal residual, gated by a no-adjacent Zeckendorf certificate. A state stores only its generated syntax; its located point is the fold of that syntax, never a stored coordinate, so no tick can fit a zero backwards. The analytic content is quarantined behind an evaluator interface whose binding, completeness, and soundness rows are the only bridge to the true zero set, and the forward dynamics constructs none of them. Under the packaged bridge the generated orbit and the true zero set stand in a displayed two-way correspondence.

Remark 9255.30 (Non-vacuity of the forward dynamics)**.** Lean4 (definition) `BEDC.Derived.RHRoute.LocatedGenera` `generated`

A toy instance fills every abstract row of the forward dynamics with concrete data: a prime-local seed at $p = 2$*, a constant located-complex algebra, and a tick whose register advances. It exhibits an inhabitant of the generated-point type at tick depth one, so the dynamics and its membership predicate are not vacuous. The instance carries no zeta semantics; it certifies only that the generation types are inhabited and that the dynamics runs.*

9255.1 Spectral reformulation and the Hilbert–Pólya wall

The completeness obligation of Definition 9255.2 can be carried by a single spectral statement rather than a pointwise zeta binding. The generation side supplies, ζ-free, a formal phase register, a self-adjoint height operator, and the coupling that removes every internal bookkeeping obligation; the only surviving analytic content is that the generated spectrum is the true zero spectrum.

Principle 9255.31 (Prime-phase character factorization). Lean4 (definition) BEDC.Derived.RHRoute.OCLSDPhaseAlg
Lean4 ✓ BEDC.Derived.RHRoute.OCLSDPhaseAlgebra.readPZGPhase tick

The prime register reads back into a formal phase algebra by multiplying one atom phase per activated Zeckendorf bit,

$$\chi_t(n) = \prod_{(p,k)} \mathsf{primePhase}(p,k),$$

multiplicatively over register concatenation. The atom phase depends on the prime and Fibonacci index alone, so it is prime-locked: no free angle enters, and the phase cannot be tuned to a target height.

Definition 9255.32 (Spectral zero identity). Lean4 (definition) BEDC.Derived.RHRoute.OCLSDSpectral.SpectralZer
Lean4 (definition) BEDC.Derived.RHRoute.OCLSDSpectral.zetaBridge from spectral

Let H_{OCLSD} be the diagonal operator whose orthonormal basis is the forward orbits and whose eigenvalue on an orbit is its cumulative angular height. The spectral zero identity is the pair of readings

$$\gamma \in \mathrm{Spec}(H_{\mathrm{OCLSD}}) \iff \zeta(\tfrac{1}{2} + i\gamma) = 0.$$

It is strictly weaker than pointwise evaluator binding, and it suffices: with a binding stub and the located readback it assembles the full zero-bridge record.

Principle 9255.33 (Self-adjoint generator, prime-locked spectrum). Lean4 (definition) BEDC.Derived.RHRoute.OCLS
selfAdjoint
Lean4 ✓ BEDC.Derived.RHRoute.OCLSDPrimeLock.primeLocked angle independent

Because the orbit heights are located-real, H_{OCLSD} is self-adjoint and generates a unitary phase flow. Because the per-tick height factors through the prime register only, equal prime data forces equal height: the spectrum is determined by prime arithmetic, not by the free angle row.

Principle 9255.34 (Critical coupling closes the internal obligations). Lean4 (definition) BEDC.Derived.RHRoute.OCL
from stateHeight
Lean4 (definition) BEDC.Derived.RHRoute.OCLSDCriticalCoupling.zetaBridge from spectral coupled

The orbit-to-critical-line readback is not an analytic wall but a coupling gap between the syntactic point readback and the accumulated height. A state-level height that commutes with both discharges it by induction over the orbit recursor. After this the entire zero-bridge record follows from the spectral zero identity and a binding stub alone. The one remaining obligation is the spectral zero identity itself — that the prime-generated spectrum is the true zeta zero spectrum. That is the Hilbert–Pólya content; it is not discharged here, and nothing in this chapter constructs it.

Concretized in §8799: The RH-free zero-generation initiality route is represented as a finite NameCert packet with an explicit no-circularity audit.

Chapter 9256

Ledger Register and Tick Reflection Positivity

chapter 9255 builds the OCLSD zero-generation dynamics: a prime-driven tick advances a syntactic term, the accumulated angular heights are the eigenvalues of a self-adjoint operator H_{OCLSD}, and the sole remaining wall is the spectral zero identity (that the prime-generated spectrum is the true zeta zero spectrum). The present chapter records two finite rational sub-layers that sit strictly *below* that wall and are fully discharged: the arithmetic of the prime–Zeckendorf register (which grounds the tick's log-time bookkeeping), and the reflection positivity classification of the tick input (which separates the tick data that admit a unitary reconstruction from those that do not). Neither sub-layer touches the spectral zero identity; both are closed by finite located-rational data.

9256.1 Prime–Zeckendorf register arithmetic

The OCLSD register is a finite list of (prime, Fibonacci-index) atoms. Its per-prime weight and the integer it encodes are the arithmetic carrier of the "register norm squared equals log-time" bookkeeping.

Definition 9256.1 (Per-prime Fibonacci weight)**.** Lean4 (definition) `BEDC.Derived.RHRoute.OCLSDRegisterWeight.`

For a prime p the weight of a register R is the sum of F_k over the atoms of R whose prime equals p,

$$w_p(R) \;=\; \sum_{(p,k)\in R} F_k,$$

where F_k is the k-th Fibonacci number. For a Zeckendorf register this reads back the prime valuation v_p.

Theorem 9256.2 (Zeckendorf carry is an isometry of the register weight)**.** Lean4 ✓ `BEDC.Derived.RHRoute.OCLSDR` `carry`

Replacing two adjacent atoms $(p,k),(p,k+1)$ by $(p,k+2)$ preserves every per-prime weight, because $F_k + F_{k+1} = F_{k+2}$. The register's per-prime Fibonacci content is therefore carry-invariant: a well-defined valuation, not an artifact of the digit representation.

Definition 9256.3 (Encoded integer)**.** Lean4 (definition) `BEDC.Derived.RHRoute.OCLSDRegisterWeight.encodedNat`

The integer a register encodes is

$$n(R) \;=\; \prod_{(p,k)\in R} p^{F_k}.$$

Grouped by prime this is $n(R) = \prod_p p^{w_p(R)}$, so the register norm squared $\sum_{(p,k)} F_k \log p = \log n(R)$ is the log-time T.

Theorem 9256.4 (The ledger is a submonoid of the integers). Lean4 ✓ BEDC.Derived.RHRoute.OCLSDRegisterWeig carry

↪ variant BEDC.Derived.RHRoute.OCLSDRegisterWeight.encodedNat append

The Zeckendorf carry preserves $n(R)$, so the log-time is a carry-invariant of the register. Register concatenation multiplies the encoded integer, $n(R_1 +\!\!+ R_2) = n(R_1)\, n(R_2)$, so the encoding is a monoid homomorphism from the ledger onto the multiplicative monoid of S-smooth integers; the log-time is additive under concatenation.

9256.2 Finite reflection positivity as a PSD classification

A single reversible tick carries a located transition weight q. Its Osterwalder–Schrader reflection form, in the manifestly completed-square shape, is

$$\Phi_q(f_0, f_1) \;=\; q\,(f_0 + f_1)^2 \;+\; (1 - 2q)\,(f_0^2 + f_1^2).$$

Definition 9256.5 (Reflection form). Lean4 (definition) BEDC.Derived.RHRoute.OCLSDReflectionForm.osForm

Φ_q is the two-state reversible reflection quadratic form. On the antisymmetric mode $(1, -1)$ the first term vanishes and $\Phi_q(1, -1) = (1 - 2q) \cdot 2$: the reflection form on that mode is exactly the small transition eigenvalue.

Theorem 9256.6 (Reflection positivity classification). Lean4 ✓ BEDC.Derived.RHRoute.OCLSDReflectionForm.ref holds

↪ variant BEDC.Derived.RHRoute.OCLSDReflectionForm.reflection fails

↪ variant BEDC.Derived.RHRoute.OCLSDReflectionForm.ratSq nonneg

If $0 \le q$ and $2q \le 1$ then $\Phi_q(f_0, f_1) \ge 0$ for every f_0, f_1 — the transition operator is positive semidefinite and the reflection form is a sum of two nonnegative terms. If $2q > 1$ then $\Phi_q(1, -1) < 0$: an explicit indefinite counterexample. Reflection positivity is thus a classification condition *on the transition weight, discharged by the located square-nonnegativity fact $0 \le x^2$.*

9256.3 Reflection positivity of the OCLSD tick input

The classification is parameterized by the actual OCLSD tick.

Definition 9256.7 (Tick reflection kit). Lean4 (definition) BEDC.Derived.RHRoute.OCLSDTickReflection.TickRefle Lean4 (definition) BEDC.Derived.RHRoute.OCLSDTickReflection.tickReflectionForm

A tick reflection kit assigns to each raw generation step g a located transition weight $q(g)$ with $0 \le q(g)$; the tick's reflection form is $\Phi_{q(g)}$. The tick is reflection-positive *when $2q(g) \le 1$.*

Theorem 9256.8 (Antisymmetric mode decides reconstructability). Lean4 ✓ BEDC.Derived.RHRoute.OCLSDTickRe reflection holds

↪ variant BEDC.Derived.RHRoute.OCLSDTickReflection.tick reflection fails

↪ variant BEDC.Derived.RHRoute.OCLSDTickReflection.reflectionPositive of flip nonneg

A tick is reflection-positive if and only if its reflection form is nonnegative on the antisymmetric mode $(1, -1)$. A reflection-positive tick has $\Phi_{q(g)} \ge 0$ on every mode (a unitary Osterwalder–Schrader reconstruction is available); a reflection-anticorrelated tick is strictly negative on the antisymmetric mode (no such reconstruction). A single located-rational check on one mode therefore decides the tick's reconstructability.

9256.4 Carrier-relative Osterwalder–Schrader reconstruction

The reflection-positivity classification is the *hypothesis* of the reconstruction theorem: from a reflection-positive transition operator P one builds a positive self-adjoint generator $H = -\Delta T^{-1} \log P$ and the unitary flow e^{itH}. That passage is analytic — located operator logarithm, monotone spectral calculus, a GNS construction — none of which the finite located-rational layer builds. It is encoded honestly as a *carrier contract*: the analytic content is posited as an obligation, never faked.

Definition 9256.9 (Reconstruction carrier)**.** Lean4 (definition) BEDC.Derived.RHRoute.OSReconstructionContract.
Lean4 (definition) BEDC.Derived.RHRoute.OSReconstructionContract.OSReconstruction
Lean4 (definition) BEDC.Derived.RHRoute.OSReconstructionContract.OSReconstructionCarrier

A reconstruction kit posits the analytic carrier: a located time axis, transfer/generator/unitary operator types, the self-adjoint, nonnegative and unitary predicates, and the operations $P \mapsto \log P$, $H \mapsto e^{-tH}$, $H \mapsto e^{itH}$. A reconstruction of a tick g is a generator H with its self-adjointness, nonnegativity and unitary-flow certificates together with the heat-kernel identity $e^{-\Delta T \cdot H} = P_g$ recovering the tick's transfer operator. A carrier bundles the obligation as a map sending a reflection-positive tick to its reconstruction.

Theorem 9256.10 (The finite check feeds the reconstruction)**.** Lean4 (definition) BEDC.Derived.RHRoute.OSReconst
8 4 from finite RP
Lean4 (definition) BEDC.Derived.RHRoute.OSReconstructionContract.theorem 8 4 carrier relative

Against any reconstruction carrier, a tick whose reflection form is ≥ 0 on the antisymmetric mode — a single located-rational inequality — admits an Osterwalder–Schrader reconstruction. The finite classification discharged above is exactly the hypothesis the carrier consumes. No concrete carrier is supplied: the analytic construction remains an obligation, and the statement "reflection positivity yields a reconstruction carrier" is deliberately not *asserted, since a degenerate all-trivial carrier would fake it. The junction is honest, not the reconstruction.*

Principle 9256.11 (The classification closes; the reconstruction does not)**.** Lean4✓ BEDC.Derived.RHRoute.OCLSD
reflectionPositive

The reflection-positive tick class is inhabited over any dynamics type (the trivial $q \equiv 0$ kit is reflection-positive), so the classification is not vacuous. What the finite rational layer supplies is exactly the positivity gate: which tick inputs admit a unitary reconstruction. What it does not *supply is the reconstruction itself — the passage from a positive transition operator to the located generator $H = -\Delta T^{-1} \log P$ and its unitary group needs located operator logarithm and monotone spectral calculus, which this layer does not build. That analytic step, and the spectral zero identity of chapter 9255, remain the walls; nothing here constructs either.*

Chapter 9257

Pigeonhole Time Recurrence

chapter 9255 isolates the source-internal zero-generation route, and Definition 9255.17 records its Hist-flow time component. The present chapter records the finite-projection recurrence row attached to that component. Pigeonhole recurrence supplies compact phase-return candidates at finite resolution. It does not supply a radial scale coordinate, a zero-presentation equivalence, or a boundary-stability certificate.

Definition 9257.1 (Finite prime phase-time flow)**.** *Let*

$$S = \{p_1, \dots, p_m\}$$

be a finite displayed prime window. The finite prime phase-time flow *is*

$$\Phi_S(t) := \left(e^{-it\log p_1}, \dots, e^{-it\log p_m}\right) \in \mathbb{T}^S.$$

The defining row is that one parameter t drives every displayed prime frequency. A family of independent parameters $(t_p)_{p\in S}$ is not a single Hist-flow time readout.

Theorem 9257.2 (Exact finite prime phase time is unique)**.** *If S contains two distinct prime rows and*

$$\Phi_S(t) = \Phi_S(t'),$$

then $t = t'$.

Proof. Put $\Delta = t - t'$. Equality of the phase windows gives, for every $p \in S$,

$$e^{-i\Delta\log p} = 1.$$

Thus

$$\Delta \log p = 2\pi k_p$$

for some integer k_p. Choose distinct primes $p, q \in S$. If $\Delta \neq 0$, then k_p and k_q are nonzero, and

$$\frac{\log p}{\log q} = \frac{k_p}{k_q} \in \mathbb{Q}.$$

Hence there are nonzero integers a, b with

$$a \log p = b \log q.$$

Exponentiating gives

$$p^a = q^b,$$

contradicting unique factorization. Therefore $\Delta = 0$, so $t = t'$. □

Definition 9257.3 (Finite phase observer)**.** *A* finite phase observer *on the prime window S is a finite quotient readout*

$$q_n : \mathbb{T}^S \to C_n$$

where C_n is a finite carrier. It records the resolution available at the observation layer n. Equality after applying q_n is a finite projection equality, not equality of the full phase state.

Theorem 9257.4 (Pigeonhole phase recurrence candidate)**.** *Let $q_n : \mathbb{T}^S \to C_n$ be a finite phase observer. For any finite time list*

$$t_0, t_1, \ldots, t_M$$

with

$$M + 1 > |C_n|,$$

there are indices $i < j$ such that

$$q_n(\Phi_S(t_i)) = q_n(\Phi_S(t_j)).$$

The difference $t_j - t_i$ is a finite-resolution phase recurrence candidate.

Proof. The list

$$q_n(\Phi_S(t_0)), \ldots, q_n(\Phi_S(t_M))$$

has $M + 1$ entries in the finite carrier C_n. Since $M + 1 > |C_n|$, two entries are equal. This gives the displayed indices $i < j$. □

Principle 9257.5 (Projection recurrence is not time collapse)**.** *Pigeonhole recurrence occurs after applying the finite observer q_n. It does not contradict Definition 9257.2. The full ledger may still distinguish $\Phi_S(t_i)$ from $\Phi_S(t_j)$, while the finite projection cannot. Thus the recurrence row is legal only as a ledgered finite projection collision.*

Principle 9257.6 (Finite phase recurrence is not inverse dynamics)**.** *The named row*

$$\mathsf{PigeonholePhaseClosureNoScaleTime}_\zeta$$

records the boundary between finite phase recurrence and inverse dynamics. A finite observer can identify two projected phase readouts,

$$q_n(\Phi_n(t_i)) = q_n(\Phi_n(t_j)),$$

but this is not an inverse evolution from the later readout to the earlier ledger. Any source, tail, winding, parity, or prime-register data erased by the projection must have been retained as ledger data if it is to be recovered.

For a centered active channel

$$e^{-(s-1/2)h_a} = e^{-rh_a} e^{-ith_a},$$

the factor e^{-ith_a} belongs to the unit phase layer and may enter the finite recurrence row. The factor e^{-rh_a} belongs to $\mathbb{R}_{>0}$. Mirror transport sends r to $-r$, but the cancellation

$$e^{-rh_a} e^{rh_a} = 1$$

uses a radial ledger carrying the value of r and the active height h_a. It is therefore not a phase recurrence produced by the finite observer and not a legal replacement for unit-boundary closure.

Definition 9257.7 (Scale-time energy in a zero tower)**.** *Let a generated zero tower have active rows A_n with heights $h_a > 0$. For*

$$s = \frac{1}{2} + r + it,$$

the scale-time defect at $a \in A_n$ is

$$d_a(s) := -rh_a.$$

The finite scale-time energy is

$$E_n(s) := \sum_{a \in A_n} d_a(s)^2, \qquad W_n := \sum_{a \in A_n} h_a^2.$$

Equivalently,

$$E_n(s) = r^2 W_n.$$

Theorem 9257.8 (Pigeonhole recurrence with bounded energy excludes scale time)**.** *Assume a generated zero tower carries* $\mathsf{ZetaHistFlowClosure}_\zeta$*, finite phase observers with pigeonhole recurrence candidates, the scale-time energy row*

$$E_n(s) = r^2 W_n,$$

cofinal growth

$$W_n \to \infty,$$

and a zero-compatible bound

$$E_n(s) \le B$$

for all displayed tower levels. Then $r = 0$.

Proof. The pigeonhole row supplies recurrence candidates only in compact finite phase projections. By Definition 9257.6, these collisions are not inverse dynamics and do not license radial-scale closure. By Definition 9255.18, a nonzero radial parameter r would be a scale-time import rather than a Hist-generated phase row. If $r \neq 0$, then $r^2 > 0$, and cofinal growth gives

$$r^2 W_n \to \infty.$$

Using the energy identity,

$$E_n(s) = r^2 W_n,$$

we obtain $E_n(s) \to \infty$, contradicting the bound $E_n(s) \le B$. Therefore $r = 0$. □

Corollary 9257.9 (The pigeonhole row is a phase-candidate row)**.** *The pigeonhole row in the RH route supplies finite-resolution phase return candidates. The exclusion of off-half scale time still requires the Hist-flow closure, cofinal active growth, and bounded normal-energy rows.*

Proof. Definition 9257.4 gives only finite projection collisions. The full no-scale conclusion uses Definition 9257.8, whose hypotheses also include Hist-flow closure, the radial energy identity, cofinal growth, and a zero-compatible bound. □

Principle 9257.10 (Pigeonhole recurrence is route structure)**.** *The pigeonhole row is a structural component of the RH route, not an inhabitant of the RH witness type. It clarifies why finite-resolution phase projections of a single time flow must contain return candidates. It does not prove that such a candidate is a canonical zeta-zero packet, that the packet closes on the unit boundary, that the far end cannot absorb radial defect, or that every accepted non-trivial zero is covered by the generated carrier.*

Corollary 9257.11 (Source obligations after finite phase recurrence)**.** *After the finite phase-recurrence row is displayed, the source obligations for the route are:*

$$\mathsf{StrongActiveCapture},$$

$$\mathsf{BoundaryStability},$$

$$\mathsf{ZetaCosmosClosure}_{\zeta},$$

and

$$\mathsf{ZeroPresentationCompleteness}.$$

Proof. Strong active capture is the row turning finite phase-return candidates into canonical zero-relevant packets. Boundary stability is the row showing that those packets close only on the unit boundary. Zeta cosmos closure is the row excluding an external real positive scale ledger at the far end. Zero-presentation completeness is the row identifying all accepted non-trivial zeta-zero packets with generated zero packets. Together these rows are exactly the source content that Definition 9257.8 assumes but does not construct. □

Definition 9257.12 (Finite zero certificate)**.** *A* finite zero certificate *for the completed zeta packet is a finite analytic packet*

$$(D, F, T, \Lambda, \Gamma)$$

where D is a rationally described located-compact box or disk, the local decomposition row is

$$\Xi = F + T$$

on a neighbourhood of D, the boundary gap row is

$$|T(s)| < |F(s)| \qquad s \in \partial D,$$

the local-degree or winding row Λ gives the zero count of F in D, and the ledger row Γ records source, tail, boundary, interval, and completeness data. The certificate is a finite packet; it does not expose a bare exact zero coordinate.

Definition 9257.13 (Zero certificate tower)**.** *A* zero certificate tower *is a compatible sequence of finite zero certificates*

$$(D_n, F_n, T_n, \Lambda_n, \Gamma_n)_{n\geq 0}$$

such that

$$D_{n+1} \subseteq D_n, \qquad \operatorname{diam}(D_n) \to 0,$$

and the refinement maps preserve the Rouché gap, local-degree or winding row, source ledger, tail ledger, and completeness ledger. This is the RH-facing reading of the convergent active-capture zero tower of Definition 9413.633.

Theorem 9257.14 (Certificate towers generate completed zeros)**.** *If a zero certificate tower has nonempty located-compact boxes and each level certifies one completed-zero island of Ξ, then its nested boxes have a unique limit readout s_∞ and*

$$\Xi(s_\infty) = 0.$$

Proof. The nesting and diameter rows give a unique point in

$$\bigcap_n D_n$$

by Definition 9413.632. The Rouché and local-degree rows certify the same completed-zero island through the refinement maps. Therefore Definition 9413.634 applies and yields $\Xi(s_\infty) = 0$. □

Corollary 9257.15 (Legal certificate towers cannot converge off half)**.** *Let a zero certificate tower be boundary-stable and carry the Hist-flow and no-scale rows used in Definition 9257.8. If its limit readout is*

$$s_\infty = \frac{1}{2} + r + it,$$

then $r = 0$.

Proof. The tower supplies a completed zero by Definition 9257.14. Boundary stability supplies the zero-compatible bound, while the active rows give the scale-time energy identity and cofinal growth. Applying Definition 9257.8 gives $r = 0$. □

Principle 9257.16 (Zeros are certificate limits)**.** *The RH route should treat a completed zero readout as the limit of compatible finite certificates rather than as a naked point supplied outside the system. The unresolved global source row is not the existence of finite approximations; it is that every accepted non-trivial zeta zero is represented by a legal boundary-stable certificate tower whose generated limit is covered by the BEDC zero carrier.*

Principle 9257.17 (No naked zero, not no zero)**.** *The certificate-tower reading does not deny the existence of completed zeros. It denies only the admissibility of an ungenerated bare coordinate as the primitive datum of the proof route. A finite zero certificate is a located analytic assertion with a source ledger, a tail ledger, a boundary or winding row, and a refinement interface. A completed zero is then the exact readout selected by a compatible tower of such finite assertions. Thus the distinction is:*

no primitive naked zero *rather than* *no zero.*

Theorem 9257.18 (Finite certificates can determine exact zeros)**.** *Let*

$$(D_n)_{n\geq 0}$$

be nonempty located-compact zero boxes with

$$D_{n+1} \subseteq D_n, \qquad \operatorname{diam}(D_n) \to 0.$$

Assume each D_n *carries a certificate that* D_n *contains a completed zero of* Ξ*. Then the tower determines a unique point*

$$\rho \in \bigcap_n D_n$$

and

$$\Xi(\rho) = 0.$$

Proof. The nesting and diameter hypotheses give a unique point in the intersection by Definition 9413.632. Choose, for each n, a certified zero $\rho_n \in D_n$. Since the boxes are nested and their diameters tend to zero, the sequence ρ_n converges to the unique intersection point ρ. The completed zeta packet Ξ is continuous on the displayed analytic neighbourhoods, so

$$\Xi(\rho) = \lim_n \Xi(\rho_n) = 0.$$

□

Corollary 9257.19 (Approximation is not the proof object)**.** *A finite numerical or analytic box is not itself the completed zero. The proof object is the compatible certificate tower whose limit readout is exact. Consequently, the RH-facing task is not to replace exact zeros by approximations, but to prove that every accepted zero is represented by a legal boundary-stable tower.*

Proof. The first sentence is the distinction of Definition 9257.17. Exactness of the limit readout follows from Definition 9257.18. The final sentence is the global coverage row already isolated in Definition 9257.16. □

Definition 9257.20 (Certificate-tower triadic invariant)**.** *For a finite zero certificate*

$$\mathcal{C} = (D, F, T, \Lambda, \Gamma),$$

write

$$\mathcal{I}_{\mathrm{BEDC}}(\mathcal{C}) := \mathcal{I}_{\mathsf{P}}(\mathcal{C}) \wedge \mathcal{I}_{\mathsf{U}}(\mathcal{C}) \wedge \mathcal{I}_{\mathsf{T}}(\mathcal{C}).$$

Here $\mathcal{I}_{\mathsf{P}}$ is the source and prime-ledger distinction row, $\mathcal{I}_{\mathsf{U}}$ is the unit-boundary and legal-gauge row, and $\mathcal{I}_{\mathsf{T}}$ is the Hist-flow single-time row. The invariant says that finite analytic capture is accompanied by a ledgered source, a unit-boundary gauge discipline, and an internal time readout. It is not merely the equation $\Xi = F + T$.

Theorem 9257.21 (Generated certificate towers preserve the triadic invariant)**.** *Assume a zero certificate tower is generated by RH-free certificate constructors, every constructor preserves $\mathcal{I}_{\mathrm{BEDC}}$, and every refinement morphism transports the invariant from the finer level to the displayed coarser level. Then every level of the tower satisfies*

$$\mathcal{I}_{\mathrm{BEDC}}(\mathcal{C}_n).$$

Proof. The generated certificate carrier is read by structural induction over its constructors. The source constructors supply the prime-ledger row. Mirror, conjugation, classifier transport, and ledger replay transport an existing invariant without adding an unrecorded radial coordinate. Analytic gluing and finite-window closure use the displayed Rouché, tail, and boundary ledgers. Compatible-limit and recursive-tower readback use the refinement hypotheses. Thus each constructor preserves $\mathcal{I}_{\mathrm{BEDC}}$, and induction gives the invariant at every generated level. The refinement morphism hypothesis then makes the levelwise readouts compatible through the tower. □

Definition 9257.22 (Legal boundary-stable certificate tower)**.** *A zero certificate tower is* legal boundary-stable *when it is an active-capture tower, preserves the triadic invariant of Definition 9257.20, carries Hist-flow closure, carries no far-end absorption, and for its limit readout*

$$s_\infty = \frac{1}{2} + r + it$$

has defect extraction

$$E_n(s_\infty) = r^2 W_n + o(W_n),$$

cofinal growth

$$W_n \to \infty,$$

and a zero-compatible bound

$$E_n(s_\infty) \le B$$

for some finite B independent of n.

Theorem 9257.23 (No scale closure for legal certificate towers)**.** *The limit readout of a legal boundary-stable certificate tower satisfies*

$$r = 0.$$

Proof. Assume $r \neq 0$. Then $r^2 > 0$. Since

$$E_n(s_\infty) = r^2 W_n + o(W_n),$$

there is a cofinal tail of levels on which

$$|o(W_n)| \leq \frac{r^2}{2} W_n.$$

Hence, on that tail,

$$E_n(s_\infty) \geq \frac{r^2}{2} W_n.$$

By cofinal growth, $W_n \to \infty$, so $E_n(s_\infty)$ is unbounded. This contradicts the zero-compatible bound $E_n(s_\infty) \leq B$. Therefore $r = 0$. □

Corollary 9257.24 (Legal certificate towers have fixed-half limits)**.** *If a zero certificate tower is legal boundary-stable and generates a completed zero readout s_∞, then*

$$\Re(s_\infty) = \frac{1}{2}.$$

Proof. Write

$$s_\infty = \frac{1}{2} + r + it.$$

By Definition 9257.23, $r = 0$. Thus $\Re(s_\infty) = 1/2$. □

Definition 9257.25 (Strong zero-presentation completeness)**.** *The strong certificate coverage target is*

$$\mathsf{StrongZeroPresentationCompleteness}_\zeta.$$

It asserts that every accepted non-trivial completed zeta zero is the limit readout of a legal boundary-stable certificate tower. This target is stronger than weak eta/Rouché capture: weak capture supplies finite analytic boxes, while strong coverage also supplies canonical source, triadic invariant preservation, boundary stability, no far-end absorption, and generated-zero coverage.

Corollary 9257.26 (Certificate-tower proof load)**.** *If* $\mathsf{StrongZeroPresentationCompleteness}_\zeta$ *holds, then every accepted non-trivial completed zeta zero has fixed-half readout.*

Proof. Let u be an accepted non-trivial completed zeta zero. Strong zero-presentation completeness supplies a legal boundary-stable certificate tower whose limit readout is u. By Definition 9257.24, that readout has real part 1/2. □

Chapter 9258

PZG Finite-Window Self-Reference Recurrence

chapter 9257 records finite phase recurrence for a Hist-flow time row. The present chapter records the corresponding PZG register form. The point is the same boundary in a different coordinate system: full PZG coding is faithful, while every finite readout window creates fibres, recurrence candidates, and ledger obligations.

9258.1 Finite PZG Windows

Definition 9258.1 (Finite PZG readout window)**.** *A finite PZG readout window is a finite set*

$$W \subset_{\mathrm{fin}} \mathsf{Prime}^{\uparrow} \times \mathbb{N}.$$

Its visible carrier B_W is the finite set of legal bit patterns on W compatible with the Zeckendorf no-adjacent condition on each displayed prime axis. The window projection is

$$\pi_W : \mathsf{Z}_{\mathsf{PZG}} \to B_W,$$

where $\mathsf{Z}_{\mathsf{PZG}}$ denotes the full finite-support PZG register carrier and π_W forgets every coordinate outside W.

Principle 9258.2 (Global faithfulness, finite fibres)**.** *The full PZG register is a faithful source code by Definition 9291.9. A finite readout window is not faithful to the full source. Equality*

$$\pi_W(z) = \pi_W(z')$$

means equality at the displayed resolution, not equality of full PZG registers. Any difference between z and z' is hidden from W and is therefore a fibre, refinement, or ledger issue.

Theorem 9258.3 (Every finite PZG window has infinite fibres)**.** *Let W be a finite PZG readout window. Every realizable window position $b \in B_W$ has infinitely many full PZG registers above it.*

Proof. Choose one full register z with $\pi_W(z) = b$. Since W uses only finitely many prime axes and depths, there are infinitely many primes q whose first coordinate $(q, 1)$ is not in W and whose axis is absent from the displayed window. For each such q, form the register obtained from z by activating the coordinate $(q, 1)$ if it is not already active on that fresh axis, leaving all coordinates in W unchanged. These registers remain legal PZG registers, are pairwise distinct, and all project to b under π_W. □

Theorem 9258.4 (Finite-window PZG recurrence)**.** *For any infinite PZG trajectory*

$$z_0, z_1, z_2, \ldots$$

and any finite PZG readout window W, there exist $i < j$ such that

$$\pi_W(z_i) = \pi_W(z_j).$$

Proof. The projected sequence

$$\pi_W(z_0), \pi_W(z_1), \pi_W(z_2), \ldots$$

takes values in the finite carrier B_W. The pigeonhole principle gives two indices $i < j$ with the same projected value. □

Principle 9258.5 (Finite return is not global repetition)**.** *The equality in Definition 9258.4 is a finite readout recurrence. It does not assert $z_i = z_j$. If the full registers differ, the difference is a window-hidden source row. A legal proof route must either refine the window until the difference is read or record the difference in the residual or tail ledger.*

Definition 9258.6 (Window-cycle residual)**.** *Given a finite-window recurrence*

$$\pi_W(z_i) = \pi_W(z_j) \qquad (i < j),$$

a window-cycle residual is the ledger row

$$\mathsf{CycleRes}_W(i, j) := (z_i, z_j, W, \pi_W(z_i) = \pi_W(z_j), \mathsf{status}).$$

Its status is closed only when the full registers classify together in the claimed scope. Otherwise it is refined to a larger window or kept as a tail residual.

Theorem 9258.7 (Window recurrence creates a ledger obligation)**.** *Every finite-window recurrence with unequal full registers creates a window-cycle residual unless a larger displayed readout separates the two registers.*

Proof. If $\pi_W(z_i) = \pi_W(z_j)$ but z_i and z_j are not classified together at the full claimed scope, then the window equality has hidden the source difference. By Definition 9258.2, that difference is not erased by the finite readout. It must either be exposed by a refinement window or recorded by the ledger row of Definition 9258.6. □

Principle 9258.8 (Zeta readout groups finite-window fibres)**.** *On a displayed convergence window, the zeta-facing PZG readout may be grouped through any finite PZG readout window:*

$$\sum_{z \in \mathsf{Z}_{\mathsf{PZG}}} e^{-sL(z)} = \sum_{b \in B_W} \sum_{\pi_W(z) = b} e^{-sL(z)}.$$

The outer sum ranges over visible finite positions, while the inner sums range over the hidden fibres of those positions. Pigeonhole recurrence supplies finite-window multiple occupancy; the phase weights supply interference; the completed carrier supplies the zero ledger.

9258.2 Zero Reads

Definition 9258.9 (Finite zero read)**.** *A finite zero read for a completed zeta-facing packet is a finite data row*

$$\mathfrak{r} = (D, \varepsilon, m, \mathcal{P}, \mathcal{E}).$$

Here D is a rationally described located-compact box or disk in the complex plane, ε is a displayed precision or tail tolerance, m is a finite zero-count readout, $\mathcal{P}$ is the finite protocol that justifies the readout, and $\mathcal{E}$ is the error, boundary, branch, source, and tail ledger. A finite zero read is a reading event; it is not the completed zero object itself.

Theorem 9258.10 (ZeroRead finite-read theorem)**.** *Every auditable zero read factors through a finite zero read.*

Proof. An auditable zero read must display a region in which the read is made, the precision or tolerance at which the read is made, the finite zero count or zero-type assertion being read, the finite protocol that justifies the assertion, and the ledger for error, boundary, branch, source, and tail data. These are exactly the fields of Definition 9258.9. Thus the read is a finite data row. □

Corollary 9258.11 (Zero reads have PZG addresses)**.** *Every finite zero read has a PZG address.*

Proof. The finite zero read $\mathfrak{r}$ is a finite data row, hence it has a finite syntactic description. By Definition 9292.6, that description has a unique PZG register address. □

Principle 9258.12 (Completed zeros are compatible readout closures)**.** *A completed zero is not a single finite zero read. It is the closed readout selected by a compatible system of finite zero reads with shrinking localisation, stable zero-count or winding data, analytic-continuation transport, and closed source, boundary, tail, and error ledgers. This is the same certificate-tower boundary as Definition 9257.13: finite reads supply the stages, while the completed zero is the globalized limit readout licensed by the compatible tower.*

Theorem 9258.13 (Finite zero reads create zero-ledger obligations)**.** *If a finite zero read is used as evidence for a completed zero, then its tail, boundary, branch, and error fields must be closed by a compatible refinement tower or retained in the zero ledger.*

Proof. By Definition 9258.10, the read supplies only finite data. By Definition 9258.12, a completed zero requires compatibility through refinement and analytic transport, together with closed source, boundary, tail, and error ledgers. Any field not closed by such a compatible tower remains outside the completed zero readout and must therefore be retained in the zero ledger. □

Chapter 9259

Resolution Refinement Induction

chapter 9257 organizes finite phase recurrence and zero certificates. This chapter records the refinement form of the same route: begin with a displayed resolution, refine the resolution through legal certificate steps, prove the triadic invariant at every level by induction, and only then take the limit readout. The statement is a conditional route. It identifies the source load required for a BEDC proof, rather than replacing that load by the existence of finite approximations.

Definition 9259.1 (Resolution scale)**.** *A* resolution scale *is a sequence*

$$\varepsilon_0 > \varepsilon_1 > \varepsilon_2 > \cdots > 0$$

with

$$\varepsilon_n \to 0.$$

At level n, a zero box D_n is displayed at this resolution when

$$\operatorname{diam}(D_n) \le \varepsilon_n.$$

The scale records observational precision; it is not an additional analytic coordinate of the zeta carrier.

Definition 9259.2 (Resolution zero certificate)**.** *A* resolution zero certificate *at level n is a finite zero certificate*

$$\mathcal{C}_n = (D_n, F_n, T_n, \Lambda_n, \Gamma_n)$$

in the sense of Definition 9257.12, together with the scale row

$$\operatorname{diam}(D_n) \le \varepsilon_n.$$

Its analytic capture component is the displayed decomposition

$$\Xi = F_n + T_n$$

and the boundary gap

$$|T_n(s)| < |F_n(s)| \qquad s \in \partial D_n.$$

Its BEDC component is the ledger row Γ_n, which must record the source, tail, phase, prime-register, boundary, defect, and energy data used by the refinement step.

Definition 9259.3 (Legal resolution refinement)**.** *A refinement*

$$\mathcal{C}_n \rightsquigarrow \mathcal{C}_{n+1}$$

is legal *when the following rows hold:*

$$D_{n+1} \subseteq D_n, \qquad \operatorname{diam}(D_{n+1}) \leq \varepsilon_{n+1},$$

the Rouché or winding certificate at level $n+1$ is valid, the source and tail ledgers refine the level-n ledgers, and the triadic invariant of Definition 9257.20 is transported from level n to level $n+1$. Equivalently, the refinement is not merely a smaller box; it is a smaller box whose analytic, source, boundary, and defect ledgers remain compatible.

Theorem 9259.4 (Resolution induction)**.** *Let*

$$(\mathcal{C}_n)_{n\geq 0}$$

be a sequence of resolution zero certificates. If

$$\mathcal{I}_{\mathrm{BEDC}}(\mathcal{C}_0)$$

holds and every step

$$\mathcal{C}_n \rightsquigarrow \mathcal{C}_{n+1}$$

is a legal resolution refinement, then

$$\mathcal{I}_{\mathrm{BEDC}}(\mathcal{C}_n)$$

holds for every n.

Proof. The proof is induction on n. The base case is the displayed hypothesis at level 0. For the induction step, assume

$$\mathcal{I}_{\mathrm{BEDC}}(\mathcal{C}_n).$$

Since $\mathcal{C}_n \rightsquigarrow \mathcal{C}_{n+1}$ is legal, Definition 9259.3 transports the triadic invariant to level $n+1$. This gives

$$\mathcal{I}_{\mathrm{BEDC}}(\mathcal{C}_{n+1}).$$

Therefore the invariant holds at every finite resolution level. □

Definition 9259.5 (Resolution certificate tower)**.** *A* resolution certificate tower *is a sequence of resolution zero certificates*

$$(\mathcal{C}_n)_{n\geq 0}$$

such that every adjacent step is a legal resolution refinement. It is strong *when, in addition, it is a legal boundary-stable certificate tower in the sense of Definition 9257.22. Thus strong resolution towers include canonical source dominance, unit-boundary stability, no far-end absorption, cofinal active growth, and defect extraction.*

Theorem 9259.6 (Resolution towers have exact completed-zero limits)**.** *If a resolution certificate tower has nonempty located-compact boxes and each level certifies the same completed-zero island of Ξ, then it has a unique limit readout s_∞ and*

$$\Xi(s_\infty) = 0.$$

Proof. The scale row gives $\operatorname{diam}(D_n) \to 0$, while legal refinement gives $D_{n+1} \subseteq D_n$. The Rouché or winding row certifies the same completed-zero island through the compatible ledgers. Therefore Definition 9257.14 applies. □

Theorem 9259.7 (Strong resolution towers have fixed-half limits)**.** *If a resolution certificate tower is strong and has limit readout*

$$s_\infty = \frac{1}{2} + r + it,$$

then $r = 0$.

Proof. By Definition 9259.4, every finite level preserves the triadic invariant. Since the tower is strong, it is legal boundary-stable and carries defect extraction, cofinal growth, and a zero-compatible energy bound. Applying Definition 9257.23 gives $r = 0$. □

Corollary 9259.8 (Resolution induction separates weak and strong refinement)**.** *Weak eta/Rouché refinement can supply smaller analytic zero boxes and tail bounds. It does not by itself supply the strong resolution tower rows: canonical source dominance, boundary stability, no far-end absorption, and zero-presentation coverage.*

Proof. The weak eta row supplies finite analytic capture as in Definition 9255.9. The strong conclusion of Definition 9259.7 additionally uses the legal boundary-stable tower hypotheses in Definition 9259.5. These rows are not consequences of a Rouché gap alone. □

Principle 9259.9 (Resolution route proof load)**.** *The refinement-induction route reduces the RH-facing source load to the following assertion:*

$$\mathsf{StrongResolutionTowerCoverage}_\zeta.$$

This means that every accepted non-trivial completed zeta zero is represented by a strong resolution certificate tower. Once such a tower is supplied, Definition 9259.7 excludes the radial scale parameter. The unresolved content is the construction and boundary-stability of the strong tower, not the formal induction over its already legal refinement steps.

Definition 9259.10 (Golden resolution ruler)**.** *Let*

$$F_0 = 0, \qquad F_1 = 1, \qquad F_{n+2} = F_{n+1} + F_n,$$

and let φ *be the golden self-scale of Definition 9346.12. A* golden resolution ruler *is the resolution scale*

$$\delta_m := \varphi^{-m}$$

together with a Fibonacci truncation schedule

$$N_m := F_{Lm},$$

where L *is a fixed positive integer chosen to dominate the local tail estimate. The spatial resolution is* δ_m*, while the analytic packet resolution is* N_m*.*

Definition 9259.11 (Zeckendorf resolution ledger)**.** *For a positive integer* N*, a* Zeckendorf resolution ledger *is a finite digit row*

$$N = \sum_{k \geq 2} z_k F_k, \qquad z_k \in \{0, 1\}, \qquad z_k z_{k+1} = 0.$$

The no-adjacent condition is the stable-window grammar of Definition 9346.1. The ledger records the Fibonacci-block source of a truncation level; it is a source address and not a proof of boundary stability.

Theorem 9259.12 (Zeckendorf ledgers give unique truncation addresses)**.** *Every positive truncation level N has at most one Zeckendorf resolution ledger.*

Proof. This is the uniqueness part of the Zeckendorf normal form. If two digit rows with no adjacent 1 represent the same N, normal-form uniqueness identifies their digits coefficientwise. Thus the Fibonacci-block source of the truncation is unique. □

Definition 9259.13 (Golden eta certificate packet)**.** *Let ρ be an eta zero in a displayed compact subdomain of $\Re(s) > 0$. For a golden ruler and a fixed L, the level-m* golden eta certificate packet *is*

$$\mathcal{G}_m(\rho) := (D_m, P_m, R_m, \Gamma_m),$$

where

$$D_m := \{s : \ |s - \rho| \le \varphi^{-m}\},$$

$$P_m(s) := \sum_{n=1}^{F_{Lm}} (-1)^{n-1} n^{-s}, \qquad R_m(s) := \eta(s) - P_m(s),$$

and Γ_m contains the Zeckendorf ledger of F_{Lm}, the tail bound, the phase rows, and the defect-energy rows. The packet is weak unless Γ_m also supplies the strong boundary-stability and no-far-end rows.

Theorem 9259.14 (Golden eta weak active capture)**.** *Let ρ be an eta zero of multiplicity q in a compact local neighbourhood contained in $\Re(s) \ge \sigma_0 > 0$. If the golden ruler uses a positive integer L with*

$$L\sigma_0 > q,$$

then, for all sufficiently large m, the golden eta packet satisfies

$$|R_m(s)| < |P_m(s)| \qquad s \in \partial D_m.$$

Hence P_m and η have the same zero count in D_m.

Proof. Write locally

$$\eta(s) = (s - \rho)^q g(s)$$

with g analytic and $g(\rho) \ne 0$. After shrinking the displayed neighbourhood, there is $c > 0$ such that $|g(s)| \ge c$ on it. For $s \in \partial D_m$ this gives

$$|\eta(s)| \ge c\varphi^{-qm}.$$

Uniform convergence of the eta series on the displayed compact subdomain gives a constant C such that

$$|R_m(s)| \le C F_{Lm}^{-\sigma_0}.$$

Since F_{Lm} grows at the golden rate, there is $C' > 0$ with

$$|R_m(s)| \le C' \varphi^{-L\sigma_0 m}.$$

The inequality $L\sigma_0 > q$ implies that, for all sufficiently large m,

$$C' \varphi^{-L\sigma_0 m} < \frac{c}{2} \varphi^{-qm}.$$

Thus $|R_m(s)| < |\eta(s)|/2$ on ∂D_m. Since $P_m = \eta - R_m$,

$$|P_m(s)| \ge |\eta(s)| - |R_m(s)| > \frac{1}{2}|\eta(s)|,$$

and therefore $|R_m(s)| < |P_m(s)|$ on ∂D_m. Rouché's theorem then gives equality of zero counts in D_m. □

Corollary 9259.15 (Golden rulers supply weak resolution towers)**.** *Every accepted non-trivial zeta zero in the open critical strip admits, after the eta readout is licensed, a weak golden resolution certificate tower.*

Proof. In the open critical strip the eta and zeta zero rows agree after the standard nonvanishing factor between them is ledgered. Applying Definition 9259.14 on a nested sequence of golden boxes gives Rouché capture at all sufficiently fine levels. The boxes have diameter tending to zero, and the Zeckendorf ledgers give unique truncation addresses by Definition 9259.12. This is exactly a weak resolution certificate tower. □

Definition 9259.16 (Strong golden resolution tower)**.** *A weak golden resolution tower is* strong *when its ledgers also carry canonical packet dominance, unit-boundary stability, no far-end absorption, cofinal active-height growth, and defect extraction. The corresponding bridge target is*

$$\mathsf{ZetaGoldenLeeYangBridge}.$$

It asks for the Fibonacci or Zeckendorf packet to be transported to a Lee–Yang type unit-boundary certificate compatible with the zeta phase and tail ledgers.

Corollary 9259.17 (Strong golden coverage is conditionally sufficient)**.** *If every accepted non-trivial completed zeta zero is represented by a strong golden resolution tower, then every such zero has fixed-half readout.*

Proof. A strong golden resolution tower is a strong resolution certificate tower. Therefore Definition 9259.7 applies to its limit readout. □

Principle 9259.18 (Golden rulers do not supply boundary stability by themselves)**.** *The golden ruler fixes a clean resolution schedule and a unique Zeckendorf address ledger. It supplies weak active capture for eta packets once the local tail estimate is dominated by the golden shrinking rate. It does not prove that the finite packets are unit-boundary stable. The remaining strong row is the* ZetaGoldenLeeYangBridge *of Definition 9259.16, not another application of Rouché capture.*

Definition 9259.19 (Zeckendorf–Gödel path packet)**.** *Let X_m be the no-adjacent Zeckendorf window of Definition 9346.1, and let $(p_k)_{1\le k\le m}$ be a displayed prime register. For*

$$z = (z_1, \dots, z_m) \in X_m$$

define the Zeckendorf–Gödel integer

$$g(z) := \prod_{k=1}^{m} p_k^{z_k}.$$

For

$$u_k(s) := p_k^{1/2-s},$$

the corresponding path packet is

$$Q_m(s) := \sum_{z\in X_m} w_z \prod_{k=1}^{m} u_k(s)^{z_k}.$$

When the weights are the stable path weights, this is the finite independent-set packet attached to the no-adjacent grammar. Its advantage over the eta truncation is structural: the monomial support is already the Zeckendorf path carrier. Its missing row is zero-island capture for the completed zeta packet.

Definition 9259.20 (Golden stable capture bridge)**.** *A* golden stable capture bridge *for a zero island D_m consists of a weak analytic packet*

$$P_m(s) = \sum_{n=1}^{F_{Lm}} (-1)^{n-1} n^{-s},$$

a Zeckendorf–Gödel path packet Q_m, and bridge data satisfying:

$$|R_m(s)| < |P_m(s)| \qquad s \in \partial D_m,$$

the packet Q_m carries a Lee–Yang type unit-boundary stability certificate, and the two packets have the same local zero-island readout, for instance by a boundary comparison

$$|P_m(s) - Q_m(s)| < |P_m(s)| \qquad s \in \partial D_m,$$

or by an explicitly ledgered equality of winding numbers

$$\mathrm{wind}_{\partial D_m}(P_m, 0) = \mathrm{wind}_{\partial D_m}(Q_m, 0).$$

The bridge is canonical only when the construction of Q_m uses the Zeckendorf, prime-register, and path-stability ledgers rather than a post hoc interpolation to the zero island.

Principle 9259.21 (Golden weak capture and stable capture are separate rows)**.** *The golden eta packet and the Zeckendorf–Gödel path packet solve different parts of the route. The eta packet supplies analytic Rouché capture of a completed zero island, but it does not carry Lee–Yang stability. The path packet is organized by the no-adjacent Zeckendorf grammar and is the natural candidate for a Lee–Yang stable finite packet, but it does not automatically capture zeta zeros. The source theorem must identify these two rows through Definition 9259.20.*

Definition 9259.22 (Golden stable capture coverage)**.** *The coverage target*

$$\mathsf{GoldenStableCaptureBridge}_\zeta$$

asserts that every accepted non-trivial completed zeta zero admits, at some sufficiently fine golden resolution level, a golden stable capture bridge in the sense of Definition 9259.20.

Theorem 9259.23 (Golden stable capture coverage gives fixed-half readout)**.** *If*

$$\mathsf{GoldenStableCaptureBridge}_\zeta$$

holds, then every accepted non-trivial completed zeta zero has fixed-half readout.

Proof. Let u be an accepted non-trivial completed zeta zero with local coordinate

$$s = \frac{1}{2} + r + it.$$

The coverage target supplies a golden stable capture bridge. The weak analytic packet captures the zero island, and the bridge transfers the same winding row to the Zeckendorf–Gödel path packet Q_m. The Lee–Yang type certificate for Q_m excludes zero readouts with all active variables strictly inside the unit boundary and also excludes the corresponding outside region. Since

$$|u_k(s)| = |p_k^{1/2-s}| = p_k^{-r},$$

an $r > 0$ readout places every active variable strictly inside the unit circle, while an $r < 0$ readout places every active variable strictly outside it. Both cases contradict the stable packet's zero-island readout. Therefore $r = 0$. □

Principle 9259.24 (Golden blueprint)**.** *The BEDC–Golden route has the following compact form. The golden ruler and Zeckendorf ledger provide weak finite-resolution active capture; the only strong row is the bridge from that analytic capture packet to a Zeckendorf–Gödel Lee–Yang stable packet with the same zero-island winding. Thus the hard source theorem is*

$$\mathsf{GoldenStableCaptureBridge}_{\zeta},$$

not the existence of the golden ruler itself.

Chapter 9260

Golden Lee–Yang Bridge Obligations

chapter 9259 supplies the golden ruler, the Zeckendorf truncation ledger, and weak eta Rouché capture. The present chapter isolates the source rows needed to turn that weak capture into a Lee–Yang type boundary-stable packet. The bridge is a source theorem about the same zero island; it is not a restatement of fixed-half readout.

Definition 9260.1 (Fibonacci path carrier)**.** *For a width m, let X_m be the stable Zeckendorf window of Definition 9346.1. A* Fibonacci path carrier *is the finite hard-core packet*

$$I_m(t) := \sum_{z \in X_m} t^{|z|}, \qquad |z| := \sum_{k=1}^{m} z_k.$$

Equivalently, X_m is the independent-set carrier of the path graph on m vertices. The no-adjacent Zeckendorf grammar therefore supplies a finite path-model source row, but this row is only combinatorial until it is tied to a completed zeta zero island.

Definition 9260.2 (Lee–Yang lift certificate)**.** *Let $A(t)$ be a finite path-model polynomial of degree d. Its Joukowsky lift is the polynomial*

$$\mathcal{L}_A(u) := (1+u)^{2d} A\left(-\frac{u}{(1+u)^2}\right).$$

A Lee–Yang lift certificate *for A is a finite ledger proving that every nontrivial zero of $\mathcal{L}_A$ lies on the unit circle, or equivalently that the lifted zero-relevant packet has no zero branch in the strict inside or strict outside regions*

$$0 < |u| < 1, \qquad |u| > 1.$$

The certificate is a unit-boundary row for the lifted path packet. It does not by itself identify that packet with an eta or zeta packet.

Definition 9260.3 (Golden bridge witness)**.** *Let*

$$\mathcal{G}_m(\rho) = (D_m, P_m, R_m, \Gamma_m)$$

be a golden eta certificate packet in the sense of Definition 9259.13. A golden Lee–Yang bridge witness *for $\mathcal{G}_m(\rho)$ consists of a Fibonacci path carrier I_{k_m}, a lifted packet $\mathcal{L}_m$, and a bridge ledger with the following rows:*

$$|R_m(s)| < |P_m(s)| \qquad s \in \partial D_m,$$

a Lee–Yang lift certificate for $\mathcal{L}_m$, a same-island transfer from P_m to $\mathcal{L}_m$, radial purity, and dominance.

The same-island transfer may be given by a boundary comparison

$$|P_m(s) - \mathcal{L}_m(s)| < |P_m(s)| \qquad s \in \partial D_m,$$

or by a ledgered homotopy H_τ with

$$H_0 = P_m, \qquad H_1 = \mathcal{L}_m, \qquad 0 \notin H_\tau(\partial D_m) \quad 0 \le \tau \le 1.$$

Radial purity means that the comparison error and homotopy rows contain only phase, finite source, and p-adic or Zeckendorf ledger data, never an unrecorded factor e^{-rh}. Dominance means that the lifted path packet is selected by the source ledger as the zero-relevant branch, rather than chosen after the zero island is known.

Principle 9260.4 (Bridge rows are independent)**.** *The rows in Definition 9260.3 have separate proof roles. The eta Rouché inequality captures the completed zero island. The path carrier supplies the no-adjacent Fibonacci grammar. The Lee–Yang lift supplies unit-boundary stability for the lifted path packet. The same-island transfer proves that the eta packet and the lifted packet read the same local zero event. Radial purity prevents the transfer from hiding a real positive scale factor. Dominance makes the lifted packet canonical rather than interpolatory.*

Definition 9260.5 (Dominant branch packet)**.** *Let a finite analytic packet on a zero island Ω_m have a spectral expansion*

$$P_m(z) = \sum_{j=1}^{d} C_j(z)\lambda_j(z)^m.$$

A pair λ_+, λ_- is a dominant branch pair on Ω_m if there is $\kappa > 0$ such that every remaining branch satisfies

$$|\lambda_j(z)| \le (1-\kappa)\max\{|\lambda_+(z)|, |\lambda_-(z)|\}$$

on Ω_m. The dominant and subdominant parts are

$$P_m^{\mathrm{dom}}(z) := C_+(z)\lambda_+(z)^m + C_-(z)\lambda_-(z)^m$$

and

$$P_m^{\mathrm{sub}}(z) := \sum_{j \ne +,-} C_j(z)\lambda_j(z)^m.$$

Theorem 9260.6 (Dominant gap gives Rouché control)**.** *If a dominant branch packet satisfies*

$$|P_m^{\mathrm{sub}}(z)| < |P_m^{\mathrm{dom}}(z)| \qquad z \in \partial\Omega_m,$$

then P_m and P_m^{dom} have the same number of zeros in Ω_m, counted with multiplicity.

Proof. By definition,

$$P_m = P_m^{\mathrm{dom}} + P_m^{\mathrm{sub}}.$$

The displayed strict boundary inequality is precisely the Rouché hypothesis for the pair $(P_m^{\mathrm{dom}}, P_m^{\mathrm{sub}})$ on $\partial\Omega_m$. Rouché's theorem gives equality of the zero counts in Ω_m. □

Principle 9260.7 (Quartic endpoint finite model)**.** *section 9413.9 gives a finite-certificate model for the dominant-branch row. The fixed quartic carrier records recurrence algebra, companion-matrix spectrum, elliptic normalization, real projection, dominant branch, and endpoint-zero ledgers inside one packet. Its dominance row is separated from its ramification row by Definition 9413.99, and its local endpoint-zero row is supplied by Definition 9413.102. The scope boundary of Definition 9413.105 is essential: the model proves a fixed finite spectral pattern, not a zeta golden spectral expansion or a growing-window theorem.*

Definition 9260.8 (Stable golden Rouché homotopy)**.** *Let P_m be the zero-relevant golden packet on Ω_m, and let $\mathcal{L}_m$ be a Fibonacci Lee–Yang lift packet in the same local coordinate u. A stable golden Rouché homotopy from P_m to $\mathcal{L}_m$ is a ledgered family H_τ, $0 \le \tau \le 1$, such that*

$$H_0 = P_m, \qquad H_1 = \mathcal{L}_m,$$

the boundary of the zero island is never crossed,

$$0 \notin H_\tau(\partial\Omega_m) \qquad 0 \le \tau \le 1,$$

and the Lee–Yang stable regions remain zero-free:

$$H_\tau(u) \neq 0 \qquad 0 < |u| < 1,$$

$$H_\tau(u) \neq 0 \qquad |u| > 1.$$

The homotopy ledger may use phase, finite source, prime-register, and Zeckendorf rows, but it may not introduce an unrecorded $\mathbb{R}_{>0}$ scale coordinate.

Theorem 9260.9 (Stable Rouché transport preserves the unit boundary)**.** *If P_m admits a stable golden Rouché homotopy to a Fibonacci Lee–Yang lift packet, then every zero of P_m in the zero-relevant local coordinate lies on the unit boundary.*

Proof. The stable-region rows in Definition 9260.8 apply at $\tau = 0$. Hence

$$P_m(u) \neq 0 \qquad 0 < |u| < 1,$$

and

$$P_m(u) \neq 0 \qquad |u| > 1.$$

Thus a zero of P_m in the zero-relevant coordinate cannot lie in the strict inside or strict outside region. The remaining boundary is $|u| = 1$. □

Principle 9260.10 (Ordinary Rouché transport is insufficient)**.** *Boundary nonvanishing alone transports winding number and zero count; it does not transport the Lee–Yang unit-boundary property. The polynomial $u - 1$ has its zero on $|u| = 1$, while $u - (1 + \varepsilon)$ has the same zero count in any sufficiently large island and its zero lies outside the unit circle. Therefore the source row needed for zeta golden boundary stability is*

$$\mathsf{GoldenStableRoucheHomotopy},$$

not merely a zero-count homotopy. The stable homotopy row must include strict inside and strict outside zero-free ledgers together with radial purity.

Definition 9260.11 (Zeckendorf–Mellin path packet)**.** *Let $F_0 = 0$, $F_1 = 1$, and*

$$F_{j+2} = F_{j+1} + F_j.$$

For the path graph on $\{1, \ldots, m\}$, let

$$\mathrm{Ind}(P_m) := \{S \subseteq \{1, \ldots, m\} : i, j \in S \Rightarrow |i - j| \neq 1\}.$$

For $S \in \mathrm{Ind}(P_m)$ set

$$N(S) := \sum_{j \in S} F_{j+1}.$$

The finite Zeckendorf ledger identifies $\mathrm{Ind}(P_m)$ with the integers

$$0 \leq N < F_{m+2}.$$

For a vector $\mathbf{x} = (x_1, \ldots, x_m)$ define the multivariable path partition function

$$I_m(\mathbf{x}) := \sum_{S \in \mathrm{Ind}(P_m)} \prod_{j \in S} x_j.$$

For $u > 0$ the Mellin fibre is

$$x_j(u) := (-1)^{F_{j+1}} e^{-uF_{j+1}}.$$

Theorem 9260.12 (Zeckendorf–Mellin exact projection)**.** *For $\Re(s) > 0$,*

$$\sum_{n=1}^{F_{m+2}-1} (-1)^{n-1} n^{-s} = -\frac{1}{\Gamma(s)} \int_0^\infty u^{s-1} \left(I_m(\mathbf{x}(u)) - 1\right) du.$$

Proof. For $n > 0$ and $\Re(s) > 0$, the Mellin–Laplace identity gives

$$n^{-s} = \frac{1}{\Gamma(s)} \int_0^\infty u^{s-1} e^{-nu} \, du.$$

The Zeckendorf ledger in Definition 9260.11 gives a bijection from nonempty independent sets S to the integers $1 \leq N(S) \leq F_{m+2} - 1$. Thus

$$\sum_{n=1}^{F_{m+2}-1} (-1)^{n-1} n^{-s} = \sum_{\varnothing \neq S \in \mathrm{Ind}(P_m)} (-1)^{N(S)-1} N(S)^{-s}.$$

Substituting the Mellin–Laplace identity and using finiteness to interchange the sum and integral yields

$$\frac{1}{\Gamma(s)} \int_0^\infty u^{s-1} \sum_{\varnothing \neq S} (-1)^{N(S)-1} e^{-uN(S)} \, du.$$

For every independent set S,

$$(-1)^{N(S)} e^{-uN(S)} = \prod_{j \in S} \left((-1)^{F_{j+1}} e^{-uF_{j+1}}\right) = \prod_{j \in S} x_j(u).$$

Therefore

$$\sum_{\varnothing \neq S} (-1)^{N(S)-1} e^{-uN(S)} = -\sum_{\varnothing \neq S} \prod_{j \in S} x_j(u) = -\left(I_m(\mathbf{x}(u)) - 1\right),$$

which is the displayed identity. □

Definition 9260.13 (Zeckendorf transfer dominated splitting)**.** *The source row*

ZeckendorfTransferDominatedSplitting

asserts that the non-autonomous path transfer product

$$\begin{pmatrix} I_j(\mathbf{x}(u)) \\ I_{j-1}(\mathbf{x}(u)) \end{pmatrix} = \begin{pmatrix} 1 & x_j(u) \\ 1 & 0 \end{pmatrix} \begin{pmatrix} I_{j-1}(\mathbf{x}(u)) \\ I_{j-2}(\mathbf{x}(u)) \end{pmatrix}$$

has a ledgered dominated splitting on the zero island after Mellin projection. Concretely, the row selects two fibre branches whose Mellin-integrated contributions form P_m^{dom}, while all remaining transfer contributions form P_m^{sub} and satisfy

$$|P_m^{\mathrm{sub}}(s)| < |P_m^{\mathrm{dom}}(s)| \qquad s \in \partial D_m.$$

Definition 9260.14 (Self-dual Mellin Lee–Yang stability operator)**.** *The source row*

SelfDualMellinLeeYangOperator

asserts that the Zeckendorf–Mellin projection is used only after a completed self-dual packet has been supplied. The raw one-sided Mellin integral of Definition 9260.12 is not a stability-preserving operator by itself. The self-dual row includes the functional-equation or Poisson-duality ledger that pairs the u and u^{-1} directions. After the fibrewise path packet is lifted by the Joukowsky Lee–Yang ledger, this completed packet produces no zero branch in

$$0 < |u| < 1$$

and no zero branch in

$$|u| > 1,$$

and the operator introduces no unrecorded $\mathbb{R}_{>0}$ scale gauge.

Theorem 9260.15 (Mellin rows supply the stable bridge source package)**.** *Assume*

ZeckendorfTransferDominatedSplitting

and

SelfDualMellinLeeYangOperator

for the golden eta zero island. Then the three analytic source rows of Definition 9260.16 are supplied for that island.

Proof. Definition 9260.12 identifies the golden eta truncation with a Mellin projection of the Zeckendorf path partition function. The dominated-splitting row supplies the branch decomposition and boundary dominance estimate required for GoldenSpectralExpansion and GoldenSpectralGap. The self-dual Mellin Lee–Yang stability operator supplies the strict inside and strict outside zero-free ledgers, with no radial scale gauge. Those are exactly the stability rows required by GoldenStableRoucheHomotopy. □

Definition 9260.16 (Golden bridge analytic source rows)**.** *The analytic source content of*

ZetaGoldenLeeYangBridge

splits into three rows:

$$\mathsf{GoldenSpectralExpansion}, \qquad \mathsf{GoldenSpectralGap}, \qquad \mathsf{GoldenStableRoucheHomotopy}.$$

The first row supplies a spectral or exponential-sum expansion for the golden packet on the displayed island. The second row identifies the dominant pair and proves the uniform gap needed by Definition 9260.6. The third row transports the selected dominant packet to the Fibonacci Lee–Yang lift while preserving the strict inside and strict outside zero-free regions. The Zeckendorf–Mellin route of Definition 9260.15 offers a more structured way to supply these rows: first identify eta golden truncation as a Mellin projection of path independent-set data, then prove dominated transfer splitting and self-dual Mellin stability preservation. Together these rows upgrade weak eta capture to a boundary-stable golden packet.

Theorem 9260.17 (A golden bridge witness supplies boundary stability)**.** *Let a completed zero island be captured by a golden eta packet $\mathcal{G}_m(\rho)$ and let Definition 9260.3 supply a bridge witness whose active lifted variables have the centered form*

$$u_a(s) = e^{-(s-1/2)h_a}, \qquad h_a > 0.$$

If the island readout is

$$s = \frac{1}{2} + r + it,$$

then the bridge witness excludes $r \neq 0$ for that island.

Proof. The same-island row transfers the local zero event from the eta packet to the lifted Lee–Yang packet without changing the winding ledger on ∂D_m. Hence the lifted packet has a zero-relevant branch at the same readout. For each active variable,

$$|u_a(s)| = \left|e^{-(s-1/2)h_a}\right| = e^{-rh_a}.$$

If $r > 0$, then every active variable lies in the strict inside region $|u_a(s)| < 1$. If $r < 0$, then every active variable lies in the strict outside region $|u_a(s)| > 1$. Both alternatives are forbidden by the Lee–Yang lift certificate, and radial purity prevents the bridge from absorbing the contradiction into an unledgered scale factor. Therefore $r = 0$. □

Definition 9260.18 (Golden Lee–Yang bridge source row)**.** *The source row*

$$\mathsf{ZetaGoldenLeeYangBridge}$$

asserts that every accepted non-trivial completed zeta zero has a cofinal golden certificate tower whose sufficiently fine levels carry golden Lee–Yang bridge witnesses. The witnesses must be compatible under refinement: the zero island, Zeckendorf address, lifted path packet, same-island transfer, radial-purity row, and dominance row at level $m+1$ restrict to the corresponding level-m rows.

Theorem 9260.19 (The bridge source row gives golden stable capture)**.** *If* $\mathsf{ZetaGoldenLeeYangBridge}$ *holds, then*

$$\mathsf{GoldenStableCaptureBridge}_\zeta$$

holds.

Proof. Let an accepted non-trivial completed zeta zero be given. The bridge source row supplies a cofinal golden tower with bridge witnesses at sufficiently fine levels. Each witness contains the weak eta capture row, the Zeckendorf or Fibonacci path packet, the Lee–Yang unit-boundary certificate, and a same-island transfer. These are exactly the rows required by the golden stable capture bridge of Definition 9259.20, with the additional radial-purity and dominance ledgers recording canonicity of the source. Thus the zero is covered by $\mathsf{GoldenStableCaptureBridge}_{\zeta}$. □

Corollary 9260.20 (Golden Lee–Yang bridge suffices for fixed-half readout)**.** *If* ZetaGoldenLeeYangBridge *holds, then every accepted non-trivial completed zeta zero has fixed-half readout.*

Proof. By Definition 9260.19, the golden stable capture coverage target holds. Apply Definition 9259.23. □

Principle 9260.21 (Dominant branch source load)**.** *The dominant branch row is the analytic load of the bridge. It must show that the lifted Fibonacci path packet is the zero-relevant finite source for the displayed island, with tail and comparison budgets strong enough to preserve the boundary gap. Without that row, a Lee–Yang stable path packet and a weak eta capture packet remain two unrelated finite objects. With it, the same island is controlled by a unit-boundary packet, and the radial scale coordinate has no legal place to close.*

Principle 9260.22 (Stable bridge proof boundary)**.** *Definition 9260.6 is an abstract finite theorem, and Definition 9260.7 records a finite model where the corresponding dominance and endpoint-isolation rows are present. The zeta golden route still requires the three analytic source rows of Definition 9260.16. Without the spectral expansion, spectral gap, and stable Rouché homotopy rows, the bridge remains a conditional source package; with them, the Lee–Yang unit-boundary certificate can be transported to the same zero island without introducing a radial scale anomaly.*

Principle 9260.23 (Mellin factorization of the bridge load)**.** *The bridge need not be approached as a direct homotopy from an eta truncation to a Lee–Yang polynomial. The exact projection of Definition 9260.12 factors the eta truncation through the Zeckendorf path partition function, where the Fibonacci transfer and Lee–Yang lift are intrinsic. The remaining analytic load is therefore the pair of source rows*

$$\mathsf{ZeckendorfTransferDominatedSplitting}$$

and

$$\mathsf{SelfDualMellinLeeYangOperator}.$$

The first row prevents the Mellin projection from selecting a non-Fibonacci dominant branch; the second replaces the raw one-sided Mellin readout by a completed self-dual readout and prevents it from creating a zero in the strict inside or strict outside region. This factorization is still a proof obligation, but it is more local than an unstructured comparison between the eta packet and an unrelated Lee–Yang packet.

Chapter 9261

Golden Bridge Three-Level Closure

chapter 9260 isolates the analytic bridge rows that remain between weak eta capture and a Lee–Yang stable golden packet. The present chapter records the same load in three strata: an abstract finite theorem, a fixed quartic finite model, and the zeta-facing golden source package. The strata are kept separate so that a verified finite pattern is not read as a global zeta theorem.

Definition 9261.1 (Three-level golden bridge package)**.** *The* three-level golden bridge package *consists of the following rows.*

The abstract row is the finite dominant-branch control theorem Definition 9260.6. It requires a displayed spectral expansion, a dominant pair, and the boundary inequality

$$|P_m^{\mathrm{sub}}(z)| < |P_m^{\mathrm{dom}}(z)| \qquad z \in \partial\Omega_m.$$

The finite-model row is the quartic endpoint carrier of Definition 9260.7. It shows that the dominant-branch, Puiseux, two-branch interference, and Rouché isolation rows can be realized inside one finite spectral carrier.

The zeta-facing row is the source package of Definition 9260.16, namely

$$\mathsf{GoldenSpectralExpansion}, \qquad \mathsf{GoldenSpectralGap}, \qquad \mathsf{GoldenStableRoucheHomotopy}.$$

This row is the only stratum that can feed the golden zeta bridge.

Theorem 9261.2 (Abstract dominant control is finite)**.** *The abstract row of Definition 9261.1 is a finite analytic theorem: it transports zero count from P_m^{dom} to P_m under the displayed strict boundary inequality.*

Proof. This is exactly Definition 9260.6. The theorem uses only the decomposition

$$P_m = P_m^{\mathrm{dom}} + P_m^{\mathrm{sub}}$$

and the strict boundary estimate. No zeta-specific coverage row, Lee–Yang bridge row, or infinite tower row is consumed. □

Principle 9261.3 (Quartic endpoint as finite witness)**.** *The quartic endpoint carrier witnesses the shape of the argument, not its zeta coverage. It contains a fixed spectral polynomial, a normalization ledger, a real projection ledger, a dominance ledger, and an endpoint-zero ledger. Its scope boundary refuses a growing-window endpoint-zero theorem and refuses any zeta conclusion. Thus it licenses the methodology of finite dominance followed by local Rouché isolation, while leaving the zeta golden spectral expansion and gap as separate source obligations.*

Definition 9261.4 (Zeta-facing strong golden bridge package)**.** *The source row*

$$\mathsf{ZetaFacingStrongGoldenBridge}_{\zeta,\varphi}$$

asserts that every accepted non-trivial completed zeta zero has a golden certificate tower on which the following compatible rows are present: golden weak eta capture, the Zeckendorf–Mellin exact projection of Definition 9260.12, the analytic source rows of Definition 9260.16, cofinal active-height growth, and no unledgered radial scale gauge. The package does not assert the analytic rows by definition; it records the source surface that must be supplied before the fixed-half readout can be exported.

Theorem 9261.5 (Strong golden bridge gives the zeta Lee–Yang bridge)**.** *If*

$$\mathsf{ZetaFacingStrongGoldenBridge}_{\zeta,\varphi}$$

holds, then

$$\mathsf{ZetaGoldenLeeYangBridge}$$

holds.

Proof. Fix an accepted non-trivial completed zeta zero. The source row of Definition 9261.4 supplies a golden certificate tower for that zero and supplies the analytic source rows of Definition 9260.16. These rows provide the dominant branch selection, the stable Rouché transport, and the Lee–Yang stable zero-free regions on the same zero island. Together with the weak eta capture and Zeckendorf address ledgers, they are precisely the golden Lee–Yang bridge witnesses required by Definition 9260.18. □

Theorem 9261.6 (Strong golden bridge gives fixed-half readout)**.** *If*

$$\mathsf{ZetaFacingStrongGoldenBridge}_{\zeta,\varphi}$$

holds, then every accepted non-trivial completed zeta zero has real part $1/2$*.*

Proof. By Definition 9261.5, the source row $\mathsf{ZetaGoldenLeeYangBridge}$ holds. Apply Definition 9260.20. □

Principle 9261.7 (Three-level proof boundary)**.** *The abstract row and the quartic endpoint row are evidence about proof shape. They do not cover zeta zeros. The zeta-facing row must still provide the analytic bridge package*

$$\mathsf{GoldenSpectralExpansion} \quad \mathsf{GoldenSpectralGap} \quad \mathsf{GoldenStableRoucheHomotopy},$$

or, through the Mellin factorization of Definition 9260.23, the two lower rows

$$\mathsf{ZeckendorfTransferDominatedSplitting} \qquad \mathsf{SelfDualMellinLeeYangOperator}.$$

Only after those rows are attached to the same golden zero island does the no-scale argument apply to the readout

$$s = \frac{1}{2} + r + it.$$

Definition 9261.8 (Renormalized Zeckendorf endpoint transfer)**.** *The endpoint scale for the Zeckendorf–Mellin fibre is not a fixed $u > 0$. It is the normalized scale*

$$u = \frac{\alpha}{F_{m+2}}.$$

At this scale the Mellin fibre variables become

$$\widetilde{x}_{m,j}(\alpha) := (-1)^{F_{j+1}} \exp\left(-\alpha \frac{F_{j+1}}{F_{m+2}}\right).$$

The associated non-autonomous path transfer matrices are

$$T_{m,j}(\alpha) := \begin{pmatrix} 1 & \widetilde{x}_{m,j}(\alpha) \\ 1 & 0 \end{pmatrix},$$

with total endpoint transfer

$$\mathcal{T}_m(\alpha) := T_{m,m}(\alpha) T_{m,m-1}(\alpha) \cdots T_{m,1}(\alpha).$$

The source row

RenormalizedZeckendorfEndpointTransfer

asserts that the zero-relevant Mellin window is read through this normalized transfer product, not through a fixed-u fibre where the large Fibonacci weights freeze the tail variables.

Principle 9261.9 (Endpoint scaling is part of dominance)**.** *For fixed $u > 0$, the variables*

$$x_j(u) = (-1)^{F_{j+1}} e^{-uF_{j+1}}$$

decay rapidly with j, so the last variables of a long Zeckendorf window no longer participate in a balanced Fibonacci competition. The renormalized scale of Definition 9261.8 keeps the terminal ratios

$$\frac{F_{j+1}}{F_{m+2}}$$

visible. Hence the dominated-splitting row in Definition 9260.13 must be proved for the normalized endpoint transfer product $\mathcal{T}_m(\alpha)$.

Definition 9261.10 (Mellin stability attack surfaces)**.** *The source row*

SelfDualMellinLeeYangOperator

may be attacked through any of the following stability-preservation surfaces.

The total-positivity surface proves that the completed Mellin kernel produces a Pólya-frequency or Laguerre–Pólya type transform compatible with the Lee–Yang zero-free regions.

The Hermite–Biehler surface rewrites the completed Mellin packet as a function

$$E(z) = A(z) - iB(z)$$

whose half-plane or unit-circle stability is controlled by a de Branges-type ledger.

The Rouché-stable discretization surface approximates the completed Mellin integral by finite sums

$$\sum_{\ell} w_\ell(s) L_{m,u_\ell},$$

with a stability-preserving choice of weights and a boundary error ledger strong enough to pass to the integral without crossing zero.

Principle 9261.11 (Mellin stability as no-demon finite form)**.** *The self-dual Mellin stability row is the finite packet analogue of the no-demon constraint. An off-half readout*

$$s = \frac{1}{2} + r + it$$

introduces the real scale factor

$$e^{-rh_a}$$

and therefore tilts any active-mode distribution by real-positive weights. If the completed self-dual Mellin readout preserves the Lee–Yang inside and outside zero-free regions, that tilt cannot be hidden as a phase or prime-register gauge. The only remaining legal readout is the unit boundary readout, where

$$|e^{-(s-1/2)h_a}| = 1.$$

Principle 9261.12 (Mellin projection obstruction)**.** *Fibrewise Lee–Yang stability is not, by itself, a stability theorem for Dirichlet-polynomial readout. The Zeckendorf fibre identity of Definition 9260.12 places the finite geometric packet*

$$K_M(u) = \sum_{N=0}^{M-1} (-1)^N e^{-uN}$$

on the unit boundary in the variable $z = e^{-u}$. The Mellin-projected Dirichlet packet, however, reads the same finite data through powers n^{-s}. The smallest non-trivial Dirichlet packet

$$P_2(s) = 1 - 2^{-s}$$

has zero set

$$s = \frac{2\pi i k}{\log 2}, \qquad k \in \mathbb{Z},$$

and therefore lies on the line $\Re(s) = 0$. Thus the unrestricted implication from unit-boundary fibre zeros to fixed-half Mellin zeros is false. Any zeta-facing use of the Mellin row must carry the additional ledger that transports the additive Zeckendorf height into the multiplicative prime height without creating a real-positive scale gauge.

Definition 9261.13 (Self-dual Zeckendorf completed packet)**.** *Let*

$$K_m(u) := I_m(\mathbf{x}(u)) - 1 = \sum_{n=1}^{F_{m+2}-1} (-1)^n e^{-nu}$$

be the one-sided Zeckendorf–Mellin kernel. A self-dual Zeckendorf completed packet *is a completed kernel in the logarithmic variable $y = \log u$ of the form*

$$\Psi_m(y) := e^{y/2} K_m(e^y) + e^{-y/2} K_m(e^{-y}),$$

or a ledger-equivalent Poisson-completed kernel with the same symmetry row

$$\Psi_m(y) = \Psi_m(-y).$$

Its completed Mellin readout is

$$\mathcal{X}_m\left(\frac{1}{2} + z\right) := \int_{-\infty}^{\infty} \Psi_m(y) e^{zy}\, dy,$$

whenever the displayed integral is replaced, if necessary, by the corresponding regularized finite-packet ledger. The point of the row is not the particular displayed completion, but the presence of a functional-equation ledger pairing the u and u^{-1} directions before Lee–Yang stability is read out.

Definition 9261.14 (Self-dual Zeckendorf Hermite–Biehler target)**.** *The source row*

$$\mathsf{SelfDualZeckendorfHB}$$

asserts that the completed transform of Definition 9261.13 belongs to a Hermite–Biehler, de Branges, or Laguerre–Pólya stability class strong enough to force every zero of

$$\mathcal{X}_m(s)$$

in the zero-relevant island to satisfy

$$\Re(s) = \frac{1}{2}.$$

Equivalently, after writing $s = 1/2 + z$, the completed transform has no zero with $\Re(z) \neq 0$ on the island covered by the certificate.

Theorem 9261.15 (Self-dual Hermite–Biehler target gives fixed-half packet)**.** *If a zero-relevant golden packet is captured by a self-dual Zeckendorf completed packet satisfying* $\mathsf{SelfDualZeckendorfHB}$*, and if the capture homotopy preserves winding on the boundary of the same island, then all zeros captured on that island have real part* $1/2$*.*

Proof. Write $s = 1/2 + z$. The self-dual completed packet supplies a transform

$$\mathcal{X}_m\left(\frac{1}{2} + z\right) = \int_{-\infty}^{\infty} \Psi_m(y) e^{zy}\, dy$$

with the symmetry ledger $\Psi_m(y) = \Psi_m(-y)$. The $\mathsf{SelfDualZeckendorfHB}$ row excludes zeros with $\Re(z) \neq 0$ on the zero-relevant island. Thus any zero of the completed packet in that island has $z = it$ and hence real part $1/2$. Boundary winding preservation transfers the same zero count from the captured golden packet to the completed packet on the island, so the captured packet zeros have the same fixed-half readout. □

Principle 9261.16 (One-sided Mellin is a source identity, not a stability row)**.** *Definition 9260.12 remains the exact source identity connecting the eta golden truncation to the Zeckendorf path partition function. Its role is to expose the finite path ledger and the cyclotomic unit-boundary fibre. It does not license unit-boundary stability after Mellin projection. The stability row must instead pass through the completed self-dual packet of Definition 9261.13 and the Hermite–Biehler target of Definition 9261.14.*

Definition 9261.17 (Zeckendorf–Gödel prime code)**.** *Let*

$$N = \sum_j z_j F_j, \qquad z_j \in \{0, 1\}, \qquad z_j z_{j+1} = 0,$$

be a Zeckendorf address, and let p_j be the j-th prime. The Zeckendorf–Gödel prime code *of this address is*

$$g(N) := \prod_j p_j^{z_j}.$$

Its prime height is

$$H_P(N) := \log g(N) = \sum_j z_j \log p_j.$$

This converts the no-adjacent Zeckendorf ledger into a prime-register ledger while keeping the address bits finite and certificate-readable.

Definition 9261.18 (Prime–Zeckendorf stable transport)**.** *A* prime–Zeckendorf stable transport *is a family of finite packet transports*

$$\mathcal{T}_\tau, \qquad 0 \le \tau \le 1,$$

from the additive Zeckendorf height

$$H_Z(N) = N$$

to a prime height such as $H_P(N) = \log g(N)$*, or to a zeta-facing height* $H_\zeta(n) = \log n$*, satisfying the following certificate rows on the same zero island: ledger uniqueness, the no-adjacent address constraint, unit phase boundary, absence of an unledgered* $\mathbb{R}_{>0}$ *scale anomaly, Rouché winding invariance, and preservation of the active dominant branch. The row records precisely the structure missing from a bare Mellin projection.*

Definition 9261.19 (Prime-compatible golden tower)**.** *A* prime-compatible golden tower *is a tower of finite packets* $\mathcal{P}_m$ *such that each layer is generated by a path-independent-set or Zeckendorf address ledger, each active address bit is read as a prime-register channel, the finite packet satisfies a multivariate Lee–Yang container ledger, refinement is cofinal in the zero-relevant packet family, Rouché capture is available for the accepted zeta zero packet under discussion, and the transport contains no unledgered real-positive scale gauge.*

Theorem 9261.20 (Prime-compatible tower gives fixed-half readout)**.** *If every accepted non-trivial completed zeta zero is captured by a prime-compatible golden tower, then every such zero has real part* $1/2$*.*

Proof. Let

$$\rho = \frac{1}{2} + r + it$$

be an accepted non-trivial completed zeta zero, and choose a prime-compatible golden tower capturing its zero packet. The tower supplies a Lee–Yang unit-boundary ledger for each active channel, hence for each active height $h_a > 0$ the centered readout satisfies

$$\left| e^{-(\rho-1/2)h_a} \right| = 1.$$

Since

$$e^{-(\rho-1/2)h_a} = e^{-rh_a} e^{-ith_a},$$

the modulus condition is

$$e^{-rh_a} = 1.$$

Because $h_a > 0$, this gives $r = 0$. Therefore $\Re(\rho) = 1/2$. □

Principle 9261.21 (Bridge factorization through prime registers)**.** *The zeta-facing golden bridge is not licensed by a single unrestricted Mellin stability assertion. Its certificate surface factors through two source rows:*

$$\mathsf{PrimeZeckendorfLift} \qquad \mathsf{PrimePacketToZetaHomotopy}.$$

The first row transports Fibonacci or path-independent-set Lee–Yang packets into Zeckendorf–Gödel prime packets. The second row transports those prime packets into the eta or zeta golden packet without changing boundary winding and without introducing a radial scale ledger. This factorization is the prime-ledger refinement of

$$\mathsf{ZetaGoldenLeeYangBridge}.$$

Definition 9261.22 (Multivariate Lee–Yang container)**.** *Let A_m be a finite active-mode set with heights $h_a > 0$. For a readout s set*

$$z_a(s) := e^{-(s-1/2)h_a}, \qquad \mathbf{z}_m(s) := (z_a(s))_{a\in A_m}.$$

A multivariate Lee–Yang container *is a finite polynomial*

$$\mathcal{Z}_m(\mathbf{z})$$

equipped with a Lee–Yang nonvanishing ledger

$$\mathcal{Z}_m(\mathbf{z}) \neq 0 \qquad \text{if } |z_a| < 1 \text{ for all } a,$$

and

$$\mathcal{Z}_m(\mathbf{z}) \neq 0 \qquad \text{if } |z_a| > 1 \text{ for all } a.$$

The container may be supplied by a finite ferromagnetic Ising packet, an Asano-contraction packet, a matching-stability packet, or a Rouché-stable specialization of such a packet.

Theorem 9261.23 (Multivariate container gives no-scale readout)**.** *Let a zero-relevant golden packet be Rouché equivalent on a zero island to a multivariate Lee–Yang container evaluated at $\mathbf{z}_m(s)$. If all active heights satisfy $h_a > 0$, then every zero captured on that island has real part $1/2$.*

Proof. Let a captured zero have readout

$$s = \frac{1}{2} + r + it.$$

If $r > 0$, then

$$|z_a(s)| = e^{-rh_a} < 1$$

for every $a \in A_m$. If $r < 0$, then

$$|z_a(s)| = e^{-rh_a} > 1$$

for every $a \in A_m$. Both cases are excluded by the multivariate Lee–Yang nonvanishing ledger of Definition 9261.22. Since the Rouché equivalence preserves the zero count on the same island, the captured zero cannot have $r \neq 0$. Therefore $r = 0$. □

Definition 9261.24 (Multivariate path Joukowsky target)**.** *For the path independent-set polynomial $I_m(\mathbf{x})$, define the multivariate Joukowsky lift*

$$\mathcal{L}_m(\mathbf{u}) := \prod_{j=1}^{m} (1+u_j)^2 I_m\left(-\frac{u_1}{(1+u_1)^2}, \ldots, -\frac{u_m}{(1+u_m)^2}\right).$$

The displayed lift is a path-skeleton candidate, not itself a stability row. The source row

GoldenIsingContainerBridge

asserts that the zero-relevant zeta or eta golden packet is Rouché equivalent, on the same zero island, to an Ising, Asano, or matching container in which the path skeleton is auditable and the active variables are read as $u_a(s) = e^{-(s-1/2)h_a}$.

Principle 9261.25 (Path hard-core data is a skeleton)**.** *The Zeckendorf path independent-set packet is the finite combinatorial skeleton of the golden bridge, not the final Lee–Yang container. Raw hard-core specialization can produce Dirichlet packets such as* $1 - p^{-s}$*, whose zeros need not have fixed-half readout. The Joukowsky, Asano, Ising, or matching lift is the row that turns the path skeleton into a unit-boundary container on the zeta logarithmic ray. Thus the zeta-facing target is not a direct homotopy to a single variable Fibonacci polynomial, but a Rouché-stable realization inside a height-specialized Lee–Yang container.*

Chapter 9262

Zeta Ray Lee–Yang Container

chapter 9261 records the multivariate Lee–Yang container direction for the golden bridge. The present chapter sharpens that direction to the actual locus available to zeta packets. The variables in a zeta packet are not independent polydisk coordinates; they are synchronized by a single complex height parameter.

Definition 9262.1 (Zeta logarithmic ray)**.** *Let A_m be a finite active-mode set with heights $h_a > 0$. The* zeta logarithmic ray *is the real two-parameter surface*

$$\mathcal{R}_{A_m} := \left\{ \left(e^{-rh_a} e^{-ith_a} \right)_{a \in A_m} : r, t \in \mathbb{R} \right\}.$$

Its off-boundary part is

$$\mathcal{R}^{\mathrm{off}}_{A_m} := \left\{ \left(e^{-rh_a} e^{-ith_a} \right)_{a \in A_m} : r, t \in \mathbb{R},\ r \neq 0 \right\},$$

and its critical phase part is

$$\mathcal{R}^{\mathrm{crit}}_{A_m} := \left\{ \left(e^{-ith_a} \right)_{a \in A_m} : t \in \mathbb{R} \right\}.$$

Definition 9262.2 (Zeta-ray Lee–Yang stability)**.** *A finite packet $\mathcal{Z}_m(\mathbf{u})$ with active heights $(h_a)_{a \in A_m}$ is* zeta-ray Lee–Yang stable *if*

$$\mathcal{Z}_m \left(\left(e^{-rh_a} e^{-ith_a} \right)_{a \in A_m} \right) \neq 0$$

for every $r \neq 0$ and every $t \in \mathbb{R}$. This is weaker than nonvanishing on the whole polydisk and stronger than a one-variable diagonal Lee–Yang assertion.

Definition 9262.3 (Exponential Lee–Yang specialization)**.** *Given a multivariate packet $\mathcal{Z}_m(u_a)_{a \in A_m}$ and heights $h_a > 0$, its* exponential specialization *is the exponential polynomial*

$$\Phi_m(w) := \mathcal{Z}_m \left((e^{-wh_a})_{a \in A_m} \right).$$

The packet is exponential Lee–Yang stable *for the height vector if*

$$\Phi_m(w) = 0 \quad \Longrightarrow \quad \Re(w) = 0.$$

Theorem 9262.4 (Zeta-ray stability gives fixed-half readout)**.** *Let a zero-relevant golden packet be Rouché equivalent on a zero island to a packet $\mathcal{Z}_m$ that is zeta-ray Lee–Yang stable for the same active heights. Then every zero captured on that island has real part* $1/2$.

Proof. Let a captured zero have readout

$$\rho = \frac{1}{2} + r + it.$$

If $r \neq 0$, then its active variables form a point of $\mathcal{R}^{\mathrm{off}}_{A_m}$:

$$\left(e^{-(\rho-1/2)h_a}\right)_{a\in A_m} = \left(e^{-rh_a}e^{-ith_a}\right)_{a\in A_m}.$$

Zeta-ray Lee–Yang stability says that $\mathcal{Z}_m$ has no zero at that point. The Rouché equivalence gives the same zero count on the same island, so the captured zero cannot have $r \neq 0$. Hence $r = 0$. □

Definition 9262.5 (Prime-height Hermite–Biehler row)**.** *The source row*

$$\mathsf{PrimeHeightHB}$$

asserts that the exponential specialization

$$\Phi_m(w) = \mathcal{Z}_m\left((e^{-wh_a})_{a\in A_m}\right)$$

of the prime-compatible Zeckendorf container belongs to a Hermite–Biehler, de Branges, or equivalent exponential-polynomial stability class forcing all zeros of Φ_m in the zero-relevant island to satisfy $\Re(w) = 0$.

Principle 9262.6 (Ray stability is the required container surface)**.** *Full polydisk Lee–Yang non-vanishing is more than the zeta bridge requires. The zeta variables are tied by the same parameter $w = s - 1/2$ and can only move on the logarithmic ray of Definition 9262.1. The relevant replacement for a global multivariate stability claim is therefore*

$$\mathsf{ZetaRayStability} \qquad \textit{or structurally} \qquad \mathsf{PrimeHeightHB}.$$

Together with a same-island capture row

$$\mathsf{PrimePacketToZetaCapture},$$

these rows are sufficient for the no-scale readout of Definition 9262.4.

Principle 9262.7 (Path Joukowsky obstruction)**.** *The path Joukowsky lift is not, by itself, a multivariate Lee–Yang container. For $m = 2$ the path independent-set polynomial is*

$$I_2(x_1, x_2) = 1 + x_1 + x_2.$$

The coordinatewise Joukowsky lift has the form

$$\mathcal{L}_2(u_1, u_2) = (1 + u_1)^2(1 + u_2)^2 - u_1(1 + u_2)^2 - u_2(1 + u_1)^2.$$

After fixing $u_1 = i/2$, this becomes

$$\left(\frac{3}{4} + \frac{i}{2}\right)u_2^2 + \frac{3}{4}u_2 + \left(\frac{3}{4} + \frac{i}{2}\right) = 0.$$

Equivalently,

$$u_2^2 + \left(\frac{9}{13} - \frac{6}{13}i\right) u_2 + 1 = 0.$$

The product of the two roots is 1*, but their sum is not real. Hence the two roots cannot both lie on the unit circle. Since their product has modulus* 1*, one root lies inside the unit disk. Thus the coordinatewise path Joukowsky lift has a zero with both variables inside the unit disk, and the unrestricted multivariate stability claim is not available.*

Definition 9262.8 (Golden–Ising container bridge)**.** *The source row*

GoldenIsingContainerBridge

asserts the following data on a zero-relevant golden island. First, there is a finite ferromagnetic Ising, Asano-stable, or matching-stable container $Z_{G_m}(\mathbf{z})$ *with a Lee–Yang nonvanishing ledger on the required zeta logarithmic ray. Second, the Zeckendorf or Fibonacci path packet is present only as an auditable skeleton inside that container. Third, the zeta golden packet and* $Z_{G_m}(\mathbf{z}(s))$ *have the same island winding, either through a Rouché gap or through a stable homotopy. Fourth, the bridge has no unledgered* $\mathbb{R}_{>0}$ *scale coordinate.*

Definition 9262.9 (Dominant container and Ising homotopy rows)**.** *The Golden–Ising bridge separates into two source rows. The row*

GoldenDominantContainerTheorem

selects the zero-relevant Lee–Yang container branch and proves the boundary gap between that branch and every subdominant contribution. The row

IsingRoucheHomotopy

transports the zeta golden packet to the selected container without crossing zero on the boundary and without losing the Lee–Yang nonvanishing ledger on the zeta logarithmic ray.

Theorem 9262.10 (Golden–Ising bridge gives zeta-ray stability)**.** *If a zero-relevant golden packet has a Golden–Ising container bridge, then it satisfies the hypotheses of Definition 9262.4.*

Proof. The bridge supplies a Lee–Yang container Z_{G_m} with nonvanishing on the off-boundary part of the zeta logarithmic ray. It also supplies a same-island Rouché gap or stable homotopy between the zeta golden packet and $Z_{G_m}(\mathbf{z}(s))$. Thus the captured zero count is read through a zeta-ray Lee–Yang stable packet with the same active heights. These are precisely the hypotheses of Definition 9262.4. □

Principle 9262.11 (Skeleton and container separation)**.** *The Zeckendorf path data supplies ledger uniqueness, finite refinement, and the no-adjacent grammar. It does not supply the full thermodynamic stability row. The Lee–Yang container supplies the unit-boundary or ray-nonvanishing row. The bridge between them is therefore a stability-preserving transport, not a coordinatewise Joukowsky substitution. This separation is the working form of the golden bridge:*

Zeckendorf skeleton + *Lee–Yang container* + *same-island Rouché transport.*

Definition 9262.12 (Prime–Asano–Ising container)**.** *A* prime–Asano–Ising container *for an active golden packet is a finite polynomial $\mathcal{Z}_m(\mathbf{z})$ with the following rows. The finite-volume row says that $\mathcal{Z}_m$ is a ferromagnetic Ising partition function, or is built from Lee–Yang stable factors by Asano-contraction or matching-stability operations. The active-variable row assigns each variable to an audited active height*

$$z_a(s) = e^{-(s-1/2)h_a}, \qquad h_a > 0.$$

The stability row gives Lee–Yang nonvanishing on the required inside/outside regions, or the zeta-ray form of Definition 9262.2. The ledger row requires the heights and active modes to be supplied by the prime or Zeckendorf address ledger rather than by interpolation after the zero island has been selected. The no-scale row forbids any unledgered $\mathbb{R}_{>0}$ gauge in the construction.

Definition 9262.13 (Zeta-to-prime-Asano capture)**.** *An accepted non-trivial completed zeta zero satisfies*

$$\mathsf{ZetaToPrimeAsanoCapture}$$

when there are a golden analytic packet $P_m(s)$, a prime–Asano–Ising container $\mathcal{Z}_m(\mathbf{z})$, and a zero island D_m containing the zero such that either the Rouché gap

$$|P_m(s) - \mathcal{Z}_m(\mathbf{z}(s))| < |P_m(s)| \qquad s \in \partial D_m$$

holds, or a boundary-nonvanishing homotopy carries P_m to $\mathcal{Z}_m(\mathbf{z}(s))$ on the same island. The capture row also requires the Zeckendorf or Fibonacci data to appear only as the internal ruler and source skeleton of the container.

Theorem 9262.14 (Prime–Asano capture gives fixed-half readout)**.** *If an accepted non-trivial completed zeta zero satisfies* ZetaToPrimeAsanoCapture*, then its readout has real part* $1/2$*.*

Proof. The capture row supplies a prime–Asano–Ising container with the same zero-island winding as the golden analytic packet. By Definition 9262.12, this container is zeta-ray Lee–Yang stable for the active heights, with no unledgered real-positive scale gauge. Applying Definition 9262.4 gives real part $1/2$ for every zero captured on that island. □

Principle 9262.15 (Internal ruler is not the final container)**.** *The golden ruler and Zeckendorf ledger remain internal: they select finite modes, supply refinement, and make the source address auditable. They do not by themselves create the no-scale thermodynamic stability row. The final stability row is carried by a prime–Asano–Ising, Hermite–Biehler, or de Branges container, and the bridge obligation is the capture row of Definition 9262.13. Thus the active proof load is not the existence of an internal ruler alone, but the same-island transport from the internally ruled golden packet to a stable container.*

Definition 9262.16 (Polarized golden Lee–Yang container)**.** *Let $L_m(u)$ be the one-variable Fibonacci Lee–Yang lift supplied by the golden ruler, and let $D_m = \deg L_m$. If*

$$L_m(u) = \sum_{k=0}^{D_m} a_k u^k,$$

its polarized container is

$$\mathcal{Z}_m^{\mathrm{pol}}(z_1, \ldots, z_{D_m}) := \sum_{k=0}^{D_m} a_k \binom{D_m}{k}^{-1} e_k(z_1, \ldots, z_{D_m}),$$

where e_k is the k-th elementary symmetric polynomial. It satisfies the diagonal readback

$$\mathcal{Z}_m^{\mathrm{pol}}(u, \ldots, u) = L_m(u).$$

The source row

GoldenPolarizedLeeYangBridge

asserts that this polarized packet is the Lee–Yang container supplied by the golden skeleton, rather than the raw multivariate hard-core path polynomial.

Principle 9262.17 (Polarization supplies the container row)**.** *If the one-variable lift L_m has all nontrivial zeros on the unit circle, then its polarization has the Lee–Yang nonvanishing ledger:*

$$\mathcal{Z}_m^{\mathrm{pol}}(\mathbf{z}) \neq 0 \qquad \text{if } |z_j| < 1 \text{ for all } j,$$

and

$$\mathcal{Z}_m^{\mathrm{pol}}(\mathbf{z}) \neq 0 \qquad \text{if } |z_j| > 1 \text{ for all } j.$$

This is the Grace–Walsh–Szegő polarization route from the reliable one-variable Fibonacci circle theorem to a genuine multivariate Lee–Yang container. It is distinct from coordinatewise Joukowsky substitution into the hard-core path polynomial, which is excluded by Definition 9262.7.

Definition 9262.18 (Zeta-to-polarized golden container Rouché row)**.** *The source row*

ZetaToPolarizedGoldenContainerRouche

asserts that, on a zero-relevant island D_m, the zeta golden packet $P_m^{\zeta}(s)$ admits active heights $h_1, \ldots, h_{D_m} > 0$ and a polarized golden container such that

$$z_j(s) = e^{-(s-1/2)h_j}$$

and

$$\left| P_m^{\zeta}(s) - \mathcal{Z}_m^{\mathrm{pol}}(z_1(s), \ldots, z_{D_m}(s)) \right| < \left| \mathcal{Z}_m^{\mathrm{pol}}(z_1(s), \ldots, z_{D_m}(s)) \right|$$

for $s \in \partial D_m$. The row also requires the error term to be subdominant in the ordinary Rouché sense and not an unledgered real-positive scale reservoir.

Theorem 9262.19 (Polarized golden capture gives fixed-half readout)**.** *If an accepted non-trivial completed zeta zero satisfies* ZetaToPolarizedGoldenContainerRouche*, then its readout has real part* $1/2$*.*

Proof. The polarized container has the Lee–Yang nonvanishing ledger by Definition 9262.17. If a captured readout $s = 1/2 + r + it$ had $r > 0$, then every active variable $z_j(s) = e^{-rh_j}e^{-ith_j}$ would lie inside the unit disk. If $r < 0$, every active variable would lie outside the unit disk. Both cases are excluded by the polarized container. The Rouché row transports the zero count between P_m^{ζ} and the polarized container on the same island, so the captured zero cannot have $r \neq 0$. □

Definition 9262.20 (Polarized golden cofinality)**.** *The source row*

PolarizedGoldenCofinality

asserts that every accepted zero-relevant zeta packet is, after passing to a sufficiently fine golden level, covered by Definition 9262.18. This is the cofinal version of the bridge: the polarized golden containers need not equal the zeta packet, but they must dominate the same zero islands with strict Rouché margins.

Definition 9262.21 (Source-side golden Lee–Yang closure)**.** *The source row*

GoldenLeeYangClosureOfXi

asserts that the completed zeta function $\Xi(s)$ is obtained as a source-side limit of internally generated polarized golden Lee–Yang containers. Concretely, there are functions

$$C_m(s) = \mathcal{Z}_m^{\mathrm{pol}}\left(e^{-(s-1/2)h_{m,1}}, \dots, e^{-(s-1/2)h_{m,d_m}}\right)$$

such that each $h_{m,j} > 0$, each C_m is supplied before any zero island is selected, each C_m has no zero in

$$\Re(s) \neq \frac{1}{2},$$

and $C_m \to \Xi$ uniformly on compact sets with enough boundary Rouché control to prevent limit zeros from entering the off-line region.

Theorem 9262.22 (Golden Lee–Yang closure gives fixed-half readout)**.** *If* GoldenLeeYangClosureOfXi *holds, then Ξ has no zero with real part different from $1/2$.*

Proof. Assume that Ξ has a zero ρ with

$$\Re(\rho) \neq \frac{1}{2}.$$

Choose a small disk D around ρ whose closure does not meet the line $\Re(s) = 1/2$ and whose boundary has no zero of Ξ. Then

$$M := \min_{s \in \partial D} |\Xi(s)| > 0.$$

Uniform convergence gives, for sufficiently large m,

$$|C_m(s) - \Xi(s)| < \frac{M}{2} \qquad s \in \partial D.$$

Hence $|C_m(s)| > M/2$ on ∂D, and therefore

$$|\Xi(s) - C_m(s)| < |C_m(s)| \qquad s \in \partial D.$$

By Rouché's theorem, Ξ and C_m have the same number of zeros in D. But C_m has no zero in the off-line disk D, contradiction. Thus no such ρ exists. □

Principle 9262.23 (Local capture is not the final bridge)**.** *The local rows*

ZetaToPrimeAsanoCapture ZetaToPolarizedGoldenContainerRouche

are useful only as finite-island consequences of a source-side construction. If they are postulated separately around each candidate zero, the bridge risks encoding the desired exclusion into the local choice of container. The non-circular target is the prior container tower of Definition 9262.21: the container sequence is constructed from the internal ruler and polarization mechanism first, and zero exclusion is then read by Rouché.

Chapter 9263

Squarefree Prime Polarized Bridge

chapter 9262 isolates the polarized golden Lee–Yang container as the stable object in the golden route. The present chapter records the arithmetic form of that container after prime-height specialization. The point is not to choose a Lee–Yang container around a zero island, but to identify a source-side prime ledger through which a zeta packet could be compared with the polarized container.

Definition 9263.1 (Squarefree prime address set)**.** *Let $p_1, \dots, p_D$ be distinct primes. The squarefree prime address set generated by this window is*

$$\mathcal{N}_D^{\mathrm{sq}} := \left\{ \prod_{j \in S} p_j : S \subseteq \{1, \dots, D\} \right\}.$$

For $n \in \mathcal{N}_D^{\mathrm{sq}}$, let

$$\omega_D(n) := \#\{j : p_j \mid n\}.$$

Definition 9263.2 (Squarefree prime packet)**.** *A* squarefree prime packet *on the prime window $p_1, \dots, p_D$ is a Dirichlet packet of the form*

$$S_D(s) := \sum_{n \in \mathcal{N}_D^{\mathrm{sq}}} b(n) n^{1/2-s}.$$

The coefficients $b(n)$ are part of the source ledger. They are not chosen after a zero island is selected unless a separate capture row records the choice and its boundary margin.

Definition 9263.3 (Prime-height polarized readback)**.** *Let*

$$\mathcal{Z}^{\mathrm{pol}}(z_1, \dots, z_D) = \sum_{k=0}^{D} a_k \binom{D}{k}^{-1} e_k(z_1, \dots, z_D)$$

be the polarization of a one-variable Lee–Yang seed. Its prime-height readback *is obtained by setting*

$$z_j(s) = e^{-(s-1/2)\log p_j}.$$

Then

$$\mathcal{Z}^{\mathrm{pol}}(z_1(s), \dots, z_D(s)) = \sum_{S \subseteq \{1,\dots,D\}} a_{|S|} \binom{D}{|S|}^{-1} \left(\prod_{j \in S} p_j \right)^{1/2-s}.$$

Thus the prime-height readback is a squarefree prime packet whose coefficient depends only on the prime-support cardinality.

Principle 9263.4 (Polarization enters the prime ledger)**.** *The polarized golden container is not merely a formal multiaffine replacement for a one-variable seed. Under the specialization $h_j = \log p_j$, every elementary symmetric term becomes a squarefree prime monomial:*

$$e^{-(s-1/2)\sum_{j\in S}\log p_j} = \left(\prod_{j\in S} p_j\right)^{1/2-s}.$$

Consequently, the bridge from the zeta packet to the polarized Lee–Yang container factors through the arithmetic surface

$$\textit{zeta packet} \quad \rightsquigarrow \quad \textit{squarefree prime packet} \quad \rightsquigarrow \quad \textit{polarized Lee–Yang container.}$$

The first arrow is analytic and zero-island dependent; the second arrow is algebraic or boundary-small once the prime window and seed coefficients have been fixed.

Definition 9263.5 (Squarefree Rouché dominance)**.** *Let $P_m^\zeta(s)$ be a zero-relevant zeta golden packet on a zero island D_m. The packet satisfies*

$$\mathsf{SquarefreeRoucheDominance}$$

if there exist a prime window $p_1, \dots, p_D$ and a squarefree prime packet $S_D(s)$ such that

$$|P_m^\zeta(s) - S_D(s)| < |S_D(s)| \qquad s \in \partial D_m.$$

Equivalently, P_m^ζ and S_D have the same zero count in D_m by Rouché's theorem. The packet S_D must be supplied by a source ledger rather than by an unrecorded interpolation around the candidate zero.

Definition 9263.6 (Polarized coefficient matching)**.** *A squarefree prime packet S_D satisfies*

$$\mathsf{PolarizedCoefficientMatching}$$

if there is a one-variable Lee–Yang seed $L(u) = \sum_{k=0}^{D} a_k u^k$ such that either

$$b(n) = a_{\omega_D(n)} \binom{D}{\omega_D(n)}^{-1} \qquad n \in \mathcal{N}_D^{\mathrm{sq}},$$

or, for the corresponding polarized container $\mathcal{Z}^{\mathrm{pol}}$, the boundary estimate

$$|S_D(s) - \mathcal{Z}^{\mathrm{pol}}(z_1(s), \dots, z_D(s))| < |\mathcal{Z}^{\mathrm{pol}}(z_1(s), \dots, z_D(s))| \qquad s \in \partial D_m$$

holds on the zero island under the prime-height specialization.

Theorem 9263.7 (Squarefree bridge gives polarized transport)**.** *Let a zero-relevant zeta golden packet P_m^ζ on an island D_m satisfy* SquarefreeRoucheDominance *through S_D. If S_D satisfies* PolarizedCoefficientMatc *through a polarized golden Lee–Yang container, then P_m^ζ and the prime-height readback of that container have the same zero-island winding on D_m.*

Proof. The first row gives a strict Rouché inequality between P_m^ζ and S_D on ∂D_m, hence the same zero count on D_m. The second row either identifies S_D with the prime-height readback of a polarized container, or supplies a second strict Rouché inequality between S_D and that readback on the same boundary. Chaining the two boundary nonvanishing comparisons gives the same zero-island winding for P_m^ζ and the polarized Lee–Yang container. □

Corollary 9263.8 (Squarefree bridge gives fixed-half readout)**.** *Under the hypotheses of Definition 9263.7, every zero captured by the island D_m has readout with real part* $1/2$*.*

Proof. By Definition 9263.7, the zeta packet and the prime-height polarized container have the same zero-island winding on D_m. If a captured readout had real part different from $1/2$, then all prime-height variables would lie strictly inside the unit disk or strictly outside it. The polarized container has no zero on either region by Definition 9262.17. Hence the container has zero winding on that off-line island, and the same is true of P_m^ζ, contradicting capture. Therefore the readout has real part $1/2$. □

Principle 9263.9 (Analytic load of the squarefree bridge)**.** *The polarization and coefficient-matching rows are structural: after a one-variable Lee–Yang seed and a prime window are fixed, their prime-height readback is a squarefree prime packet by construction. The analytic burden is the dominance row*

SquarefreeRoucheDominance.

It asks whether the zero-relevant zeta packet can be compared, with a strict boundary gap, to a packet supported on squarefree products of a finite prime window. Prime powers and the non-squarefree tail must therefore enter only through a controlled remainder, a reciprocal Euler-product contour row, or an explicit-formula tail ledger. Without such a ledger, squarefree support is only a formal address surface and does not supply the local Rouché bridge.

Definition 9263.10 (Stable squarefree prime approximation of Xi)**.** *The source row*

StableSquarefreePrimeApproximationOfXi

asserts that there is a source-side sequence of functions

$$C_m(s) = \sum_{n \in \mathcal{N}_{D_m}^{\mathrm{sq}}} b_m(n) n^{1/2-s}$$

such that each C_m is the prime-height readback of a polarized Lee–Yang seed in the sense of Definition 9263.3, and

$$C_m \to \Xi$$

uniformly on compact subsets, with the ordinary contour margins obtained from compact-uniform convergence on each boundary curve. The construction of C_m is fixed by the source ledger before any zero island is selected.

Theorem 9263.11 (Stable squarefree approximation gives golden closure)**.** *If* StableSquarefreePrimeApproximationO *holds, then the source row* GoldenLeeYangClosureOfXi *of Definition 9262.21 holds.*

Proof. Each C_m is a prime-height readback of a polarized Lee–Yang seed. Hence, by Definition 9262.17, it has no zeros when all prime-height variables lie strictly inside the unit disk or strictly outside it. For

$$s = \frac{1}{2} + r + it$$

with $r \neq 0$, the variables

$$e^{-(s-1/2)\log p_j}$$

all have modulus $e^{-r \log p_j}$, hence are all strictly inside the unit disk when $r > 0$ and all strictly outside it when $r < 0$. Therefore each C_m has no zero off the critical line. The stated compact-uniform convergence supplies the boundary Rouché margins on every fixed zero-exclusion contour, and the construction is source-side. These are precisely the closure rows of Definition 9262.21. □

Corollary 9263.12 (Stable squarefree approximation gives fixed-half readout)**.** *If* StableSquarefreePrimeApproxima *holds, then* Ξ *has no zero with real part different from* $1/2$*.*

Proof. Apply Definition 9263.11 and then Definition 9262.22. □

Principle 9263.13 (Source-side squarefree obstruction)**.** *The row*

StableSquarefreePrimeApproximationOfXi

is stronger and less circular than local squarefree dominance. It does not compare a packet to a container chosen near a zero; it asks for a single source-side compact-uniform container tower. Its difficulty is arithmetic: squarefree prime products naturally occur in Euler factors for reciprocal or signed product packets, while Ξ *contains the completed zeta numerator. Thus prime powers, reciprocal contours, logarithmic derivatives, or explicit-formula tails must be accounted for by a displayed ledger before the source-side closure row can be claimed.*

Definition 9263.14 (Squarefree closure companion rows)**.** *The squarefree source-side route has three companion rows. The row*

$\mathsf{StableSquarefreePrimeApproximationOfXi}^{-1}$

uses stable squarefree packets to control the reciprocal completed function or an argument-principle contour, so that zeros of Ξ *are recorded as poles in a no-scale ledger. The row*

LeeYangWeilPositivity

translates Lee–Yang stability of the squarefree packets into a Weil positivity inequality through the explicit formula. The row

LeeYangToHermiteBiehlerSourceContainer

transports the polarized squarefree packets into a Hermite–Biehler or de Branges source container. These rows are alternatives to direct compact-uniform approximation of Ξ*; none is a consequence of local Rouché capture alone.*

Chapter 9264

Xi Jensen Internal Container

chapter 9262 and chapter 9263 formulate Lee–Yang containers as source-side packets to which zeta data may be transported. The Jensen route records a stricter internal alternative: the finite containers are obtained from the completed Xi function itself. The route is conditional. It does not discharge the hyperbolicity obligation, but it places that obligation on an intrinsic finite-resolution surface rather than on an externally selected thermodynamic model.

Definition 9264.1 (Xi Jensen coefficient row)**.** *Let $F(T)$ be the even entire readout of the completed Xi function in a real Taylor coordinate,*

$$F(T) = \sum_{k\geq 0} \gamma(k) \frac{T^k}{k!}.$$

The coefficient sequence γ is the source ledger for the Jensen container family. No zero island or auxiliary Lee–Yang packet is used to define these coefficients.

Definition 9264.2 (Jensen section)**.** *For integers $d, n \geq 0$, the Jensen section of degree d and shift n attached to γ is*

$$J_\gamma^{d,n}(X) := \sum_{j=0}^{d} \binom{d}{j} \gamma(n+j) X^j.$$

It is the finite observation at resolution d and source position n.

Definition 9264.3 (Jensen no-demon row)**.** *A Jensen section is* no-demon *when it is hyperbolic, i.e. when all of its zeros are real. The full Jensen no-demon row is*

$$\mathsf{JensenNoDemon}_\Xi := \forall d, n \geq 0, \quad J_\gamma^{d,n} \text{ is hyperbolic.}$$

This row is the finite-container form of the Laguerre–Pólya obligation for the Xi readout.

Principle 9264.4 (Jensen–Pólya finite-container criterion)**.** *The classical Jensen–Pólya criterion identifies* $\mathsf{JensenNoDemon}_\Xi$ *as the finite-container route to placing the Xi readout in the Laguerre–Pólya class. For the RH vision this means that the zero-location burden can be expressed as hyperbolicity of the internally generated Jensen sections. The criterion is used here only as a conditional bridge: the chapter does not assert the hyperbolicity row.*

Theorem 9264.5 (Jensen shift derivative identity)**.** *For all $d, n \geq 0$,*

$$\frac{d}{dX} J_\gamma^{d+1,n}(X) = (d+1) J_\gamma^{d,n+1}(X).$$

Proof. By definition,

$$J_\gamma^{d+1,n}(X) = \sum_{j=0}^{d+1} \binom{d+1}{j} \gamma(n+j) X^j.$$

Differentiating gives

$$\frac{d}{dX} J_\gamma^{d+1,n}(X) = \sum_{j=1}^{d+1} j \binom{d+1}{j} \gamma(n+j) X^{j-1}.$$

Set $k = j - 1$. Since

$$(k+1)\binom{d+1}{k+1} = (d+1)\binom{d}{k},$$

the derivative becomes

$$(d+1) \sum_{k=0}^{d} \binom{d}{k} \gamma(n+1+k) X^k = (d+1) J_\gamma^{d,n+1}(X).$$

□

Corollary 9264.6 (Derivative propagation of no-demon rows)**.** *If $J_\gamma^{d+1,n}$ is hyperbolic, then $J_\gamma^{d,n+1}$ is hyperbolic.*

Proof. The derivative of a real-rooted polynomial is real-rooted. By Definition 9264.5, $J_\gamma^{d,n+1}$ is a nonzero scalar multiple of such a derivative. □

Definition 9264.7 (Top-row Jensen no-demon)**.** *The source row*

$$\mathsf{TopRowJensenNoDemon}_\Xi$$

asserts that

$$J_\gamma^{D,0}$$

is hyperbolic for every $D \geq 0$.

Theorem 9264.8 (Top row supplies all Jensen sections)**.** *If* $\mathsf{TopRowJensenNoDemon}_\Xi$ *holds, then* $\mathsf{JensenNoDemon}_\Xi$ *holds.*

Proof. For fixed $d, n \geq 0$, repeated use of Definition 9264.5 gives

$$\frac{d^n}{dX^n} J_\gamma^{d+n,0}(X) = \frac{(d+n)!}{d!} J_\gamma^{d,n}(X).$$

The top-row hypothesis gives hyperbolicity of $J_\gamma^{d+n,0}$. Repeated differentiation preserves hyperbolicity, hence $J_\gamma^{d,n}$ is hyperbolic. □

Definition 9264.9 (Cayley circularization of a Jensen section)**.** *For a degree d Jensen section, define its Cayley circularization by*

$$\mathcal{L}_\gamma^{d,n}(u) := (1-u)^d J_\gamma^{d,n}\left(i\frac{1+u}{1-u}\right).$$

The map $u \mapsto i(1+u)/(1-u)$ sends the unit circle, away from $u = 1$, to the real line.

Theorem 9264.10 (Hyperbolic Jensen sections give Lee–Yang circles)**.** *If $J_\gamma^{d,n}$ is hyperbolic, then every zero of $\mathcal{L}_\gamma^{d,n}$ lies on the unit circle.*

Proof. Let $\mathcal{L}_\gamma^{d,n}(u) = 0$. If $u \neq 1$, then

$$X = i\frac{1+u}{1-u}$$

is a zero of $J_\gamma^{d,n}$, hence $X \in \mathbb{R}$. The inverse Cayley transform sends real X to $|u| = 1$. If $u = 1$ occurs, it is the point added by the circularizing factor and still lies on the unit circle. □

Definition 9264.11 (Polarized Jensen Lee–Yang container)**.** *Let*

$$\mathcal{L}_\gamma^{D,0}(u) = \sum_{k=0}^{D} a_k u^k.$$

The polarized Jensen Lee–Yang container is

$$\mathcal{C}_\gamma^{D}(z_1, \ldots, z_D) := \sum_{k=0}^{D} a_k \binom{D}{k}^{-1} e_k(z_1, \ldots, z_D).$$

It is internal because both the seed polynomial and the polarization degree are read from the Jensen section of Xi.

Principle 9264.12 (Jensen containers are internal no-scale containers)**.** *If* $\mathsf{TopRowJensenNoDemon}_\Xi$ *holds, then every top-row Jensen section yields, by Cayley circularization and polarization, a multivariate Lee–Yang container with no zeros when all variables lie strictly inside the unit disk or strictly outside it. Thus the container row is generated from Xi itself. The remaining source obligation is not the construction of an external Ising approximation, but the hyperbolicity of the top-row Jensen sections.*

Definition 9264.13 (Golden Jensen refinement operator)**.** *The source row*

$$\mathsf{GoldenJensenRefinementOperator}$$

asserts the existence of a Fibonacci-indexed family of stability preserving transformations

$$\mathcal{R}_m : J_\gamma^{F_m,0} \rightsquigarrow J_\gamma^{F_{m+1},0}$$

which are generated from the Xi coefficient ledger and the internal golden ruler, and which preserve hyperbolicity. Such a row would turn the top-row no-demon obligation into a golden refinement induction.

Principle 9264.14 (Top-row location of the Jensen obstruction)**.** *The derivative identity removes no-demon propagation from the shift direction: every shifted Jensen section is a normalized derivative of a top-row section. The irreducible obstruction in the Jensen route is therefore the source row*

$$\mathsf{TopRowJensenNoDemon}_\Xi,$$

or, more constructively, the refinement row

$$\mathsf{GoldenJensenRefinementOperator}.$$

These rows are not consequences of the golden ruler alone; they require a stability mechanism for the Xi coefficient ledger.

Chapter 9265

Global Weil Positive Container Tower

chapter 9263 records the squarefree prime surface for polarized Lee–Yang containers, and chapter 9264 records the Jensen hyperbolicity surface generated from Xi itself. The common global target behind these routes is a Weil-positive tower: finite positive containers whose limit is the Weil quadratic form supplied by the explicit formula. This chapter records that target as the non-local form of the no-scale route.

Definition 9265.1 (Multiplicative test row)**.** *Let $\mathcal{A}$ be a source test space on $\mathbb{R}_+^\times$ stable under the operations required by the explicit formula. For $f \in \mathcal{A}$, its Mellin readout is*

$$\widehat{f}(s) := \int_0^\infty f(x) x^s \frac{dx}{x},$$

whenever this integral is read directly, and otherwise by the regularized test-row convention of the explicit formula. In logarithmic coordinates $x = e^u$, with $\phi(u) = f(e^u)$, this is the Laplace–Fourier readout

$$\widehat{f}(s) = \int_{-\infty}^\infty \phi(u) e^{su}\, du.$$

Definition 9265.2 (Weil quadratic form row)**.** *The Weil quadratic form attached to the completed zeta zero ledger is the regularized pairing*

$$\mathcal{W}(f) := \sum_\rho \widehat{f}(\rho)\, \overline{\widehat{f}(1-\overline{\rho})},$$

where ρ ranges over the completed zeta zero ledger with the standard symmetry and multiplicity conventions of the explicit formula. The displayed formula records the zero-side contribution; the regularization and archimedean rows are part of the Weil-form source ledger.

Definition 9265.3 (Global Weil positivity)**.** *The source row*

$$\mathsf{GlobalWeilPositivity}$$

asserts that

$$\mathcal{W}(f) \geq 0 \qquad (f \in \mathcal{A}).$$

It is the global test-function version of the no-scale condition: no displayed test row may extract negative energy from the zero ledger.

Principle 9265.4 (Weil positivity as the no-scale global target)**.** *The local no-scale route reads an off-half parameter as a radial defect*

$$e^{-(s-1/2)h} = e^{-rh}e^{-ith}.$$

Finite packets express this as a scale-energy row. The global Weil route expresses the same obstruction as a test-function positivity row: an off-half mirror pair would allow a test readout that separates the two mirror points and contributes a negative term to Definition 9265.2. Thus the thermodynamic no-demon condition and the explicit-formula positivity condition have a common target, namely GlobalWeilPositivity*.*

Definition 9265.5 (Finite Weil-positive container)**.** *A* finite Weil-positive container *is a pair*

$$(\mathcal{A}_N, \mathcal{W}_N)$$

where $\mathcal{A}_N \subseteq \mathcal{A}$ is a finite displayed test space and

$$\mathcal{W}_N : \mathcal{A}_N \to \mathbb{R}$$

is a positive semidefinite quadratic row:

$$\mathcal{W}_N(f) \geq 0 \qquad (f \in \mathcal{A}_N).$$

The container is source-side when $\mathcal{A}_N$ and $\mathcal{W}_N$ are generated before any zero island is selected and carry no unledgered $\mathbb{R}_{>0}$ scale coordinate.

Definition 9265.6 (Cofinal Weil-positive container tower)**.** *The source row*

CofinalWeilPositiveContainerTower

asserts the existence of finite Weil-positive containers

$$(\mathcal{A}_N, \mathcal{W}_N)_{N\geq 1}$$

with the following rows.

The nesting row is

$$\mathcal{A}_N \subseteq \mathcal{A}_{N+1}.$$

The cofinality row says that

$$\bigcup_N \mathcal{A}_N$$

is dense in the test space used by Definition 9265.2. The compatibility row says that the restrictions of later quadratic forms to earlier test spaces agree with earlier forms up to a displayed error ledger tending to zero. The limit row says that for every test function f and every admissible cofinal approximation $f_N \in \mathcal{A}_N$ with $f_N \to f$,

$$\mathcal{W}_N(f_N) \to \mathcal{W}(f).$$

Theorem 9265.7 (Cofinal Weil-positive tower gives global positivity)**.** *If* CofinalWeilPositiveContainerTower *holds, then* GlobalWeilPositivity *holds.*

Proof. Let $f \in \mathcal{A}$. By cofinality choose admissible $f_N \in \mathcal{A}_N$ with $f_N \to f$. Finite positivity gives

$$\mathcal{W}_N(f_N) \geq 0$$

for every N. The limit row gives

$$\mathcal{W}_N(f_N) \to \mathcal{W}(f).$$

The limit of nonnegative real numbers is nonnegative, so

$$\mathcal{W}(f) \geq 0.$$

Since f was arbitrary, GlobalWeilPositivity holds. □

Definition 9265.8 (Weil criterion consumption row)**.** *The source row*

WeilCriterionConsumesGlobalPositivity

is the classical criterion that consumes GlobalWeilPositivity *and returns the fixed-half zero ledger for the completed zeta function. In this vision it is treated as a named bridge row, separate from the construction of the finite positive tower.*

Theorem 9265.9 (Finite Weil-positive tower gives fixed-half readout)**.** *Assume* CofinalWeilPositiveContainerTower *and* WeilCriterionConsumesGlobalPositivity*. Then the completed zeta zero ledger has fixed-half readout.*

Proof. By Definition 9265.7, the tower gives GlobalWeilPositivity. The consumption row then returns the fixed-half zero ledger. □

Principle 9265.10 (Finite container routes as Weil-tower candidates)**.** *The Lee–Yang, Jensen, golden-ruler, squarefree-prime, and quartic endpoint routes are best read as candidate constructions of the finite rows in Definition 9265.6. A Lee–Yang packet supplies finite nonvanishing and stability; a Jensen section supplies finite hyperbolicity; a golden ruler supplies source-side cofinal refinement; a squarefree prime packet supplies arithmetic ledgering; and a quartic endpoint model supplies a finite dominance and Rouché laboratory. None of these finite rows is by itself the global argument. The global argument is the cofinal passage from finite positivity to* GlobalWeilPositivity*.*

Definition 9265.11 (Scale-closure to Weil positivity row)**.** *The source row*

ZetaUnitaryScaleClosureToWeilPositivity

asserts that the bounded-energy, no-unledgered-scale, and cofinal-growth rows of the zeta unitary scale route assemble into finite Weil-positive containers compatible with Definition 9265.2. It is the bridge from local radial-defect exclusion to the global positivity row.

Principle 9265.12 (Final non-local proof obligation)**.** *The non-local proof obligation is not to build a stable packet around a candidate zero. It is to construct a source-side cofinal tower of finite positive quadratic rows. In symbols, the active target is*

$$\mathsf{CofinalWeilPositiveContainerTower} \Longrightarrow \mathsf{GlobalWeilPositivity} \Longrightarrow \textit{fixed-half zero readout.}$$

The first implication is the finite-container reduction proved in this chapter; the second is delegated to the Weil criterion consumption row.

Definition 9265.13 (Offline mirror pair)**.** *An* offline mirror pair *in the completed zeta zero ledger is a pair*

$$\rho_+ = \frac{1}{2} + r + i\gamma, \qquad \rho_- = \frac{1}{2} - r + i\gamma,$$

with $r \neq 0$, related by

$$\rho_- = 1 - \overline{\rho_+}.$$

It is the zero-side expression of a radial scale split: the two points have the same phase height and opposite real scale directions.

Definition 9265.14 (Diagonal negative probe)**.** *A* diagonal negative probe *for an offline mirror pair is a test row $f \in \mathcal{A}$ whose Mellin readout separates the pair by opposite signs,*

$$\widehat{f}(\rho_+) = 1, \qquad \widehat{f}(\rho_-) = -1,$$

while all remaining zero-side contributions are controlled by the regularized tail ledger of Definition 9265.2. The row is diagonal because it reads precisely the mirror coordinate that a local scale selector would try to hide.

Principle 9265.15 (Offline mirror pairs create negative Weil directions)**.** *If an offline mirror pair admits a diagonal negative probe, then the pair contributes*

$$\widehat{f}(\rho_+)\overline{\widehat{f}(\rho_-)} + \widehat{f}(\rho_-)\overline{\widehat{f}(\rho_+)} = -2$$

to the zero-side Weil pairing. With the remaining zero contributions made smaller by the displayed tail ledger, this gives a negative direction for $\mathcal{W}$. Hence an off-half mirror pair is not merely a local radial defect; it is a global obstruction to GlobalWeilPositivity*.*

Definition 9265.16 (No diagonal negative probe)**.** *The row*

NoDiagonalNegativeProbe

asserts that the Weil quadratic form has no diagonal negative direction: there is no test row $f \in \mathcal{A}$ with

$$\mathcal{W}(f) < 0.$$

Thus NoDiagonalNegativeProbe *is the same positivity surface as* GlobalWeilPositivity*, but with emphasis on the diagonal obstruction created by an offline mirror pair.*

Principle 9265.17 (Halting boundary forbids universal local closure tests)**.** *Definition 9336.11 and Definition 9336.13 rule out a universal classifier deciding closure of all sufficiently expressive theorem routes. The RH zero route must therefore not be framed as a global local decider that inspects every zero box and declares it legal or illegal. Such a decider would be a theorem-route closure oracle at the certificate stratum. The diagonal-safe alternative is a source-side positive tower: each finite container is positive by construction, and the global no-negative-probe row is read only after cofinal passage.*

Definition 9265.18 (Diagonal-safe Weil tower)**.** *A cofinal Weil-positive container tower is* diagonal-safe *when each finite positivity row is supplied by internal structure, for example by a displayed factorization*

$$\mathcal{W}_N(f) = \|T_N f\|^2$$

or by a positive kernel row

$$\mathcal{W}_N(f) = \langle K_N f, f\rangle, \qquad K_N \geq 0,$$

and not by a procedure that searches for future negative probes and repairs the container after they are found. The corresponding source row is

$$\mathsf{DiagonalSafeWeilTower}.$$

Theorem 9265.19 (Diagonal-safe tower gives global positivity)**.** *If* DiagonalSafeWeilTower *holds, then* GlobalWeilPositivity *holds.*

Proof. A diagonal-safe tower is, in particular, a cofinal Weil-positive container tower. Apply Definition 9265.7. □

Principle 9265.20 (Diagonal-safe final target)**.** *The diagonal role of the halting boundary is negative and structural: it forbids a universal local legality decider. The diagonal role of the Weil form is positive and global: any off-half mirror pair would expose a negative probe. The compatible proof target is therefore*

$$\mathsf{DiagonalSafeWeilTower} \Longrightarrow \mathsf{GlobalWeilPositivity} \Longrightarrow \textit{fixed-half zero readout.}$$

This target is source-side and non-local. It asks for a cofinal family of internally positive finite containers rather than a decision procedure over all zero boxes.

Definition 9265.21 (Li–Weil coefficient row)**.** *Let $\xi(s)$ be the completed zeta function used by the zero ledger. The n-th Li–Weil coefficient is the source-side scalar*

$$\lambda_n := \frac{1}{(n-1)!}\,\frac{d^n}{ds^n}\left[s^{n-1}\log\xi(s)\right]\Big|_{s=1}.$$

Equivalently, when read through the regularized zero ledger,

$$\lambda_n = \sum_{\rho}\left[1-\left(1-\frac{1}{\rho}\right)^n\right].$$

Definition 9265.22 (Li–Weil finite negative witness)**.** *A* Li–Weil finite negative witness *is a positive integer n with*

$$\lambda_n < 0.$$

The row is finite: it is indexed by one displayed natural number rather than by an open-ended search through certificate towers.

Definition 9265.23 (Global Li–Weil positivity)**.** *The source row*

$$\mathsf{GlobalLiWeilPositivity}$$

asserts that

$$\lambda_n \geq 0 \qquad (n \geq 1).$$

Definition 9265.24 (Li criterion consumption row)**.** *The source row*

$$\mathsf{LiCriterionConsumesGlobalLiPositivity}$$

is the classical bridge consuming GlobalLiWeilPositivity *and returning fixed-half zero readout. It is used here as a criterion row, not as a construction of the coefficients' positivity.*

Principle 9265.25 (Li–Weil reduction gives finite bad witnesses)**.** *The Li–Weil row gives a concrete form of the diagonal negative-probe principle. If the fixed-half zero readout fails, then the Li criterion consumption row presents a finite negative witness*

$$\exists n \geq 1, \qquad \lambda_n < 0.$$

Thus an off-half defect is not allowed to remain an indefinitely delayed failure of an infinite tower: it must project to a finite Li–Weil coefficient. This is the finite-witness refinement of Definition 9265.16.

Definition 9265.26 (Source-side Li positivity certificate)**.** *A source-side positivity certificate for λ_n consists of internally generated data, such as a Hilbert space row and vector*

$$(\mathcal{H}_n, \Psi_n),$$

with

$$\lambda_n = \|\Psi_n\|^2_{\mathcal{H}_n},$$

or a finite positive-kernel decomposition whose displayed cancellation ledger leaves a nonnegative remainder. The certificate must be generated from the prime, phase, solenoid, golden, Lee–Yang, or explicit-formula source rows; it may not be obtained by searching for negative witnesses and repairing them afterward.

Definition 9265.27 (Source global Li positivity)**.** *The source row*

$$\mathsf{SourceGlobalLiPositivity}$$

asserts that every λ_n has a source-side positivity certificate in the sense of Definition 9265.26.

Theorem 9265.28 (Source Li positivity gives fixed-half readout)**.** *Assume* SourceGlobalLiPositivity *and* LiCriterionConsumesGlobalLiPositivity*. Then the completed zeta zero ledger has fixed-half readout.*

Proof. The source-side certificates give $\lambda_n \geq 0$ for every n, hence GlobalLiWeilPositivity. The Li criterion consumption row then returns the fixed-half zero ledger. □

Definition 9265.29 (Golden Li positivity limit)**.** *The source row*

$$\mathsf{GoldenLiPositivityLimit}$$

asserts that there are source-side golden Lee–Yang containers C_m with finite Li coefficients

$$\lambda_{n,m} := \frac{1}{(n-1)!} \frac{d^n}{ds^n} \left[s^{n-1} \log C_m(s) \right] \Big|_{s=1}$$

such that $\lambda_{n,m} \geq 0$ for all n, m, and for each fixed n,

$$\lambda_{n,m} \to \lambda_n.$$

Theorem 9265.30 (Golden Li positivity limit gives global Li positivity)**.** *If* GoldenLiPositivityLimit *holds, then* GlobalLiWeilPositivity *holds.*

Proof. Fix $n \geq 1$. The finite rows give $\lambda_{n,m} \geq 0$ for every m. Taking the displayed limit in m gives $\lambda_n \geq 0$. Since n was arbitrary, GlobalLiWeilPositivity holds. □

Principle 9265.31 (Li route separates stability from convergence)**.** *The Li–Weil refinement separates the remaining analytic load into two source rows. The finite stability row requires the finite containers C_m to have fixed-half zero readout, which yields $\lambda_{n,m} \geq 0$ by the usual Li coefficient computation for critical-line zero multisets. The convergence row requires enough log-derivative convergence to pass*

$$\lambda_{n,m} \to \lambda_n$$

for every fixed n. In named form the open source obligations are

$$\mathsf{FiniteGoldenLeeYangStability} \qquad \textit{and} \qquad \mathsf{LogDerivativeConvergence}.$$

Chapter 9266

Li Time Negative Witness

Definition 9265.22 records the finite Li–Weil witness produced by the Li criterion consumption row. This chapter gives the geometric readout of that witness. The Li coordinate turns the fixed-half line into the unit circle; off-half displacement becomes radial scale, and the discrete Li time n amplifies that radial component into a finite negative-energy row.

Definition 9266.1 (Li time coordinate)**.** *For a nontrivial zero row ρ of the completed zeta function, define*

$$z(\rho) := 1 - \frac{1}{\rho} = \frac{\rho - 1}{\rho}.$$

Theorem 9266.2 (Li coordinate reads the fixed-half circle)**.** *For $\rho = \sigma + i\gamma$,*

$$|z(\rho)| = 1$$

if and only if

$$\sigma = \frac{1}{2}.$$

Proof. By definition,

$$|z(\rho)| = \left|\frac{\rho - 1}{\rho}\right| = \frac{|\rho - 1|}{|\rho|}.$$

Thus $|z(\rho)| = 1$ exactly when $|\rho - 1| = |\rho|$. Squaring gives

$$(\sigma - 1)^2 + \gamma^2 = \sigma^2 + \gamma^2,$$

hence $\sigma = 1/2$. □

Definition 9266.3 (Li discrete time energy)**.** *For a finite reflected zero ledger Z, the nth Li time energy is*

$$\lambda_n^Z := \sum_{\rho \in Z} \left(1 - z(\rho)^n\right), \qquad n \geq 1.$$

The completed zeta Li–Weil row of Definition 9265.21 is the regularized infinite version of the same readout.

Theorem 9266.4 (Fixed-line pairs have nonnegative Li time energy)**.** *Let Z be a finite conjugation-stable zero multiset on the fixed line. Then*

$$\lambda_n^Z \geq 0 \qquad (n \geq 1).$$

Proof. By Definition 9266.2, each zero row has $z(\rho) = e^{i\theta_\rho}$. A conjugate pair contributes

$$\left(1 - e^{in\theta_\rho}\right) + \left(1 - e^{-in\theta_\rho}\right) = 2 - 2\cos(n\theta_\rho) \geq 0.$$

Summing over the finite conjugate pairs gives the claim. □

Definition 9266.5 (Radial Li pair)**.** *A radial Li pair is a reflected pair of zero rows whose Li coordinates are*

$$z, \qquad \frac{1}{\overline{z}},$$

with $|z| \neq 1$. Equivalently, one member of the pair lies inside the unit circle and the other lies outside it.

Principle 9266.6 (Radial Li time amplification)**.** *For a radial Li pair, some discrete time n detects the radial scale. Indeed, if the outside coordinate is $z_* = Re^{i\theta}$ with $R > 1$, then along a subsequence of n the real part of $e^{in\theta}$ stays positive. The term z_*^n then has real part of order R^n, so the contribution of $1 - z_*^n$ eventually gives a negative finite Li direction unless an equally large source row is displayed. The Li criterion consumption row packages this amplification as the finite negative witness of Definition 9265.22.*

Definition 9266.7 (Li time positive tower)**.** *The source row*

$$\mathsf{LiTimePositiveTower}$$

is GlobalLiWeilPositivity *read as a discrete-time energy tower:*

$$\lambda_n \geq 0 \qquad (n \geq 1).$$

Definition 9266.8 (Li coefficient square representation)**.** *The source row*

$$\mathsf{LiCoefficientSquareRepresentation}$$

asserts that every Li–Weil coefficient has a source-side nonnegative presentation, either as a finite Hilbert square

$$\lambda_n = \|T_n\|^2_{\mathcal{H}_n}$$

or as a displayed limit of such squares

$$\lambda_n = \lim_m \|T_{n,m}\|^2_{\mathcal{H}_{n,m}}.$$

Theorem 9266.9 (Li coefficient squares give the Li time tower)**.** *If* LiCoefficientSquareRepresentation *holds, then*

$$\mathsf{LiTimePositiveTower}$$

holds.

Proof. Each displayed square is nonnegative, and a displayed limit of nonnegative real rows is nonnegative. Hence $\lambda_n \geq 0$ for every $n \geq 1$, which is LiTimePositiveTower. □

Corollary 9266.10 (Li coefficient squares give fixed-half readout)**.** *Assume* LiCoefficientSquareRepresentation *and*

$$\mathsf{LiCriterionConsumesGlobalLiPositivity}.$$

Then the completed zeta zero ledger has fixed-half readout.

Proof. Definition 9266.9 gives GlobalLiWeilPositivity. The Li criterion consumption row then returns fixed-half readout. □

Principle 9266.11 (Li time no-scale target)**.** *The Li time coordinate is the finite witness version of the no-scale principle. Unit Li coordinates give phase iteration on S^1; radial Li pairs carry nonunit scale, and discrete time powers expose that scale as a finite negative Li witness. In named form the non-circular source target is*

$$\mathsf{LiCoefficientSquareRepresentation} \Longrightarrow \mathsf{LiTimePositiveTower} \Longrightarrow \textit{fixed-half zero readout.}$$

Chapter 9267

Balanced Golden Li Closure

chapter 9265 records the Li–Weil coefficient row and the golden Li positivity limit. The Lee–Yang input required for that limit is not merely a finite zero-location statement. A finite container may have all displayed zeros on the fixed line while its logarithmic derivative still carries an unledgered exponential drift. The Li–Weil route therefore requires a balanced source container: the critical-line divisor, the real structure, and the exponential normalization must be licensed by the same source data.

Definition 9267.1 (Raw critical-line exponential packet)**.** *For $h > 0$ set*

$$C_h(s) := 1 + e^{-h(s-1/2)}.$$

Its zeros satisfy

$$e^{-h(s-1/2)} = -1,$$

hence

$$s = \frac{1}{2} + \frac{(2k+1)\pi i}{h} \qquad (k \in \mathbb{Z}).$$

Thus the zero divisor of C_h lies on the fixed line.

Lemma 9267.2 (Critical-line zeros do not force raw Li positivity)**.** *The packet C_h of Definition 9267.1 has fixed-line zeros, but its raw first logarithmic derivative at $s = 1$ is negative:*

$$\frac{d}{ds} \log C_h(s)\Big|_{s=1} = \frac{-he^{-h/2}}{1 + e^{-h/2}} < 0.$$

Proof. The zero computation is part of Definition 9267.1. Differentiating gives

$$C_h'(s) = -he^{-h(s-1/2)}.$$

Therefore

$$\frac{d}{ds} \log C_h(s)\Big|_{s=1} = \frac{C_h'(1)}{C_h(1)} = \frac{-he^{-h/2}}{1 + e^{-h/2}},$$

which is strictly negative. □

Definition 9267.3 (Balanced elementary packet)**.** *The balanced normalization of C_h is*

$$B_h(s) := e^{h(s-1/2)/2} C_h(s) = e^{h(s-1/2)/2} + e^{-h(s-1/2)/2}.$$

Equivalently,

$$B_h(s) = 2\cosh\left(\frac{h(s-1/2)}{2}\right).$$

Writing $w = s - 1/2$, it satisfies the self-dual balance row

$$B_h\left(\frac{1}{2}+w\right) = B_h\left(\frac{1}{2}-w\right).$$

Definition 9267.4 (Balanced Lee–Yang source container)**.** *A finite entire container $C(s)$ is a balanced Lee–Yang source container when it satisfies the following rows.*

The real row is

$$C(\overline{s}) = \overline{C(s)}.$$

The fixed-line divisor row is

$$C(\rho) = 0 \Longrightarrow \mathrm{Re}(\rho) = \frac{1}{2}.$$

The balance row says that, after the source-determined exponential normalization has been applied,

$$C\left(\frac{1}{2}+w\right) = C\left(\frac{1}{2}-w\right)$$

as an identity in w. The no-free-exponential row says that the canonical product for C contains no independent factor

$$e^{a(s-1/2)}$$

whose coefficient a is chosen outside the source ledger. The source row says that all divisor, height, and normalization data are generated before any zero box is selected.

Definition 9267.5 (Finite balanced Li coefficient)**.** *Let F be a finite balanced container with $F(1) \neq 0$ and finite zero multiset Z_F. Its finite Li coefficient is read from the balanced canonical product by*

$$\lambda_n(F) := \sum_{\rho \in Z_F} \left[1 - \left(1 - \frac{1}{\rho}\right)^n\right] \qquad (n \geq 1).$$

The definition is tied to the no-free-exponential row of Definition 9267.4; adding an independent exponential factor would add logarithmic derivative terms not represented by the displayed divisor sum.

Theorem 9267.6 (Finite balanced critical-line divisors give Li positivity)**.** *Let F be a finite balanced container. If Z_F lies on the fixed line and is closed under complex conjugation, then*

$$\lambda_n(F) \geq 0 \qquad (n \geq 1).$$

Proof. Let

$$\rho = \frac{1}{2} + i\gamma \qquad \text{and} \qquad \overline{\rho} = \frac{1}{2} - i\gamma$$

be a conjugate pair in Z_F. Then

$$1 - \frac{1}{\rho} = \frac{\rho - 1}{\rho} = \frac{-1/2 + i\gamma}{1/2 + i\gamma}.$$

The numerator and denominator have the same absolute value, so there is some real θ with

$$1 - \frac{1}{\rho} = e^{i\theta}.$$

The conjugate zero gives

$$1 - \frac{1}{\bar{\rho}} = e^{-i\theta}.$$

The pair contribution to $\lambda_n(F)$ is therefore

$$\left[1 - e^{in\theta}\right] + \left[1 - e^{-in\theta}\right] = 2\left(1 - \cos(n\theta)\right) \geq 0.$$

Summing over the conjugate pairs gives the claim. □

Definition 9267.7 (Balanced golden normalization row)**.** *Let $L_m(u)$ be a finite Fibonacci or golden Lee–Yang seed and let*

$$\mathcal{Z}_m^{\mathrm{pol}}(z_1, \ldots, z_{D_m})$$

be its polarized container. Given source heights

$$h_{m,1}, \ldots, h_{m,D_m} > 0,$$

the raw zeta-mode substitution is

$$C_m^{\mathrm{raw}}(s) := \mathcal{Z}_m^{\mathrm{pol}}\left(e^{-(s-1/2)h_{m,1}}, \ldots, e^{-(s-1/2)h_{m,D_m}}\right).$$

A balanced golden normalization is a source-determined real number A_m such that

$$C_m(s) := e^{A_m(s-1/2)} C_m^{\mathrm{raw}}(s)$$

is a balanced Lee–Yang source container. The row is source-determined only when A_m is forced by the displayed degree, height, reciprocity, or self-duality ledger of the container.

Definition 9267.8 (Balanced golden construction)**.** *The source row*

BalancedGoldenConstruction

asserts that the golden polarized Lee–Yang containers of Definition 9267.7 admit balanced normalizations C_m whose divisor rows remain fixed-line, whose real rows remain conjugation-stable, and whose no-free-exponential rows are licensed by source data rather than by zero-specific choice.

Definition 9267.9 (Log-derivative convergence)**.** *The source row*

LogDerivativeConvergence

asserts that for each fixed $n \geq 1$ the balanced finite containers C_m satisfy

$$\frac{1}{(n-1)!} \frac{d^n}{ds^n} \left[s^{n-1} \log C_m(s)\right]\Big|_{s=1} \longrightarrow \frac{1}{(n-1)!} \frac{d^n}{ds^n} \left[s^{n-1} \log \xi(s)\right]\Big|_{s=1}.$$

In the notation of Definition 9265.21, this is the row

$$\lambda_n(C_m) \to \lambda_n.$$

Theorem 9267.10 (A local analytic condition gives log-derivative convergence)**.** *Let D be a closed disk centered at $s = 1$ with interior containing $s = 1$. Assume ξ is nonzero on D, the sequence C_m converges uniformly to ξ on D, the functions C_m are nonzero on D for all sufficiently large m, and the logarithm branches are normalized so that*

$$\log C_m(1) \to \log \xi(1).$$

Then LogDerivativeConvergence *holds for every fixed order whose Cauchy circle lies in the interior of D.*

Proof. Since ξ is nonzero on D, there is a holomorphic branch of $\log \xi$ in a neighborhood of D. Uniform convergence and the nonvanishing assumption give compatible holomorphic branches $\log C_m$ on the same neighborhood for all sufficiently large m. The normalization at $s = 1$ fixes the additive constants, so

$$\log C_m \to \log \xi$$

uniformly on smaller disks. Cauchy's integral formula then gives convergence of every fixed derivative of $\log C_m$ at $s = 1$. Since $\lambda_n(C_m)$ is a finite linear combination of derivatives of $\log C_m$ up to order n, the displayed Li–Weil coefficients converge. □

Definition 9267.11 (Balanced golden Lee–Yang Li closure)**.** *The source row*

BalancedGoldenLeeYangLiClosure

asserts the existence of balanced golden Lee–Yang containers C_m such that:

- *each C_m is supplied by* BalancedGoldenConstruction*;*
- *each finite divisor is fixed-line and conjugation-stable;*
- *the finite coefficients $\lambda_n(C_m)$ are read through the balanced product row of Definition 9267.5;*
- LogDerivativeConvergence *holds for the sequence (C_m).*

Theorem 9267.12 (Balanced golden closure gives global Li positivity)**.** *If* BalancedGoldenLeeYangLiClosure *holds, then*

GlobalLiWeilPositivity

holds.

Proof. Fix $n \geq 1$. By the fixed-line and conjugation-stable divisor rows, Definition 9267.6 gives

$$\lambda_n(C_m) \geq 0$$

for every m. By Definition 9267.9,

$$\lambda_n(C_m) \to \lambda_n.$$

The limit of nonnegative real numbers is nonnegative, hence

$$\lambda_n \geq 0.$$

Since n was arbitrary, GlobalLiWeilPositivity holds. □

Corollary 9267.13 (Balanced golden closure gives fixed-half readout)**.** *Assume* BalancedGoldenLeeYangLiClosure *and*

LiCriterionConsumesGlobalLiPositivity.

Then the completed zeta zero ledger has fixed-half readout.

Proof. Definition 9267.12 gives GlobalLiWeilPositivity. The Li criterion consumption row then returns the fixed-half zero ledger. □

Principle 9267.14 (Balanced Li closure target)**.** *The finite Lee–Yang condition required by the Li–Weil route is a balanced condition. Fixed-line zero location supplies the divisor part; the real row supplies conjugate pairing; the no-free-exponential row prevents logarithmic derivative drift; and local analytic convergence transfers finite positivity to the completed zeta coefficient row. In source-row form the target is*

BalancedGoldenConstruction *with* LogDerivativeConvergence,

which is the balanced realization of Definition 9265.29.

Chapter 9268

Balanced Polarized Lee–Yang CND

chapter 9262 supplies the polarized Lee–Yang container row, and chapter 9267 records the balanced normalization row. This chapter inserts the finite source implication between them and chapter 9269: balanced polarized Lee–Yang containers have fixed-line divisors and therefore supply Li conditional negative definiteness.

Definition 9268.1 (Self-inversive polarized packet)**.** *Let*

$$\mathcal{Z}(z_1, \dots, z_D)$$

be a multi-affine polarized Lee–Yang packet. It is self-inversive after phase normalization when

$$\mathcal{Z}(z_1, \dots, z_D) = \left(\prod_{j=1}^{D} z_j \right) \mathcal{Z}(z_1^{-1}, \dots, z_D^{-1}).$$

The phase normalization is part of the source ledger; it is not a zero-specific adjustment.

Definition 9268.2 (Balanced polarized readback)**.** *Let $h_1, \dots, h_D > 0$ be source heights and write*

$$H := \sum_{j=1}^{D} h_j.$$

For the logarithmic central variable $w = s - 1/2$, the raw readback is

$$C^{\mathrm{raw}}(w) := \mathcal{Z}(e^{-wh_1}, \dots, e^{-wh_D}).$$

The balanced readback is

$$C(w) := e^{Hw/2} C^{\mathrm{raw}}(w).$$

Theorem 9268.3 (Self-inversive packets have canonical balance)**.** *If $\mathcal{Z}$ is self-inversive in the sense of Definition 9268.1, then the balanced readback of Definition 9268.2 satisfies*

$$C(w) = C(-w).$$

Proof. Substitute $z_j = e^{-wh_j}$ into the self-inversive identity. Since

$$\prod_{j=1}^{D} e^{-wh_j} = e^{-wH},$$

one gets

$$\mathcal{Z}(e^{-wh_1}, \dots, e^{-wh_D}) = e^{-wH}\mathcal{Z}(e^{wh_1}, \dots, e^{wh_D}).$$

Multiplying by $e^{Hw/2}$ gives

$$C(w) = e^{-Hw/2}\mathcal{Z}(e^{wh_1}, \dots, e^{wh_D}).$$

The right side is exactly $C(-w)$. □

Theorem 9268.4 (Polarized Lee–Yang readback has fixed-line divisor)**.** *Assume $\mathcal{Z}$ has the Lee–Yang nonvanishing ledger of Definition 9262.17. Then every zero of the balanced readback $C(w)$ lies on*

$$\mathrm{Re}(w) = 0.$$

Proof. The exponential factor $e^{Hw/2}$ has no zeros, so $C(w) = 0$ is equivalent to

$$\mathcal{Z}(e^{-wh_1}, \dots, e^{-wh_D}) = 0.$$

If $\mathrm{Re}(w) > 0$, then

$$|e^{-wh_j}| = e^{-\mathrm{Re}(w)h_j} < 1$$

for every j, contradicting the inner Lee–Yang nonvanishing row. If $\mathrm{Re}(w) < 0$, then every $|e^{-wh_j}| > 1$, contradicting the outer Lee–Yang nonvanishing row. Thus every zero has $\mathrm{Re}(w) = 0$. □

Definition 9268.5 (Balanced polarized Lee–Yang CND packet)**.** *A balanced polarized Lee–Yang CND packet consists of:*

- *a polarized Lee–Yang packet $\mathcal{Z}$ with the nonvanishing ledger of Definition 9262.17;*
- *source heights $h_1, \dots, h_D > 0$;*
- *the self-inversive balance row of Definition 9268.1;*
- *the balanced readback $C(w)$ of Definition 9268.2;*
- *the real structure needed to pair conjugate fixed-line zeros.*

Theorem 9268.6 (Balanced polarized packets give finite Li CND)**.** *Every balanced polarized Lee–Yang CND packet supplies a finite Li kernel that is conditionally negative definite.*

Proof. By Definition 9268.4, the zeros of the balanced readback lie on $\mathrm{Re}(w) = 0$, hence the corresponding s-zeros lie on $\mathrm{Re}(s) = 1/2$. The real structure pairs them by conjugation. Therefore the zero multiset is a finite conjugation-stable fixed-line divisor. Apply Definition 9269.6. □

Definition 9268.7 (Source balanced golden approximation)**.** *The source row*

$$\mathsf{SourceBalancedGoldenApproximation}$$

asserts that the completed zeta function is approximated near $s = 1$ by balanced polarized golden Lee–Yang CND packets

$$C_m(s) = e^{A_m(s-1/2)}\mathcal{Z}_m^{\mathrm{pol}}\left(e^{-(s-1/2)h_{m,1}}, \dots, e^{-(s-1/2)h_{m,D_m}}\right),$$

where A_m is forced by the self-inversive height ledger and the approximation is source-side, not selected from the zero locations of ξ.

Theorem 9268.8 (Source approximation gives Li CND convergence under local analytic control)**.** *Assume* SourceBalancedGoldenApproximation *and the local analytic hypotheses of Definition 9267.10 for the approximating packets C_m. Then*

$$\mathsf{LiCNDConvergence}$$

holds.

Proof. The local analytic theorem gives convergence of every fixed Li coefficient:

$$\lambda_n(C_m) \to \lambda_n.$$

For each finite kernel matrix only finitely many differences $i - j$ are used, so the same fixed-coefficient convergence gives entrywise convergence of that matrix. This is precisely LiCNDConvergence. □

Corollary 9268.9 (Balanced polarized source approximation gives fixed-half readout)**.** *Assume* SourceBalancedGoldenApproximation*, the local analytic control row of Definition 9268.8, and*

$$\mathsf{LiCriterionConsumesGlobalLiPositivity}.$$

Then the completed zeta zero ledger has fixed-half readout.

Proof. Each balanced polarized packet gives a finite Li CND kernel by Definition 9268.6. The source approximation and local analytic control give LiCNDConvergence. Thus Definition 9269.9 gives LiCND, and Definition 9269.4 gives the fixed-half readout. □

Definition 9268.10 (Balanced Lee–Yang kernel closure)**.** *Let Φ denote the even Fourier–Laplace kernel whose transform reads the completed zeta function on the central line variable. The source row*

$$\mathsf{BalancedLeeYangKernelClosure}$$

asserts that Φ is the limit, in a topology strong enough to imply the local analytic control above, of discrete even source kernels whose Laplace transforms are balanced polarized Lee–Yang CND packets.

Principle 9268.11 (Kernel closure is the CND convergence load)**.** *The finite balanced polarized Lee–Yang construction supplies Li CND without further zero-side input. The analytic load is the convergence row: the source kernels must approximate the Riemann kernel strongly enough to pass logarithmic derivatives at $s = 1$. In named form the target is*

$$\mathsf{BalancedLeeYangKernelClosure} \Longrightarrow \mathsf{LiCNDConvergence} \Longrightarrow \mathsf{LiCND} \Longrightarrow \textit{fixed-half zero readout.}$$

Chapter 9269

Balanced Golden Li CND Closure

chapter 9267 records the balanced Lee–Yang route to pointwise Li positivity. The same source rows carry a stronger structure: the Li coefficients form a conditionally negative definite kernel on the integer ledger. This chapter records that kernel form. The advantage is that the finite input is a single quadratic negative-type statement rather than a list of separate coefficient inequalities.

Definition 9269.1 (Two-sided Li kernel row)**.** *Let $(\lambda_n)_{n\geq 1}$ be the Li–Weil coefficients of Definition 9265.21. Set*

$$\lambda_0 := 0$$

and extend the sequence to $\mathbb{Z}$ by

$$\lambda_{-n} := \lambda_n \qquad (n \geq 1).$$

The associated two-sided Li kernel is

$$K_\lambda(i,j) := \lambda_{i-j} \qquad (i,j \in \mathbb{Z}).$$

Definition 9269.2 (Li conditional negative definiteness)**.** *The source row*

$$\mathsf{LiCND}$$

asserts that the two-sided Li kernel of Definition 9269.1 is conditionally negative definite: for every finite coefficient family

$$c_1, \ldots, c_N \in \mathbb{C}$$

with

$$\sum_{i=1}^{N} c_i = 0,$$

one has

$$\sum_{i,j=1}^{N} c_i \overline{c_j} \lambda_{i-j} \leq 0.$$

Theorem 9269.3 (Li CND gives pointwise Li positivity)**.** *If* LiCND *holds, then*

$$\lambda_n \geq 0 \qquad (n \geq 1).$$

Proof. Fix $n \geq 1$ and use the two-point zero-sum family

$$c_0 = 1, \qquad c_n = -1.$$

The conditional negative definiteness inequality gives

$$\lambda_0 - \lambda_{-n} - \lambda_n + \lambda_0 \leq 0.$$

Since $\lambda_0 = 0$ and $\lambda_{-n} = \lambda_n$, this becomes

$$-2\lambda_n \leq 0.$$

Hence $\lambda_n \geq 0$. □

Corollary 9269.4 (Li CND gives fixed-half readout)**.** *Assume* LiCND *and*

LiCriterionConsumesGlobalLiPositivity.

Then the completed zeta zero ledger has fixed-half readout.

Proof. By Definition 9269.3, $\lambda_n \geq 0$ for every $n \geq 1$. This is GlobalLiWeilPositivity. The Li criterion consumption row then returns fixed-half readout. □

Definition 9269.5 (Finite balanced Li CND sequence)**.** *Let Z be a finite conjugation-stable zero multiset on the fixed line. For each $\rho \in Z$ define*

$$\alpha_\rho := 1 - \frac{1}{\rho}.$$

The finite balanced Li sequence attached to Z is

$$\lambda_n^Z := \sum_{\rho \in Z} \left(1 - \alpha_\rho^n\right) \qquad (n \geq 1),$$

with

$$\lambda_0^Z := 0, \qquad \lambda_{-n}^Z := \lambda_n^Z.$$

Theorem 9269.6 (Balanced critical divisors give Li CND)**.** *Let Z be a finite conjugation-stable zero multiset on the fixed line. Then the sequence $(\lambda_n^Z)_{n \in \mathbb{Z}}$ of Definition 9269.5 is conditionally negative definite.*

Proof. For

$$\rho = \frac{1}{2} + i\gamma$$

one has

$$\left|1 - \frac{1}{\rho}\right| = \left|\frac{\rho - 1}{\rho}\right| = 1.$$

Thus every conjugate pair contributes phases

$$\alpha = e^{i\theta}, \qquad \overline{\alpha} = e^{-i\theta}.$$

The pair contribution to λ_n^Z is

$$2 - e^{in\theta} - e^{-in\theta} = 2(1 - \cos(n\theta)).$$

Hence there is a positive finite measure μ_Z on the circle such that

$$\lambda_n^Z = \int_{\mathbb{T}} (1 - \cos(n\theta))\, d\mu_Z(\theta).$$

Let $c_1, \ldots, c_N$ be a finite zero-sum family. Then

$$\sum_{i,j} c_i \overline{c_j} \lambda_{i-j}^Z = \int_{\mathbb{T}} \sum_{i,j} c_i \overline{c_j}\, (1 - \cos((i-j)\theta))\, d\mu_Z(\theta).$$

The constant part vanishes because

$$\sum_{i,j} c_i \overline{c_j} = \left| \sum_i c_i \right|^2 = 0.$$

The remaining part is

$$-\int_{\mathbb{T}} \mathrm{Re}\left(\sum_{i,j} c_i \overline{c_j} e^{i(i-j)\theta} \right) d\mu_Z(\theta).$$

But

$$\sum_{i,j} c_i \overline{c_j} e^{i(i-j)\theta} = \left| \sum_i c_i e^{ii\theta} \right|^2 \geq 0.$$

Therefore the displayed quadratic form is nonpositive. This is conditional negative definiteness. □

Corollary 9269.7 (Balanced finite containers give Li CND)**.** *Let C be a balanced Lee–Yang source container whose finite zero multiset is fixed-line and conjugation-stable. Then the finite Li sequence of C is conditionally negative definite.*

Proof. The zero multiset of C is a finite conjugation-stable fixed-line divisor. Apply Definition 9269.6. □

Definition 9269.8 (Li CND convergence)**.** *Let C_m be balanced finite containers with finite Li sequences $(\lambda_n(C_m))_{n\in\mathbb{Z}}$. They satisfy*

$$\mathsf{LiCNDConvergence}$$

to the completed zeta Li kernel when for every fixed $n \in \mathbb{Z}$,

$$\lambda_n(C_m) \to \lambda_n,$$

or equivalently, for every finite matrix size, the kernel entries

$$\lambda_{i-j}(C_m)$$

converge entrywise to

$$\lambda_{i-j}.$$

Theorem 9269.9 (CND is closed under finite kernel limits)**.** *Assume each finite kernel $(\lambda_{i-j}(C_m))$ is conditionally negative definite and* LiCNDConvergence *holds. Then*

$$\mathsf{LiCND}$$

holds for the completed zeta Li kernel.

Proof. Let $c_1, \ldots, c_N$ be a finite zero-sum family. For each m, conditional negative definiteness gives

$$\sum_{i,j=1}^{N} c_i \overline{c_j} \lambda_{i-j}(C_m) \leq 0.$$

By entrywise convergence on this finite matrix,

$$\sum_{i,j=1}^{N} c_i \overline{c_j} \lambda_{i-j}(C_m) \longrightarrow \sum_{i,j=1}^{N} c_i \overline{c_j} \lambda_{i-j}.$$

The limit of nonpositive real numbers is nonpositive, so the completed zeta Li kernel is conditionally negative definite. □

Definition 9269.10 (Balanced golden Li CND closure)**.** *The source row*

BalancedGoldenLiCNDClosure

asserts the existence of balanced golden Lee–Yang containers C_m such that:

- *the containers are generated by* BalancedGoldenConstruction*;*
- *each finite zero multiset is fixed-line and conjugation-stable;*
- *each finite Li kernel is read through the balanced product row;*
- LiCNDConvergence *holds.*

Theorem 9269.11 (Balanced golden Li CND closure gives Li CND)**.** *If* BalancedGoldenLiCNDClosure *holds, then*

LiCND

holds.

Proof. By Definition 9269.7, each finite container supplies a conditionally negative definite Li kernel. The closure row supplies LiCNDConvergence. Apply Definition 9269.9. □

Corollary 9269.12 (Balanced golden Li CND closure gives fixed-half readout)**.** *Assume* BalancedGoldenLiCNDClos *and*

LiCriterionConsumesGlobalLiPositivity.

Then the completed zeta zero ledger has fixed-half readout.

Proof. Definition 9269.11 gives LiCND. Then Definition 9269.4 applies. □

Principle 9269.13 (CND closure as Li–Weil source positivity)**.** *The conditionally negative definite formulation strengthens pointwise Li positivity into a source-side kernel statement. Finite balanced Lee–Yang divisors give negative type on the integer ledger; finite kernel limits preserve negative type; and the two-point zero-sum test recovers the usual coefficient inequalities. Thus a source target is*

BalancedGoldenConstruction *with* LiCNDConvergence,

rather than a separate inspection of the individual coefficients.

Definition 9269.14 (Li second-difference kernel)**.** *For the two-sided Li kernel of Definition 9269.1, define*

$$\beta_n := \lambda_{n+1} + \lambda_{n-1} - 2\lambda_n \qquad (n \in \mathbb{Z}).$$

The source row

LiSecondDifferencePositiveDefinite

asserts that $(\beta_n)_{n\in\mathbb{Z}}$ *is a positive definite translation kernel on* $\mathbb{Z}$*: for every finite family*

$$a_1, \ldots, a_N \in \mathbb{C}, \qquad k_1, \ldots, k_N \in \mathbb{Z},$$

one has

$$\sum_{i,j=1}^{N} a_i \overline{a_j} \beta_{k_i - k_j} \geq 0.$$

Theorem 9269.15 (Second-difference positivity gives Li CND)**.** *If* LiSecondDifferencePositiveDefinite *holds, then*

LiCND

holds.

Proof. Let $(c_k)_{k\in\mathbb{Z}}$ be a finitely supported family with

$$\sum_k c_k = 0.$$

Choose a finitely supported antiderivative $(b_k)_{k\in\mathbb{Z}}$ with

$$c_k = b_k - b_{k-1}.$$

Such a b is obtained by cumulative summation across an interval containing the support of c; the zero-sum condition makes the cumulative row return to 0 outside that interval. Expanding gives

$$\sum_{r,s} c_r \overline{c_s} \lambda_{r-s} = \sum_{r,s} b_r \overline{b_s} \left(2\lambda_{r-s} - \lambda_{r-s+1} - \lambda_{r-s-1}\right).$$

By the definition of β,

$$2\lambda_{r-s} - \lambda_{r-s+1} - \lambda_{r-s-1} = -\beta_{r-s}.$$

Therefore

$$\sum_{r,s} c_r \overline{c_s} \lambda_{r-s} = -\sum_{r,s} b_r \overline{b_s} \beta_{r-s} \leq 0$$

by positive definiteness of the β kernel. This is precisely LiCND. □

Corollary 9269.16 (Second-difference positivity gives fixed-half readout)**.** *Assume* LiSecondDifferencePositiveDefin *and*

LiCriterionConsumesGlobalLiPositivity.

Then the completed zeta zero ledger has fixed-half readout.

Proof. Definition 9269.15 gives LiCND. Apply Definition 9269.4. □

Definition 9269.17 (Finite balanced beta kernel)**.** *For a finite balanced Li sequence* $(\lambda_n^Z)_{n\in\mathbb{Z}}$ *from Definition 9269.5, define*

$$\beta_n^Z := \lambda_{n+1}^Z + \lambda_{n-1}^Z - 2\lambda_n^Z.$$

Theorem 9269.18 (Balanced critical divisors give beta positivity)**.** *Let Z be a finite conjugation-stable zero multiset on the fixed line. Then $(\beta_n^Z)_{n\in\mathbb{Z}}$ is positive definite.*

Proof. The proof of Definition 9269.6 gives a positive finite measure μ_Z on the circle such that

$$\lambda_n^Z = \int_{\mathbb{T}} (1-\cos(n\theta))\, d\mu_Z(\theta).$$

Taking the second difference gives

$$\beta_n^Z = \int_{\mathbb{T}} 2(1-\cos\theta)\cos(n\theta)\, d\mu_Z(\theta).$$

Equivalently, β_n^Z is the nth Fourier coefficient of the positive finite measure

$$d\sigma_Z(\theta) := 2(1-\cos\theta)\, d\mu_Z(\theta).$$

Hence for every finite family (a_i, k_i),

$$\sum_{i,j} a_i\overline{a_j}\beta_{k_i-k_j}^Z = \int_{\mathbb{T}} \left|\sum_i a_i e^{ik_i\theta}\right|^2 d\sigma_Z(\theta) \geq 0.$$

□

Definition 9269.19 (Beta-kernel convergence)**.** *Balanced finite containers C_m satisfy*

$$\mathsf{BetaKernelConvergence}$$

when, for every fixed $n \in \mathbb{Z}$,

$$\beta_n(C_m) \to \beta_n.$$

Equivalently, every finite Toeplitz matrix

$$\Big(\beta_{k_i-k_j}(C_m)\Big)_{i,j}$$

converges entrywise to the corresponding completed zeta beta-kernel matrix.

Theorem 9269.20 (Positive beta kernels are closed under finite limits)**.** *Assume every finite beta kernel $\beta(C_m)$ is positive definite and that* BetaKernelConvergence *holds. Then*

$$\mathsf{LiSecondDifferencePositiveDefinite}$$

holds for the completed zeta Li sequence.

Proof. Fix a finite family (a_i, k_i). For each m,

$$\sum_{i,j} a_i\overline{a_j}\beta_{k_i-k_j}(C_m) \geq 0.$$

Entrywise convergence on this finite matrix gives

$$\sum_{i,j} a_i\overline{a_j}\beta_{k_i-k_j}(C_m) \longrightarrow \sum_{i,j} a_i\overline{a_j}\beta_{k_i-k_j}.$$

The limit of nonnegative real numbers is nonnegative, so the completed zeta beta kernel is positive definite. □

Definition 9269.21 (Balanced golden beta closure)**.** *The source row*

BalancedGoldenBetaClosure

asserts the existence of balanced golden Lee–Yang containers C_m such that:

- *the containers are generated by* BalancedGoldenConstruction*;*
- *each finite zero multiset is fixed-line and conjugation-stable;*
- *each finite beta kernel is read from the balanced product row;*
- BetaKernelConvergence *holds.*

Theorem 9269.22 (Balanced golden beta closure gives Li second-difference positivity)**.** *If* BalancedGoldenBetaClos *holds, then*

LiSecondDifferencePositiveDefinite

holds.

Proof. By Definition 9269.18, each finite container supplies a positive definite beta kernel. The closure row supplies BetaKernelConvergence. Apply Definition 9269.20. □

Corollary 9269.23 (Balanced golden beta closure gives fixed-half readout)**.** *Assume* BalancedGoldenBetaClosure *and*

LiCriterionConsumesGlobalLiPositivity.

Then the completed zeta zero ledger has fixed-half readout.

Proof. Definition 9269.22 gives LiSecondDifferencePositiveDefinite. Then Definition 9269.16 applies. □

Principle 9269.24 (Beta closure as Toeplitz Li–Weil positivity)**.** *The beta-kernel formulation replaces separate Li coefficient inspection by one Toeplitz positive-definiteness row. Finite balanced critical divisors supply this row as Fourier positivity of a positive circle measure; finite kernel limits preserve it; and the discrete antiderivative identity converts it into* LiCND*. Thus*

BalancedGoldenBetaClosure

is a sharper source-side target than entrywise Li positivity, while its fixed-half readout still passes through the displayed Li criterion consumption row.

Chapter 9270

Li–Weil Herglotz Target

chapter 9269 turns the Li–Weil route into the positive definiteness of the second-difference kernel β. This chapter records the same target as a positive-real log-derivative row. The purpose is not to claim the row; it is to name the Herglotz interface through which beta-kernel positivity, balanced Lee–Yang limits, and fixed-half readout can be compared.

Definition 9270.1 (Li beta Herglotz function)**.** *Let $(\beta_n)_{n\in\mathbb{Z}}$ be the Li second-difference kernel of Definition 9269.14. Its Herglotz readout is the holomorphic disk function*

$$H_\beta(z) := \beta_0 + 2\sum_{n\geq 1} \beta_n z^n$$

on every disk where the series is defined by the Li–Weil generating row.

Definition 9270.2 (Xi log-derivative Herglotz row)**.** *The source row*

$$\mathsf{XiLogDerivativeHerglotz}$$

asserts

$$\operatorname{Re}\frac{\xi'(s)}{\xi(s)} \geq 0 \qquad \left(\operatorname{Re}(s) > \frac{1}{2}\right).$$

It is a positive-real row for the logarithmic derivative of the completed zeta function on the open half-plane to the right of the fixed line.

Theorem 9270.3 (Li beta readout is the xi log-derivative readout)**.** *With*

$$s = \frac{1}{1-z},$$

one has the formal identity

$$H_\beta(z) = 2\frac{\xi'(s)}{\xi(s)}.$$

Proof. Let

$$L(z) := \sum_{n\geq 1} \lambda_n z^n.$$

The Li generating row gives

$$L(z) = z\frac{d}{dz}\log\xi\left(\frac{1}{1-z}\right).$$

Let

$$B_+(z) := \sum_{n\geq 0} \beta_n z^n.$$

Using $\lambda_0 = 0$ and $\beta_0 = 2\lambda_1$, the definition of β_n gives

$$B_+(z) = \lambda_1 + (z + z^{-1} - 2)L(z).$$

Since $H_\beta(z) = 2B_+(z) - \beta_0$, this becomes

$$H_\beta(z) = 2(z + z^{-1} - 2)L(z).$$

Now

$$z + z^{-1} - 2 = \frac{(1-z)^2}{z}.$$

Therefore

$$H_\beta(z) = 2(1-z)^2 \frac{d}{dz} \log \xi \left(\frac{1}{1-z} \right).$$

For $s = 1/(1-z)$,

$$\frac{ds}{dz} = \frac{1}{(1-z)^2}.$$

The displayed expression reduces to

$$2\frac{\xi'(s)}{\xi(s)}.$$

□

Theorem 9270.4 (Herglotz row gives beta positivity)**.** *If H_β is a Herglotz function on the unit disk, then*

LiSecondDifferencePositiveDefinite

holds.

Proof. The Herglotz representation theorem gives a positive finite circle measure σ such that

$$H_\beta(z) = \int_{\mathbb{T}} \frac{\zeta + z}{\zeta - z}\, d\sigma(\zeta)$$

after the standard normalization of the imaginary constant. Comparing Taylor coefficients gives

$$\beta_n = \int_{\mathbb{T}} \zeta^{-n}\, d\sigma(\zeta).$$

Thus for every finite family (a_i, k_i),

$$\sum_{i,j} a_i \overline{a_j} \beta_{k_i - k_j} = \int_{\mathbb{T}} \left| \sum_i a_i \zeta^{-k_i} \right|^2 d\sigma(\zeta) \geq 0.$$

□

Theorem 9270.5 (Xi Herglotz row gives fixed-half readout)**.** *Assume* XiLogDerivativeHerglotz *and the usual reflection consumption row for the completed zeta zero ledger. Then the completed zeta zero ledger has fixed-half readout.*

Proof. Suppose a zero ρ of multiplicity $m \geq 1$ satisfies

$$\mathrm{Re}(\rho) > \frac{1}{2}.$$

Near ρ,

$$\frac{\xi'(s)}{\xi(s)} = \frac{m}{s-\rho} + \text{holomorphic row}.$$

Taking $s = \rho - \varepsilon$ with $\varepsilon > 0$ real and sufficiently small keeps s in the half-plane $\mathrm{Re}(s) > 1/2$ while

$$\mathrm{Re}\,\frac{m}{s-\rho} = -\frac{m}{\varepsilon} \to -\infty.$$

The holomorphic part is bounded near ρ, so the real part of ξ'/ξ is negative at such points. This contradicts XiLogDerivativeHerglotz. The reflection consumption row excludes the opposite open side by reflecting any such zero into the side already excluded. Hence the zero ledger reads through the fixed-half surface. □

Definition 9270.6 (Positive spectral measure for xi)**.** *The source row*

PositiveSpectralMeasureForXi

asserts the existence of a positive measure ν on $\mathbb{R}$ such that, for $\mathrm{Re}(w) > 0$,

$$\frac{\xi'}{\xi}\left(\frac{1}{2} + w\right) = \int_{\mathbb{R}} \frac{2w}{w^2 + t^2}\, d\nu(t).$$

The measure must be constructed from source rows rather than from a post-read zero spectrum.

Theorem 9270.7 (Positive spectral measure gives xi Herglotz row)**.** *If* PositiveSpectralMeasureForXi *holds, then*

XiLogDerivativeHerglotz

holds.

Proof. Write $w = x + iy$ with $x > 0$. For each real t,

$$\mathrm{Re}\,\frac{w}{w^2 + t^2} = \frac{x(|w|^2 + t^2)}{|w^2 + t^2|^2} \geq 0.$$

Integrating against the positive measure ν gives the claimed positive-real row. □

Definition 9270.8 (Balanced golden Herglotz closure)**.** *The source row*

BalancedGoldenHerglotzClosure

asserts the existence of balanced golden Lee–Yang containers C_m whose logarithmic derivatives have positive spectral representations on the right half-plane and converge locally uniformly to ξ'/ξ there.

Theorem 9270.9 (Balanced golden Herglotz closure gives xi Herglotz row)**.** *If* BalancedGoldenHerglotzClosure *holds, then*

XiLogDerivativeHerglotz

holds.

Proof. Each container log-derivative has nonnegative real part by its positive spectral representation. Local uniform convergence preserves nonnegative real part pointwise in the open half-plane. The limit is ξ'/ξ, hence XiLogDerivativeHerglotz holds. □

Corollary 9270.10 (Balanced golden Herglotz closure gives fixed-half readout)**.** *Assume* BalancedGoldenHerglotzCl *and the usual reflection consumption row for the completed zeta zero ledger. Then the completed zeta zero ledger has fixed-half readout.*

Proof. Definition 9270.9 gives XiLogDerivativeHerglotz. Apply Definition 9270.5. □

Principle 9270.11 (Herglotz target as Li–Weil source positivity)**.** *The Herglotz row is the analytic positive-real face of the Li–Weil beta kernel. The source-side target is not the posterior placement of zeros on the fixed line; it is a positive spectral representation, or a balanced golden sequence of such representations, whose log-derivative readout converges to that of ξ. In named form the route is*

$$\mathsf{BalancedGoldenHerglotzClosure} \Longrightarrow \mathsf{XiLogDerivativeHerglotz} \Longrightarrow \textit{fixed-half zero readout.}$$

Definition 9270.12 (Centered xi square coordinate)**.** *Let*

$$F_\xi(w) := \xi\left(\frac{1}{2} + w\right).$$

The functional equation makes F_ξ an even entire row. The associated square-coordinate row is

$$G_\xi(x) := F_\xi(\sqrt{x}),$$

understood as the entire function induced by the even power series of F_ξ. Its logarithmic derivative is

$$S_\xi(x) := \frac{G'_\xi(x)}{G_\xi(x)}.$$

Whenever $x = w^2$ and w lies in the right half-plane, the chain rule gives

$$S_\xi(w^2) = \frac{1}{2w}\frac{\xi'}{\xi}\left(\frac{1}{2} + w\right).$$

Definition 9270.13 (Xi Stieltjes log-derivative row)**.** *The source row*

$$\mathsf{XiStieltjesLogDerivative}$$

asserts that there exists a positive measure ν on $[0, \infty)$ such that

$$S_\xi(x) = \int_0^\infty \frac{1}{x+t}\, d\nu(t)$$

on the slit plane where the Stieltjes transform is defined. The measure is source data: it is not obtained by first reading a fixed-half zero divisor and then placing atoms at the squared ordinates.

Theorem 9270.14 (Stieltjes row gives the xi Herglotz row)**.** *If* XiStieltjesLogDerivative *holds, then*

$$\mathsf{XiLogDerivativeHerglotz}$$

holds.

Proof. For $w = a + ib$ with $a > 0$, the Stieltjes representation gives

$$\frac{\xi'}{\xi}\left(\frac{1}{2} + w\right) = 2w \int_0^\infty \frac{1}{w^2 + t}\, d\nu(t) = \int_0^\infty \frac{2w}{w^2 + t}\, d\nu(t).$$

For each $t \geq 0$,

$$\operatorname{Re} \frac{2w}{w^2 + t} = \frac{2a(|w|^2 + t)}{|w^2 + t|^2} \geq 0.$$

Integration against the positive measure ν gives the positive-real row on the right half-plane, hence XiLogDerivativeHerglotz. □

Corollary 9270.15 (Stieltjes log-derivative gives fixed-half readout)**.** *Assume* XiStieltjesLogDerivative *and the usual reflection consumption row for the completed zeta zero ledger. Then the completed zeta zero ledger has fixed-half readout.*

Proof. Definition 9270.14 gives XiLogDerivativeHerglotz. Apply Definition 9270.5. □

Theorem 9270.16 (Fixed-half divisor gives posterior Stieltjes readback)**.** *Assume the completed zeta zero ledger has fixed-half readout and admits the symmetric product row whose logarithmic derivative is locally uniformly obtained from finite divisor truncations. Then S_ξ has a posterior Stieltjes readback*

$$S_\xi(x) = \int_0^\infty \frac{1}{x + t}\, d\nu_{\text{post}}(t)$$

with positive atomic measure ν_{post}.

Proof. The fixed-half divisor has centered zeros

$$w = \pm i\gamma_j$$

with multiplicities. The symmetric product row gives

$$F_\xi(w) = F_\xi(0) \prod_j \left(1 + \frac{w^2}{\gamma_j^2}\right)$$

in the displayed regularized sense. With $x = w^2$ this becomes

$$G_\xi(x) = F_\xi(0) \prod_j \left(1 + \frac{x}{\gamma_j^2}\right).$$

Logarithmic differentiation through the accepted truncation limit gives

$$S_\xi(x) = \sum_j \frac{1}{x + \gamma_j^2}.$$

Thus S_ξ is the Stieltjes transform of the positive atomic measure

$$\nu_{\text{post}} = \sum_j \delta_{\gamma_j^2},$$

counting multiplicity. □

Definition 9270.17 (Stieltjes Hankel positivity target)**.** *The source row*

$$\mathsf{XiStieltjesHankelPositivity}$$

asserts that the moment sequence extracted from the expansion

$$S_\xi(x) = \sum_{k\geq 0}(-1)^k \mu_k x^k$$

satisfies the Stieltjes Hankel inequalities

$$\det(\mu_{i+j})_{i,j=0}^N \geq 0, \qquad \det(\mu_{i+j+1})_{i,j=0}^N \geq 0$$

for every $N \geq 0$, together with the analytic determinacy data required to reconstruct the positive measure in Definition 9270.13.

Definition 9270.18 (Stieltjes Pade approximation target)**.** *The source row*

$$\mathsf{XiStieltjesPadeApproximation}$$

asserts the existence of rational source approximants

$$S_m(x) = \sum_j \frac{a_{m,j}}{x + t_{m,j}}, \qquad a_{m,j} > 0, \quad t_{m,j} \geq 0,$$

which converge locally uniformly to S_ξ on compact subsets of the Stieltjes domain. This is the finite positive-spectrum version of XiStieltjesLogDerivative*.*

Principle 9270.19 (Stieltjes row as compressed source target)**.** *The Stieltjes row is the centered square-coordinate form of the Li–Weil, Herglotz, and no-scale targets. It replaces local zero boxes and posterior containers by a single positive spectral statement for the logarithmic derivative:*

$$\mathsf{XiStieltjesLogDerivative} \Longrightarrow \mathsf{XiLogDerivativeHerglotz} \Longrightarrow \textit{fixed-half zero readout.}$$

The reverse direction is only a posterior readback unless the positive measure is generated before the zero divisor is consumed.

Chapter 9271

Pick Kernel Triadic Positivity

chapter 9270 records the positive-real log-derivative row, and chapter 9277 records the P, U, and T audit discipline for RH-facing source rows. This chapter rewrites the Herglotz target as a Pick-kernel target. The purpose is to make the unit side finite-matrix checkable: a failure of positivity is witnessed by a finite Pick matrix, while a source-side Hilbert factorization supplies the right-triangle norm form.

Definition 9271.1 (Cayley right-half-plane readout)**.** *Let*

$$s(z) := \frac{1}{1-z}.$$

Then

$$s(z) - \frac{1}{2} = \frac{1+z}{2(1-z)}.$$

Thus the unit disk is the Cayley coordinate for the open half-plane to the right of the fixed line. Define the completed-zeta logarithmic Pick readout by

$$f_\xi(z) := 2\frac{\xi'(s(z))}{\xi(s(z))}$$

on the disk locus where this expression is holomorphic.

Definition 9271.2 (Xi Pick kernel)**.** *The Xi Pick kernel attached to Definition 9271.1 is*

$$K_\xi(z,w) := \frac{f_\xi(z) + \overline{f_\xi(w)}}{1 - z\overline{w}}.$$

The source row

$$\mathsf{TriadicPickPositivity}_\xi$$

asserts that f_ξ is holomorphic on the unit disk and that K_ξ is positive definite: for every finite family $z_1, \ldots, z_N \in \mathbb{D}$ and $c_1, \ldots, c_N \in \mathbb{C}$,

$$\sum_{i,j=1}^{N} c_i \overline{c_j} K_\xi(z_i, z_j) \geq 0.$$

Theorem 9271.3 (Pick positivity gives the Herglotz row)**.** *If $\mathsf{TriadicPickPositivity}_\xi$ holds, then*

$$\mathsf{XiLogDerivativeHerglotz}$$

holds.

Proof. Positive definiteness of K_ξ applied to the one-point family z gives

$$K_\xi(z,z) = \frac{2\operatorname{Re} f_\xi(z)}{1-|z|^2} \geq 0.$$

Since $1-|z|^2 > 0$ in the disk,

$$\operatorname{Re} f_\xi(z) \geq 0.$$

Under the coordinate $s = s(z)$ this is precisely the positive-real row for

$$2\frac{\xi'(s)}{\xi(s)}$$

on $\operatorname{Re}(s) > 1/2$, which is XiLogDerivativeHerglotz. □

Theorem 9271.4 (Herglotz row gives Pick positivity)**.** *Assume f_ξ is holomorphic on the unit disk and has a Herglotz representation*

$$f_\xi(z) = ib + \int_{\mathbb{T}} \frac{\zeta+z}{\zeta-z}\, d\mu(\zeta),$$

where $b \in \mathbb{R}$ and μ is a positive finite measure. Then K_ξ is positive definite.

Proof. The imaginary constant cancels in $f_\xi(z) + \overline{f_\xi(w)}$. Substituting the integral representation gives

$$K_\xi(z,w) = 2\int_{\mathbb{T}} \frac{1}{\zeta-z}\frac{1}{\overline{\zeta-w}}\, d\mu(\zeta).$$

For a finite family z_i and coefficients c_i,

$$\sum_{i,j} c_i\overline{c_j}K_\xi(z_i,z_j) = 2\int_{\mathbb{T}} \left|\sum_i \frac{c_i}{\zeta-z_i}\right|^2 d\mu(\zeta) \geq 0.$$

Thus the kernel is positive definite. □

Corollary 9271.5 (Pick positivity gives fixed-half readout)**.** *Assume* $\mathsf{TriadicPickPositivity}_\xi$ *and the usual reflection consumption row for the completed zeta zero ledger. Then the completed zeta zero ledger has fixed-half readout.*

Proof. By Definition 9271.3, XiLogDerivativeHerglotz holds. Apply Definition 9270.5. □

Definition 9271.6 (Finite Pick witness)**.** *A finite Pick witness against the Xi Pick row is a tuple*

$$(z_1,\ldots,z_N; c_1,\ldots,c_N)$$

with $z_i \in \mathbb{D}$ and $c_i \in \mathbb{C}$ such that

$$\sum_{i,j=1}^{N} c_i\overline{c_j}K_\xi(z_i,z_j) < 0.$$

It is the finite-matrix form of a negative energy witness.

Principle 9271.7 (Pick witness as the time side)**.** *The Pick formulation supplies the* T *side of the audit in a finite form. If the kernel row fails, the failure appears at some finite matrix size with finitely many disk points and coefficients. Thus the obstruction is not postponed to an unbounded search through all certificate levels; it has a displayed finite witness.*

Definition 9271.8 (Source Pick Hilbert factorization)**.** *The source row*

$$\mathsf{SourcePickHilbertFactorization}_\xi$$

asserts that there are a Hilbert space $\mathcal{H}$ and a source-side map

$$\Phi_\xi : \mathbb{D} \to \mathcal{H}$$

such that

$$K_\xi(z, w) = \langle \Phi_\xi(z), \Phi_\xi(w) \rangle_{\mathcal{H}}.$$

The map Φ_ξ must be constructed from prime, gamma, normalization, golden, Stieltjes, Herglotz, or explicit-formula source rows before the completed zero divisor is read.

Theorem 9271.9 (Hilbert factorization supplies Pick positivity)**.** *If* $\mathsf{SourcePickHilbertFactorization}_\xi$ *holds, then*

$$\mathsf{TriadicPickPositivity}_\xi$$

holds.

Proof. For any finite family,

$$\sum_{i,j} c_i \overline{c_j} K_\xi(z_i, z_j) = \left\| \sum_i c_i \Phi_\xi(z_i) \right\|_{\mathcal{H}}^2 \geq 0.$$

□

Definition 9271.10 (Finite source Pick approximation)**.** *A finite source Pick approximation is a sequence of positive kernels*

$$K_m(z, w) = \langle \Phi_m(z), \Phi_m(w) \rangle_{\mathcal{H}_m}$$

whose construction is source-side and whose finite matrix entries converge to the Xi Pick entries:

$$K_m(z_i, z_j) \to K_\xi(z_i, z_j)$$

for every finite disk family $z_1, \ldots, z_N$.

Theorem 9271.11 (Finite Pick approximations close the Pick row)**.** *If a finite source Pick approximation exists, then*

$$\mathsf{TriadicPickPositivity}_\xi$$

holds.

Proof. For each m and every finite coefficient family,

$$\sum_{i,j} c_i \overline{c_j} K_m(z_i, z_j) \geq 0.$$

Passing to the displayed finite-matrix limit gives

$$\sum_{i,j} c_i \overline{c_j} K_\xi(z_i, z_j) \geq 0.$$

This is positive definiteness of K_ξ. □

Principle 9271.12 (Triadic meaning of the Pick row)**.** *The Pick row is the compact Hilbert-kernel form of the triadic audit. Its* P *side is the requirement that K_ξ or its approximants are built from prime, gamma, and normalization ledgers. Its* U *side is positive definiteness, equivalently the norm square in Definition 9271.8. Its* T *side is the finite Pick witness row of Definition 9271.6. The same obstruction that appears as a scale leg in Definition 9276.1 appears here as a failure of a finite Gram matrix.*

Theorem 9271.13 (Right-side zero gives a one-point Pick witness)**.** *Assume ρ is a zero of ξ with multiplicity $m \geq 1$ and*

$$\mathrm{Re}(\rho) > \frac{1}{2}.$$

Then the Xi Pick row has a one-point negative witness at some $z_0 \in \mathbb{D}$.

Proof. Near ρ,

$$\frac{\xi'(s)}{\xi(s)} = \frac{m}{s-\rho} + \text{holomorphic row}.$$

Choose $\varepsilon > 0$ so small that

$$s_0 := \rho - \varepsilon$$

still satisfies $\mathrm{Re}(s_0) > 1/2$ and lies outside the zero locus. The holomorphic row is bounded near ρ, while

$$\mathrm{Re}\,\frac{m}{s_0-\rho} = -\frac{m}{\varepsilon}.$$

Hence, for sufficiently small ε,

$$\mathrm{Re}\,\frac{\xi'(s_0)}{\xi(s_0)} < 0.$$

Let

$$z_0 := 1 - \frac{1}{s_0}.$$

The Cayley readout of Definition 9271.1 places z_0 in the unit disk. By definition of f_ξ,

$$\mathrm{Re}\, f_\xi(z_0) < 0.$$

Therefore

$$K_\xi(z_0, z_0) = \frac{2\,\mathrm{Re}\, f_\xi(z_0)}{1-|z_0|^2} < 0,$$

which is the one-point instance of Definition 9271.6. □

Definition 9271.14 (Triadic Pick obstruction packet)**.** *A triadic Pick obstruction packet is the source-side audit row*

$$\mathsf{TriadicPickObstruction}_\xi$$

with three displayed sides. Its P *side is the prime-ledger and solenoid-fibre row: hidden coordinates may refine phase and prime-register data, as in Definition 9286.1, but may not supply an unrecorded $\mathbb{R}_{>0}$ scale gauge. Its* T *side is the finite witness extraction of Definition 9271.13. Its* U *side is the positive kernel row*

$$\mathsf{TriadicPickPositivity}_\xi.$$

The packet is closed when these three sides read the same radial defect: the prime side refuses it as hidden scale, the time side extracts it as a finite Pick witness, and the unit side excludes that witness by positive definiteness.

Theorem 9271.15 (Triadic Pick obstruction gives fixed-half readout)**.** *Assume* $\mathsf{TriadicPickObstruction}_\xi$*, assume*

$$\mathsf{TriadicPickPositivity}_\xi,$$

and assume the usual reflection consumption row for the completed zeta zero ledger. Then the represented completed zero ledger has fixed-half readout.

Proof. Suppose there is a represented zero with readout on the right open side of the fixed-half surface. By Definition 9271.13, it supplies a one-point finite Pick witness

$$K_\xi(z_0, z_0) < 0.$$

However, $\mathsf{TriadicPickPositivity}_\xi$ applied to the same one-point family gives

$$K_\xi(z_0, z_0) \geq 0.$$

This contradiction excludes the right open side. The reflection consumption row excludes the opposite open side by transporting it to the side already excluded. Hence the represented completed zero ledger reads through the fixed-half surface. □

Principle 9271.16 (Pick tower as the common triangular target)**.** *The finite source Pick approximation of Definition 9271.10 is the compact target for the three-sided route. Its* P_m *row is the source construction of* Φ_m *from prime, gamma, normalization, and ledger data. Its* U_m *row is the finite square identity*

$$K_m(z, w) = \langle \Phi_m(z), \Phi_m(w) \rangle_{\mathcal{H}_m}.$$

Its T_m *row is finite-matrix convergence*

$$K_m(z_i, z_j) \to K_\xi(z_i, z_j)$$

for every displayed finite disk family. Thus the remaining source burden is not a separate search along Li, Weil, and Nyman lines; it is the construction of a source-side Hilbert factorization whose finite positive kernels converge to the Xi Pick kernel.

Definition 9271.17 (Zeta positive triangular observation system)**.** *The source row*

$$\mathsf{ZetaPositiveTriangle}_\xi$$

is a finite-to-limit observation system consisting of source-side Hilbert kernels

$$K_m(z, w) = \langle \Phi_m(z), \Phi_m(w) \rangle_{\mathcal{H}_m}, \qquad m \geq 1,$$

finite-matrix convergence to K_ξ*, and projection readout rows*

$$\pi_{\mathsf{T}}, \qquad \pi_{\mathsf{W}}, \qquad \pi_{\mathsf{N}}.$$

The projections read, respectively, the Li-time, Weil-energy, and Nyman-container observations. The row requires that every zero-relevant accepted observation used by the fixed-half route factors through this positive triangular system or through one of its finite source kernels before any zero-divisor conclusion is consumed.

Definition 9271.18 (Same-leg compatibility)**.** *Let ρ be a represented completed zero row and put*

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell(\rho)+i\theta(\rho)}.$$

The projections of Definition 9271.17 are same-leg compatible at ρ when the time, energy, and container readouts all use the same scalar

$$\ell(\rho) = \log\left|1 - \frac{1}{\rho}\right|$$

as their radial defect. Equivalently, a nonzero radial readout may not disappear under a change of projection: it must be visible as a Li-time finite witness, a Weil negative direction, a Nyman residual separator, or a displayed positive-kernel obstruction row.

Definition 9271.19 (Triangular residual exhaustion)**.** *Let*

$$\mathcal{H}_1 \subseteq \mathcal{H}_2 \subseteq \cdots$$

be the Hilbert tower underlying Definition 9271.17. For an observation vector v, write

$$\eta_m(v) := (I - P_m)v$$

for the residual after projection to $\mathcal{H}_m$. The tower has triangular residual exhaustion for v when

$$\|\eta_m(v)\|^2 \to 0.$$

If this limit is not zero, the system must display a separating functional for the residual. In the Nyman projection this separating functional is the Mellin row of Definition 9281.8.

Theorem 9271.20 (Positive triangle controls represented observations)**.** *Assume* $\mathsf{ZetaPositiveTriangle}_\xi$*, same-leg compatibility for represented completed zero rows, triangular residual exhaustion for the accepted observation tower, and the usual reflection consumption row. Then every represented completed zero ledger that factors through this system has fixed-half readout.*

Proof. Let ρ be such a represented completed zero row. Suppose

$$\ell(\rho) \neq 0.$$

By same-leg compatibility, this same radial scalar must be visible in the Li-time, Weil-energy, and Nyman-container projections, or as a positive-kernel obstruction row. A finite Pick obstruction contradicts the positive definiteness of the kernels in Definition 9271.17. A Li-time or Weil-energy negative witness contradicts the corresponding positive side of the same Hilbert square ledger. A residual Nyman separator contradicts triangular residual exhaustion. Thus $\ell(\rho) \neq 0$ is impossible. Hence $\ell(\rho) = 0$, and Definition 9278.2 gives the fixed-half readout. □

Principle 9271.21 (Single positive triangle burden)**.** *The Li, Weil, Nyman, Lee–Yang, and finite endpoint rows are acceptable in the fixed-half route only as projections or finite models of one positive triangular observation system. The common burden is not to produce another isolated criterion, but to construct source kernels, same-leg projection readouts, and residual exhaustion in one package. When such a package is displayed, a nonzero radial scale cannot be hidden in prime fibres, cancelled by phase motion, or postponed to an unread infinite residual.*

Chapter 9272

Global Observation Triangle Invariant

chapter 9271 names the Pick-kernel form of the positive side, while chapter 9278 names the radial coordinate shared by the Li, Weil, and Nyman projections. The present chapter packages these rows as one global observation invariant. The target is not another isolated criterion. It is the source-side claim that every zero-relevant observation factors through one positive triangle before a fixed-half readout is consumed.

Definition 9272.1 (Global zeta observation triangle)**.** *The source row*

$$\mathsf{GlobalObservationTriangle}_\xi$$

consists of four compatible pieces:

$$\mathsf{Src}_\xi, \qquad \mathsf{Pos}_\xi, \qquad \mathsf{Leg}_\xi, \qquad \mathsf{Exh}_\xi.$$

The source piece Src_ξ *constructs the kernels* K_m *and maps* Φ_m *from prime, gamma, normalization, solenoid, golden, explicit-formula, or Stieltjes rows before the zero divisor is read. The positive piece* Pos_ξ *is the finite Hilbert square identity*

$$K_m(z,w) = \langle \Phi_m(z), \Phi_m(w) \rangle_{\mathcal{H}_m}$$

together with finite-matrix convergence to K_ξ*. The same-leg piece* Leg_ξ *says that the Li, Weil, Nyman, and Pick readouts use one radial scalar*

$$\ell(\rho) = \log \left| 1 - \frac{1}{\rho} \right|.$$

The exhaustion piece Exh_ξ *says that residual Hilbert energy is either exhausted by the observation tower or displayed by a separating functional.*

Definition 9272.2 (Legal global observation)**.** *A zero-relevant observation row* $\mathcal{O}$ *is legal for the global triangle when it factors through the source row of Definition 9272.1. Thus* $\mathcal{O}$ *is read either as a finite positive-kernel observation, as a limit of such observations on a finite matrix family, or as one of the displayed projection readouts of the same finite-to-limit system. A row that uses a completed zero divisor to define its Hilbert space, measure, or positive kernel is not a source-side legal observation for this purpose.*

Definition 9272.3 (Global triangle invariant)**.** *The global triangle invariant is the requirement that every legal zero-relevant observation satisfies the following three rows.*

First, the ledger row permits compact phase and compact prime-register fibres, as in Definition 9286.1, but does not permit an unrecorded $\mathbb{R}_{>0}$ radial gauge.

Second, the positive row represents observation energy by Hilbert squares:

$$\sum_{i,j} c_i \overline{c_j} K_m(z_i, z_j) = \left\| \sum_i c_i \Phi_m(z_i) \right\|_{\mathcal{H}_m}^2 \geq 0.$$

Third, the refinement row preserves finite matrix readouts and orthogonal residuals under passage to the limit. If a residual remains nonzero, it must be read by a displayed separator rather than hidden at the end of the tower.

Principle 9272.4 (Common radial leg)**.** *The Li, Weil, Nyman, Pick, Lee–Yang, and endpoint rows may have different finite presentations, but their off-fixed-half obstruction must read the same radial scalar. In Li time it appears as the radial factor in $z(\rho)^n$. In the Weil row it appears as a negative direction for a reflected orbit. In the Nyman row it appears as a Mellin separator for an unexhausted residual. In the Pick row it appears as a finite matrix obstruction. The global triangle invariant requires these readings to be transports of one scale leg, not separate defects that can be independently hidden.*

Theorem 9272.5 (Global triangle invariant gives Pick positivity)**.** *Assume* $\mathsf{GlobalObservationTriangle}_\xi$ *and assume its finite matrix convergence row holds for every displayed disk family. Then*

$$\mathsf{TriadicPickPositivity}_\xi$$

holds.

Proof. Fix a finite disk family $z_1, \ldots, z_N$ and coefficients $c_1, \ldots, c_N$. For every finite source level m, the positive piece of Definition 9272.1 gives

$$\sum_{i,j} c_i \overline{c_j} K_m(z_i, z_j) = \left\| \sum_i c_i \Phi_m(z_i) \right\|_{\mathcal{H}_m}^2 \geq 0.$$

The convergence row identifies the limit of the left side with

$$\sum_{i,j} c_i \overline{c_j} K_\xi(z_i, z_j).$$

Hence this latter finite quadratic form is nonnegative. Since the finite family was arbitrary, K_ξ is positive definite. □

Theorem 9272.6 (Global observation triangle gives fixed-half readout)**.** *Assume* $\mathsf{GlobalObservationTriangle}_\xi$*, the global triangle invariant, common radial-leg transport, triangular residual exhaustion, and the usual reflection consumption row for represented completed zero ledgers. Then every represented completed zero ledger legal for the global triangle has fixed-half readout.*

Proof. By Definition 9272.5, the global observation triangle supplies $\mathsf{TriadicPickPositivity}_\xi$. Let ρ be a represented completed zero ledger legal for the triangle. Suppose

$$\ell(\rho) \neq 0.$$

By common radial-leg transport, this nonzero scale leg must appear in one of the displayed projection rows: as a finite Li-time witness, a Weil negative direction, a Nyman residual separator,

or a Pick finite matrix obstruction. The positive row forbids negative finite Hilbert energy and Pick matrix obstructions. The residual exhaustion row forbids an unread Nyman residual; if such a residual remains, it is a displayed separator and therefore not hidden by the tower. The ledger row forbids reclassifying the same radial scalar as a compact phase or prime-register fibre. Thus $\ell(\rho) \neq 0$ is impossible. Hence $\ell(\rho) = 0$, and Definition 9278.2 gives the fixed-half readout. □

Definition 9272.7 (Zeta BEDC embedding row)**.** *The source row*

$$\mathsf{ZetaBEDCEmbedding}$$

asserts that every represented critical-strip completed zero row ρ is presented by a BEDC legal observation certificate

$$\mathcal{O}_\rho.$$

The certificate carries a carrier coordinate, a classifier coordinate, a ledger coordinate, the zero-row provenance, and the boundary rows needed to compare its Li, Weil, Nyman, and Pick projections. This row is stronger than a statement-level encoding of the RH predicate: it asserts that the analytic zero object has entered the BEDC observation system with the source data required by Definition 9272.1.

Definition 9272.8 (Zeta scale-leg coverage obstruction)**.** *The source row*

$$\mathsf{ZetaScaleLegCoverageObstruction}$$

asserts the following. Let ρ be a represented critical-strip completed zero row with

$$\ell(\rho) = \log\left|1 - \frac{1}{\rho}\right| \neq 0.$$

Then the associated radial scale leg cannot be covered by any of the three BEDC observation coordinates of Definition 9272.7: it is not a legal carrier coordinate, not a legal classifier coordinate, and not a legal ledger endpoint coordinate. It must therefore appear as an explicit defect row in the global observation triangle, rather than as hidden source structure.

Theorem 9272.9 (Embedding plus scale obstruction gives fixed-half readout)**.** *Assume* $\mathsf{ZetaBEDCEmbedding}$,

$$\mathsf{ZetaScaleLegCoverageObstruction},$$

and the global observation triangle hypotheses of Definition 9272.6. Then every represented critical-strip completed zero row in the embedding has fixed-half readout.

Proof. Let ρ be a represented critical-strip completed zero row. The embedding row supplies the BEDC legal observation certificate $\mathcal{O}_\rho$ and its carrier, classifier, ledger, and boundary coordinates. If $\ell(\rho) \neq 0$, the scale-leg obstruction row says that this radial coordinate cannot be absorbed by any of the three BEDC observation coordinates. Hence it remains an explicit defect row of the global observation triangle. Applying Definition 9272.6 to $\mathcal{O}_\rho$ rules out that explicit defect. Thus $\ell(\rho) = 0$, and Definition 9278.2 gives the fixed-half readout. □

Principle 9272.10 (Boundary of the BEDC route)**.** *The BEDC route does not consist merely of writing the RH statement in BEDC syntax. It requires the embedding row* $\mathsf{ZetaBEDCEmbedding}$ *and the obstruction row* $\mathsf{ZetaScaleLegCoverageObstruction}$. *Only then can the abstract kernel discipline of observation, distinction, time, carrier, classifier, and ledger be consumed by the analytic zeta object. The non-circular source burden is to prove that a nonzero radial scale leg cannot be one of the legal BEDC coordinates, rather than to assume fixed-half readout in advance.*

Definition 9272.11 (BEDC formalization success for zeta)**.** *The source row*

$$\mathsf{BEDCFormalizationSuccess}_\zeta$$

is the conjunction of four rows:

$$\mathsf{BEDCSoundness}, \quad \mathsf{ZetaInterpretation}, \quad \mathsf{ZetaCoverage}, \quad \mathsf{GlobalTriadicPositivity}_\xi.$$

Here BEDCSoundness *says that BEDC legal objects satisfy the carrier, classifier, ledger, unit-boundary, and generated-time discipline. The row* ZetaInterpretation *says that the completed zeta carrier, its centered channels, and its zero-relevant observations are interpreted inside that discipline. The row* ZetaCoverage *says that every represented non-trivial critical-strip zero is covered by such a legal observation certificate. The row* $\mathsf{GlobalTriadicPositivity}_\xi$ *says that the resulting global observation kernels have a source-side Hilbert/Pick/Herglotz positive representation.*

Definition 9272.12 (Strict sufficiency boundary)**.** *The strict sufficiency boundary is the separation between two claims. The weak claim is that BEDC supplies a formal language of observation, distinction, generated time, and ledgered residuals. The strong claim is that* $\mathsf{BEDCFormalizationSuccess}_\zeta$ *holds. Only the strong claim can be consumed by the fixed-half route, because only it asserts zeta interpretation, zero coverage, and global triadic positivity in addition to the abstract BEDC discipline.*

Theorem 9272.13 (Formalization success supplies fixed-half readout)**.** *Assume* $\mathsf{BEDCFormalizationSuccess}_\zeta$*, the scale-leg obstruction row*

$$\mathsf{ZetaScaleLegCoverageObstruction},$$

and the usual reflection consumption row for represented completed zero ledgers. Then every represented non-trivial critical-strip zero has fixed-half readout.

Proof. By ZetaInterpretation and ZetaCoverage, each represented non-trivial critical-strip zero is presented by a BEDC legal observation certificate inside the global zeta observation triangle. By $\mathsf{GlobalTriadicPositivity}_\xi$, the triangle carries the positive Hilbert/Pick/Herglotz row required by Definition 9272.6. By BEDCSoundness, the carrier, classifier, ledger, unit-boundary, and generated-time rows are legal BEDC rows. The scale-leg obstruction then prevents a nonzero radial scale from being absorbed by those legal coordinates. Applying Definition 9272.9 gives fixed-half readout for the represented zero. □

Principle 9272.14 (Strong meaning of formalization success)**.** *The phrase "formalization success" is used in this route only in the strong sense of Definition 9272.11. Formalizing the abstract BEDC principles gives the invariant language, but it does not by itself supply zeta interpretation, zero coverage, or the source-side positive representation*

$$K_\xi(z, w) = \langle \Phi_\xi(z), \Phi_\xi(w) \rangle.$$

The analytic core remains the construction of this positive global observation system from source data rather than from a posterior fixed-half zero divisor.

Definition 9272.15 (Xi observation cord)**.** *Let*

$$F(w) := \xi\left(\frac{1}{2} + w\right).$$

An Xi observation cord is a path

$$\gamma : [0,1] \to \{w : F(w) \neq 0\}$$

together with its image

$$F \circ \gamma : [0,1] \to \mathbb{C}^{\times}.$$

The cord has a radial readout $|F(\gamma(t))|$ *and a phase readout* $\arg F(\gamma(t))$ *on every branch where the argument is chosen. For a closed cord, its winding readout is*

$$\mathrm{Wind}_F(\gamma) := \frac{1}{2\pi i} \int_\gamma \frac{F'(w)}{F(w)}\, dw.$$

Definition 9272.16 (Off-axis cord defect)**.** *An off-axis cord defect is a closed Xi observation cord whose winding number is nonzero and whose enclosed zero row has centered coordinate*

$$w_0 = r + it$$

with $r \neq 0$*. Under the Li coordinate*

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta},$$

the same defect is read by the radial scalar

$$\ell = \log |z(\rho)| \neq 0.$$

Thus the off-axis cord defect is the topological form of the same scale leg appearing in Definition 9272.8.

Definition 9272.17 (Li-framed observation cylinder)**.** *The Li-framed observation cylinder is*

$$\mathcal{C}_{\mathrm{Li}} := S^1_\theta \times \mathbb{R}_\ell.$$

A completed zero row with

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta}$$

has phase centre line θ *and scale framing* ℓ*. The core circle is*

$$\mathcal{U}_{\mathrm{Li}} := S^1_\theta \times \{0\}.$$

Discrete Li time sends the framed coordinate to

$$z(\rho)^n = e^{n\ell} e^{in\theta},$$

so the phase coordinate winds on S^1_θ *while the framing coordinate is multiplied by* n*.*

Definition 9272.18 (Framed Xi cord)**.** *A framed Xi cord is an Xi observation cord whose enclosed completed zero row is equipped with the Li-framed lift of Definition 9272.17. It is core-framed when its scale framing is zero:*

$$\ell = 0.$$

It is nonunit-framed when

$$\ell \neq 0.$$

The framing is part of the observation ledger: it may be transported between Li, Weil, Nyman, and Pick readouts only as the same radial coordinate, not as a separately chosen gauge.

Theorem 9272.19 (Off-axis cords are nonunit-framed cords)**.** *Among closed represented Xi cords with nonzero winding readout, an off-axis cord defect is exactly a framed Xi cord with nonunit scale framing.*

Proof. The winding condition is common to both sides of the statement. The remaining distinction is the radial position of the enclosed zero row. An off-axis cord defect has centered coordinate

$$w_0 = r + it$$

with $r \neq 0$. Under the Li coordinate, the same row is read by

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta}.$$

By Definition 9278.2, the condition $\ell = 0$ is precisely fixed-half readout, and hence $r = 0$ on the represented zero row. Therefore $r \neq 0$ is equivalent to $\ell \neq 0$, which is the nonunit-framed condition of Definition 9272.18. □

Definition 9272.20 (Framed Li closure defect)**.** *For a framed Xi cord with Li coordinate*

$$z = e^{\ell + i\theta},$$

the nth framed Li closure defect is

$$\Delta_n(z) := 1 - z^n.$$

Its squared size decomposes as

$$|\Delta_n(z)|^2 = (e^{n\ell} - 1)^2 + 2e^{n\ell}(1 - \cos(n\theta)).$$

The first summand is the framing-energy row, and the second summand is the phase-winding row.

Principle 9272.21 (Framing energy cannot be cancelled by phase winding)**.** *The decomposition of Definition 9272.20 is a Pythagorean readout in the Li-framed cylinder. A nonzero scale framing contributes the nonnegative term*

$$(e^{n\ell} - 1)^2.$$

The phase row contributes

$$2e^{n\ell}(1 - \cos(n\theta)).$$

Since these terms occupy orthogonal readout rows, phase winding cannot erase a nonzero framing-energy row. The legal route must either display that energy in a projection ledger or rule out the nonunit framing at the source side.

Definition 9272.22 (Zeta framed cord triviality)**.** *The source row*

$$\mathsf{ZetaFramedCordTriviality}$$

asserts that every represented closed Xi observation cord legal for the global triangle and carrying nonzero winding readout is core-framed in the sense of Definition 9272.18. Equivalently, every such cord has

$$\ell = 0.$$

This is a source-side triviality row for the Li framing; it does not assert that all analytic zero rows are already covered by the global triangle.

Theorem 9272.23 (Framed cord triviality gives fixed-half readout)**.** *Assume* ZetaFramedCordTriviality *and the zero-coverage row that represents each completed critical-strip zero by a legal closed Xi observation cord with nonzero winding readout enclosing its zero row. each represented completed critical-strip zero has fixed-half readout.*

Proof. Let ρ be a represented completed critical-strip zero. The zero-coverage row supplies a legal closed Xi observation cord whose winding readout encloses the zero row of ρ. By ZetaFramedCordTriviality, the associated framed cord is core-framed, so its Li scale coordinate satisfies

$$\ell(\rho) = 0.$$

By Definition 9278.2, this is precisely fixed-half readout for ρ. □

Principle 9272.24 (Cord invariants are triadic invariants)**.** *The three sides of the global observation triangle read an off-axis cord defect as three invariants. The ledger side reads the fibre type: a radial factor belongs to $\mathbb{R}_{>0}$ rather than to compact phase or prime-register fibres. The time side reads finite detectability: the same defect supplies a finite Pick or Li–Weil witness. The unit side reads Hilbert positivity: a source-side factorization of K_ξ would make the corresponding finite quadratic form a norm square. Hence an off-axis cord defect cannot be hidden as a merely topological loop; it must pass the same carrier, classifier, ledger, positivity, and refinement audits as every other legal observation.*

Definition 9272.25 (Source unknotting for xi)**.** *The source row*

$$\mathsf{SourceUnknotting}_\xi$$

asserts that the Xi observation cords legal for the global triangle have a source-side Hilbert–Pick factorization:

$$K_\xi(z, w) = \langle \Phi_\xi(z), \Phi_\xi(w) \rangle.$$

The map Φ_ξ must be constructed from source data and must respect the projection readouts of Definition 9272.1. In this terminology, "unknotting" means positive Hilbert realization plus same-leg transport; it is not an external topological operation on a completed zero set.

Theorem 9272.26 (Source unknotting excludes off-axis cord defects)**.** *Assume* $\mathsf{SourceUnknotting}_\xi$*, common radial-leg transport, the scale-leg obstruction row*

$$\mathsf{ZetaScaleLegCoverageObstruction},$$

and the usual reflection consumption row. Then no represented legal Xi observation cord has an off-axis cord defect.

Proof. The source unknotting row gives

$$K_\xi(z, w) = \langle \Phi_\xi(z), \Phi_\xi(w) \rangle,$$

so every finite Pick quadratic form is a Hilbert norm square and is nonnegative. If an off-axis cord defect were represented, then by Definition 9272.16 it would carry a nonzero radial scalar ℓ. Common radial-leg transport reads this scalar in the finite Pick witness row, while Definition 9272.8 prevents it from being absorbed as a legal carrier, classifier, or ledger coordinate. Thus the defect would have to appear as a negative finite Pick witness, contradicting the Hilbert norm-square representation. Therefore no represented legal cord has such a defect. □

Principle 9272.27 (Global observation source load)**.** *The mathematical load is concentrated in the construction of the source piece* Src_ξ *and the convergence piece of Definition 9272.1. The positive side is then Hilbert-square formal, the time side is finite-matrix witnessability, and the ledger side is the refusal of an unrecorded real-positive scale gauge. This is the global form of the triangle route: every legal zeta observation is constrained by one positive Hilbert–Pick–Herglotz system, and every nonzero radial scale must be read rather than hidden.*

Chapter 9273

Xi Log-Potential No-Scale Field

chapter 9274 records the observation-vector form of the scale defect. The same obstruction has a global analytic readout through the centered completed zeta potential. This chapter names that readout and connects it to the Herglotz and Stieltjes targets of chapter 9270.

Definition 9273.1 (Centered xi log-potential)**.** *Let*

$$F_\xi(w) := \xi\left(\frac{1}{2} + w\right), \qquad w = x + iy.$$

On the nonzero locus of F_ξ, define the log-potential

$$u_\xi(w) := \log|F_\xi(w)|.$$

The coordinate x is the centered scale direction, and y is the centered phase-time direction.

Definition 9273.2 (Xi log-potential gradient energy)**.** *On the nonzero locus of F_ξ, define the observation gradient row*

$$\nabla u_\xi(w) := (\partial_x u_\xi(w), \partial_y u_\xi(w)).$$

Its Pythagorean energy decomposition is

$$\mathcal{E}_\xi(w) := |\nabla u_\xi(w)|^2 = (\partial_x u_\xi(w))^2 + (\partial_y u_\xi(w))^2.$$

The scale component is

$$\mathcal{E}_{\xi,\mathrm{scale}}(w) := (\partial_x u_\xi(w))^2.$$

Principle 9273.3 (Holomorphic coordinates are orthogonal)**.** *Where a local branch of* $\log F_\xi$ *exists, write*

$$\log F_\xi = u_\xi + iv_\xi.$$

The Cauchy–Riemann equations give the orthogonality of the potential and phase gradients. Thus the centered analytic carrier supplies the same orthogonal scale and phase coordinates as the observation-vector row of Definition 9274.6.

Definition 9273.4 (Xi no-scale-demon row)**.** *The source row*

$$\mathsf{XiNoScaleDemon}$$

asserts

$$\partial_x u_\xi(x + iy) \geq 0 \qquad (x > 0,\ F_\xi(x + iy) \neq 0).$$

Equivalently,

$$\operatorname{Re}\frac{F_\xi'(w)}{F_\xi(w)} \geq 0 \qquad (\operatorname{Re}(w) > 0).$$

Under $s = 1/2 + w$, this is the positive-real row XiLogDerivativeHerglotz *of Definition 9270.2.*

Theorem 9273.5 (Off-fixed-half zero creates negative scale flow)**.** *Suppose F_ξ has a zero $w_0 = x_0 + iy_0$ of multiplicity $m \geq 1$ with $x_0 > 0$. Then $\partial_x u_\xi(w) < 0$ at points of the right half-plane arbitrarily close to w_0.*

Proof. Near w_0,

$$F_\xi(w) = (w - w_0)^m g(w), \qquad g(w_0) \neq 0.$$

Hence

$$u_\xi(w) = m \log|w - w_0| + \log|g(w)|.$$

Take $w = w_0 - \varepsilon$ with $\varepsilon > 0$ real and sufficiently small. Then w remains in the right half-plane and

$$\partial_x u_\xi(w) = m\frac{x - x_0}{|w - w_0|^2} + O(1) = -\frac{m}{\varepsilon} + O(1),$$

which is negative for small enough ε. □

Theorem 9273.6 (No-scale-demon row gives fixed-half readout)**.** *Assume* XiNoScaleDemon *and the usual reflection consumption row for the completed zeta zero ledger. Then the completed zeta zero ledger has fixed-half readout.*

Proof. If a completed zero had centered coordinate w_0 with $\operatorname{Re}(w_0) > 0$, then Definition 9273.5 would give a right-half-plane point where

$$\partial_x u_\xi < 0,$$

contradicting XiNoScaleDemon. The reflection consumption row excludes the opposite open side by reflecting any such zero into the right half-plane. Thus every accepted completed zero reads through the fixed-half surface. □

Theorem 9273.7 (Stieltjes source row supplies no-scale demon)**.** *If* XiStieltjesLogDerivative *holds, then*

XiNoScaleDemon

holds.

Proof. By Definition 9270.14, XiStieltjesLogDerivative gives XiLogDerivativeHerglotz. Under the centered coordinate $s = 1/2 + w$, this is exactly the positive-real inequality in Definition 9273.4. □

Principle 9273.8 (Log-potential field as the global Pythagorean target)**.** *The log-potential row is the global field version of the finite observation-vector identity. A local active mode records the scale leg as $-rh_a$ and yields the finite energy $r^2 W_m$; the centered potential records the same leg as $\partial_x \log|F_\xi|$. A zero away from the fixed line is therefore a scale source or sink in the potential field. The source-side positive spectral target is*

XiStieltjesLogDerivative $\Longrightarrow$ XiNoScaleDemon $\Longrightarrow$ *fixed-half zero readout.*

Chapter 9274

Triadic Pythagorean Obstruction

Definition 9257.20 records the three certificate rows P, U, and T level by level. chapter 9270 records the unit-positive analytic face, while chapter 9286 records the no-scale energy face. This chapter packages these rows as one obstruction rather than as independent routes. The obstruction says that an off-fixed-half readout must appear simultaneously as an illegal prime-ledger scale, a finite-time witness, and a violation of the positive spectral row.

Definition 9274.1 (Observation ledger)**.** *An observation ledger is an increasing family of finite records*

$$\Lambda_0 \subseteq \Lambda_1 \subseteq \Lambda_2 \subseteq \cdots ,$$

where each record in Λ_m has the form

$$o = (p, r, \varepsilon)$$

for a displayed probe p, a displayed result r, and a tolerance or error row ε. The ledger is append-only: later levels may refine or extend the record, but they may not erase an earlier source row without a displayed transport ledger.

Principle 9274.2 (Observation order as internal time)**.** *The order carried by Definition 9274.1 is the observation-side form of internal time. The relation*

$$\Lambda_m \subseteq \Lambda_{m+1}$$

is not an external clock parameter; it is the generated order of recorded distinctions. If the inclusion is strict along a level, no forward append operation returns the ledger to the earlier finite record.

Definition 9274.3 (Residual coordinate from an observation)**.** *Let*

$$\mathcal{H}_m := \operatorname{span}\{v_1, \ldots, v_m\}$$

be the observation subspace generated by the first m ledger vectors, and let P_m denote orthogonal projection onto $\mathcal{H}_m$. A further observation vector v_{m+1} has the residual decomposition

$$v_{m+1} = P_m v_{m+1} + \eta_{m+1}, \qquad \eta_{m+1} \perp \mathcal{H}_m.$$

The projected term is the part explained by the previous observation coordinates. The residual η_{m+1} is the conditionally unexplained row. When $\eta_{m+1} \neq 0$, its normalized direction

$$e_{m+1} := \frac{\eta_{m+1}}{\|\eta_{m+1}\|}$$

is the additional orthogonal coordinate generated by the observation.

Theorem 9274.4 (Residual Pythagorean identity)**.** *For the decomposition of Definition 9274.3,*

$$\|v_{m+1}\|^2 = \|P_m v_{m+1}\|^2 + \|\eta_{m+1}\|^2.$$

Proof. The two summands are orthogonal. Expanding the squared norm gives

$$\|P_m v_{m+1} + \eta_{m+1}\|^2 = \|P_m v_{m+1}\|^2 + \|\eta_{m+1}\|^2.$$

□

Principle 9274.5 (Residual coordinate conservation)**.** *Observation order supplies the ledger time, while residual projection supplies the coordinate creation rule. A coordinate not already explained by the ledger cannot be removed by changing phase notation; it must either be recorded as an orthogonal residual or be ruled out by a closed-system invariant. The scale term in the zeta packet is such a residual coordinate.*

Definition 9274.6 (Observation vector decomposition)**.** *Let an active zero packet at level m have active set A_m and heights $h_a > 0$. For a centered readout*

$$s = \frac{1}{2} + r + it,$$

define the observation vector in the real Hilbert row

$$\mathbb{R}^{A_m} \oplus \mathbb{R}^{A_m}$$

by

$$V_m(s) := ((-rh_a)_{a\in A_m}, (-th_a)_{a\in A_m}).$$

Its scale and phase components are

$$V_{m,\mathrm{scale}}(s) := (-rh_a)_{a\in A_m}, \qquad V_{m,\mathrm{phase}}(s) := (-th_a)_{a\in A_m}.$$

The two summands are orthogonal coordinate rows: the first records radial scale and the second records phase lift.

Theorem 9274.7 (Observation vector Pythagorean identity)**.** *For the observation vector of Definition 9274.6, if*

$$W_m := \sum_{a\in A_m} h_a^2,$$

then

$$\|V_m(s)\|^2 = r^2 W_m + t^2 W_m,$$

and its scale component satisfies

$$\|V_{m,\mathrm{scale}}(s)\|^2 = r^2 W_m.$$

Proof. The two coordinate summands of $\mathbb{R}^{A_m} \oplus \mathbb{R}^{A_m}$ are orthogonal. Therefore

$$\|V_m(s)\|^2 = \sum_{a\in A_m} r^2 h_a^2 + \sum_{a\in A_m} t^2 h_a^2 = r^2 W_m + t^2 W_m.$$

The displayed formula for the scale component is the first summand. □

Principle 9274.8 (Observation, orthogonality, invariant)**.** *The observation ledger supplies the internal order, orthogonal decomposition supplies independent coordinates, and the Pythagorean identity supplies the quadratic invariant. In the zeta packet the phase coordinate is a legal unit-circle row, while the scale coordinate is a real-positive row. Thus the closed-packet obstruction is not the total length of $V_m(s)$, but the scale energy*

$$\|V_{m,\mathrm{scale}}(s)\|^2 = r^2 W_m.$$

This is the observation-vector form of the defect energy later recorded in Definition 9274.11.

Definition 9274.9 (Triadic obstruction coordinates)**.** *A triadic obstruction coordinate system for an active zero packet consists of three source rows:*

$$\mathsf{P}, \qquad \mathsf{U}, \qquad \mathsf{T}.$$

The row P is the prime-ledger row: hidden coordinates may live in compact phase and prime-register fibres, as in Definition 9286.1, but no independent real-positive scale ledger is accepted as a gauge. The row U is the unit-positive row: it may be presented as Lee–Yang boundary stability, global Weil positivity, Li CND, Herglotz positivity, or the Stieltjes source row of Definition 9270.13. The row T is the finite-time row: any off-fixed-half defect must project to a finite Li–Weil witness of the kind isolated in Definition 9265.22, rather than to an open-ended search through certificate levels.

Definition 9274.10 (Triadic closure relation)**.** *For a zero-relevant active packet with heights $h_a > 0$, write the centered readout as*

$$s = \frac{1}{2} + r + it.$$

The active channel at mode a is

$$U_a(s) := e^{-(s-1/2)h_a} = e^{-rh_a} e^{-ith_a}.$$

The triadic closure relation

$$\mathcal{C}(\mathsf{P}, \mathsf{U}, \mathsf{T}; s) = 0$$

means that the same active packet satisfies the prime-ledger gauge row, the unit-positive boundary row, and the finite-time witness row without introducing an unledgered $\mathbb{R}_{>0}$ coordinate.

Definition 9274.11 (Triadic scale defect energy)**.** *For a finite active packet A_m, define the scale defect at mode a by*

$$d_a(s) := \log |U_a(s)| = -rh_a.$$

The triadic defect vector and its quadratic energy are

$$\Omega_m(s) := (d_a(s))_{a \in A_m},$$

and

$$\mathcal{E}_m(s) := \sum_{a \in A_m} d_a(s)^2.$$

With

$$W_m := \sum_{a \in A_m} h_a^2,$$

one has the exact finite identity

$$\mathcal{E}_m(s) = r^2 W_m.$$

Principle 9274.12 (Pythagorean reading of the defect)**.** *The equation of Definition 9274.11 is the quadratic obstruction behind the triadic route. Linear phase cancellation may make a projected sum vanish, and reflection may exchange r with $-r$, but the squared defect*

$$r^2 W_m$$

has no sign that can be cancelled by phase or by mirror exchange. Thus an off-fixed-half readout can be hidden only by supplying an external scale ledger, by losing the finite witness row, or by breaking the unit-positive row.

Theorem 9274.13 (Triadic Pythagorean obstruction)**.** *Let a zero-relevant certificate tower have limit readout*

$$s_\infty = \frac{1}{2} + r + it.$$

Assume that it satisfies the triadic closure relation of Definition 9274.10, has cofinal active-weight growth

$$W_m \to \infty,$$

has defect extraction

$$\mathcal{E}_m(s_\infty) = r^2 W_m + o(W_m),$$

and carries a unit-positive stability bound

$$\mathcal{E}_m(s_\infty) \le B$$

with B independent of m. Then

$$r = 0.$$

Proof. Assume $r \neq 0$. Then $r^2 > 0$. From the defect extraction row there is a cofinal tail on which

$$|o(W_m)| \le \frac{r^2}{2} W_m.$$

Hence

$$\mathcal{E}_m(s_\infty) \ge \frac{r^2}{2} W_m$$

on that tail. Since $W_m \to \infty$, the energies $\mathcal{E}_m(s_\infty)$ are unbounded along the tail. This contradicts the stability bound $\mathcal{E}_m(s_\infty) \le B$. Therefore $r = 0$. □

Corollary 9274.14 (Triadic obstruction gives fixed-half readout)**.** *If every accepted non-trivial completed zeta zero is represented by a zero-relevant certificate tower satisfying the hypotheses of Definition 9274.13, then every such accepted zero has fixed-half readout.*

Proof. Let u be an accepted non-trivial completed zeta zero and let

$$s_\infty = \frac{1}{2} + r + it$$

be its represented readout. The tower hypotheses give $r = 0$ by Definition 9274.13. Thus $\mathrm{Re}(s_\infty) = 1/2$. □

Definition 9274.15 (Triadic positive-spectrum closure)**.** *The source row*

$$\mathsf{TriadicPositiveSpectrumClosure}_\zeta$$

asserts that the unit row U *of Definition 9274.9 is carried by one of the positive spectral presentations already named in the RH route:*

$\mathsf{XiStieltjesLogDerivative}$, $\mathsf{XiLogDerivativeHerglotz}$, $\mathsf{LiSecondDifferencePositiveDefinite}$, $\mathsf{GlobalLiWeilPosit}$

The row is source-side: it supplies positivity before the zero divisor is read, and it may not be manufactured by first assuming fixed-half readout and then placing a posterior spectral measure.

Theorem 9274.16 (Positive spectrum supplies the unit side)**.** *If* $\mathsf{TriadicPositiveSpectrumClosure}_\zeta$ *is realized through* $\mathsf{XiStieltjesLogDerivative}$*, then the unit row* U *of the triadic obstruction is available.*

Proof. Definition 9270.14 turns $\mathsf{XiStieltjesLogDerivative}$ into $\mathsf{XiLogDerivativeHerglotz}$. The latter is the positive-real unit row of Definition 9270.2; equivalently, by the Li–Weil comparison of Definition 9270.3, it is the analytic face of the Li beta positivity row. Hence the unit-positive component of the triadic closure relation is supplied. □

Principle 9274.17 (Three rows as one obstruction)**.** *The triadic route should be consumed as a single obstruction. The prime-ledger row says that* e^{-rh_a} *cannot be hidden in the compact phase or prime-register fibre. The finite-time row says that any such scale defect must have a finite Li–Weil witness. The unit-positive row says that the relevant witness functional is nonnegative through Weil, Li, Herglotz, or Stieltjes positivity. Therefore a nonzero real offset cannot be discharged by moving among the three rows; it is the same defect seen in three projections.*

Definition 9274.18 (Analytic triadic closure)**.** *The analytic specialization of the triadic obstruction has three rows:*

$$\mathsf{T}, \qquad \mathsf{W}, \qquad \mathsf{N}.$$

The time row T *is* $\mathsf{GlobalLiWeilPositivity}$*, or any source-side stronger row such as Li CND or a Stieltjes log-derivative representation that implies it. The energy row* W *is* $\mathsf{GlobalWeilPositivity}$ *for the Weil quadratic form of Definition 9265.2. The container row* N *is* $\mathsf{NymanBeurlingExhaustion}$ *of Definition 9281.6. The analytic triadic closure row*

$$\mathsf{AnalyticTriadicClosure}_\zeta$$

asserts that these three rows are supplied by one source carrier rather than by three posterior arguments over an already-read zero divisor.

Theorem 9274.19 (Li coordinate Pythagorean decomposition)**.** *Let*

$$z = e^{\ell + i\theta}$$

with $\ell, \theta \in \mathbb{R}$*. For every* $n \geq 1$*,*

$$|1 - z^n|^2 = (e^{n\ell} - 1)^2 + 2e^{n\ell}(1 - \cos(n\theta)).$$

Proof. Since

$$z^n = e^{n\ell}(\cos(n\theta) + i\sin(n\theta)),$$

one has

$$|1 - z^n|^2 = (1 - e^{n\ell}\cos(n\theta))^2 + (e^{n\ell}\sin(n\theta))^2.$$

Expanding and using

$$\cos^2(n\theta) + \sin^2(n\theta) = 1$$

gives

$$|1 - z^n|^2 = 1 - 2e^{n\ell}\cos(n\theta) + e^{2n\ell}.$$

The right-hand side also equals

$$(e^{n\ell} - 1)^2 + 2e^{n\ell}(1 - \cos(n\theta)),$$

which proves the identity. □

Principle 9274.20 (Radial Li defect is the time projection)**.** *For a zero row ρ, the Li coordinate of Definition 9266.1 has polar form*

$$z(\rho) = e^{\ell + i\theta}.$$

By Definition 9266.2, the fixed-half readout is exactly $\ell = 0$. If $\ell \neq 0$, the radial factor $e^{n\ell}$ is amplified by Li time. The real reflected-pair contribution is the form already isolated in Definition 9266.6: along suitable finite times, the radial term produces a finite Li–Weil negative witness unless the source carrier supplies a positive row that forbids it.

Definition 9274.21 (Weil negative direction projection)**.** *Let ρ_+ and ρ_- be a reflected off-fixed-half pair in the completed zero ledger. A Weil negative direction projection is a test-row packet f whose Weil transforms separate the reflected pair with opposite signs, while the remaining displayed zero rows are controlled by the interpolation and tail ledgers of the Weil packet. It is the zero-side obstruction described by Definition 9265.15: an off-fixed-half pair creates a negative direction unless* GlobalWeilPositivity *forbids such a packet.*

Definition 9274.22 (Nyman residual projection)**.** *Let s_0 be a zero with $\mathrm{Re}(s_0) > 1/2$. The Nyman residual projection is the continuous Mellin functional*

$$L_{s_0}(f) := \int_0^1 f(x)x^{s_0 - 1}\,dx$$

of Definition 9281.8. It annihilates every Nyman generator $\rho_{1/n}$ and satisfies

$$L_{s_0}(\mathbf{1}) = \frac{1}{s_0} \neq 0.$$

Thus it separates the constant row from the generated Nyman closure whenever the Nyman exhaustion row is absent.

Theorem 9274.23 (Nyman separator gives a quantitative residual)**.** *Assume the Nyman Mellin bridge row. If $s_0 = \sigma + i\tau$ is a nontrivial zeta zero with $\sigma > 1/2$, then*

$$\mathrm{dist}_{L^2}\left(\mathbf{1}, \overline{\mathrm{span}\{\rho_{1/n} : n \geq 1\}}^{L^2(0,1)}\right) \geq \frac{\sqrt{2\sigma - 1}}{|s_0|}.$$

Proof. By Definition 9281.8, the functional L_{s_0} vanishes on every generator $\rho_{1/n}$ and $L_{s_0}(\mathbf{1}) = 1/s_0$. Its representing vector is $x^{\overline{s_0}-1}$, hence

$$\|L_{s_0}\| = \left(\int_0^1 x^{2\sigma-2}\,dx\right)^{1/2} = \frac{1}{\sqrt{2\sigma-1}}.$$

For any v in the closed Nyman span,

$$|L_{s_0}(\mathbf{1}-v)| = |L_{s_0}(\mathbf{1})| = \frac{1}{|s_0|}.$$

Therefore

$$\|\mathbf{1}-v\|_2 \geq \frac{|L_{s_0}(\mathbf{1}-v)|}{\|L_{s_0}\|} = \frac{\sqrt{2\sigma-1}}{|s_0|}.$$

Taking the infimum over v gives the claim. □

Principle 9274.24 (Analytic triangle as one scale defect)**.** *The rows* T, W, *and* N *are not three unrelated proof attempts. They are three projections of the same nonunit Li coordinate. In the time projection, the radial parameter* $\ell = \log|z(\rho)|$ *is amplified by* $z(\rho)^n$ *and appears as a finite Li–Weil negative witness. In the energy projection, the reflected off-fixed-half pair supplies a negative Weil direction unless global Weil positivity forbids it. In the container projection, the Mellin functional* L_{s_0} *separates* $\mathbf{1}$ *from the Nyman closure unless Nyman exhaustion forbids the residual. Thus a nonzero scale coordinate is not a local anomaly that can be moved from one row to another; it is the same obstruction read by time, energy, and container coordinates.*

Theorem 9274.25 (Analytic triadic closure gives fixed-half readout)**.** *Assume* $\mathsf{AnalyticTriadicClosure}_\zeta$ *and the usual reflection consumption rows for the completed zeta zero ledger. Then every accepted non-trivial completed zeta zero has fixed-half readout.*

Proof. The row $\mathsf{AnalyticTriadicClosure}_\zeta$ includes $\mathsf{NymanBeurlingExhaustion}$. By Definition 9281.9, the Nyman row and the reflection consumption row exclude zero readouts off the fixed-half surface. The Li and Weil rows give the same exclusion through their finite-witness and energy forms; they are recorded here to identify that the excluded residual is the same scale defect as in Definition 9274.24. Hence every accepted non-trivial completed zero has fixed-half readout. □

Principle 9274.26 (Ontic closure target for the analytic triangle)**.** *The remaining source-side target is not to prove the Li, Weil, and Nyman rows by unrelated searches. It is to show that BEDC triadic closure supplies them as one source carrier:*

$$\mathsf{OnticTriadicClosure}_\zeta \Longrightarrow \mathsf{GlobalLiWeilPositivity} \wedge \mathsf{GlobalWeilPositivity} \wedge \mathsf{NymanBeurlingExhaustion}.$$

Once this carrier is present, an off-fixed-half readout has no place to hide: Li time detects it finitely, Weil energy detects it as a negative direction, and the Nyman container detects it as a positive residual distance.

Chapter 9275

Fermat Triangle Obstruction Prototype

chapter 9274 isolates the RH-facing scale defect as a quadratic residual, and chapter 9290 records the prime-register boundary behind triangle closure. The present chapter records the Fermat-shaped prototype for that obstruction. The purpose is not to import Fermat's Last Theorem as a BEDC theorem. It is to separate the legal quadratic triangle row from higher-power displays that require a separate branch, scale, ideal, or arithmetic ledger before they can be consumed.

9275.1 Quadratic Triangle Closure

Definition 9275.1 (Primitive orthogonal triangle closure)**.** *A primitive orthogonal triangle closure is a displayed packet*

$$X \perp Y, \qquad Z = X \oplus Y,$$

together with the quadratic readout

$$E(V) := \|V\|^2$$

and the energy ledger

$$E(Z) = E(X) + E(Y).$$

In BEDC terms, the packet is legal only when the source rows carrying X, Y, the orthogonality witness, the direct-sum readout, and the quadratic energy readback all remain visible in the ledger.

The residual identities of Definition 9274.4 and Definition 9274.7 are instances of Definition 9275.1. They are the formal reason why the observation route naturally produces square energy: orthogonal residuals add through the norm square, not through an arbitrary power.

Principle 9275.2 (Square energy as orthogonal information readout)**.** *The square in a Pythagorean row is not a decorative exponent. It is the energy readout of an orthogonal decomposition. When a generated object has the form*

$$B_{m+1} = B_m \oplus R_{m+1}, \qquad R_{m+1} \perp B_m,$$

the ledgered invariant is

$$\|B_{m+1}\|^2 = \|B_m\|^2 + \|R_{m+1}\|^2.$$

This is the quadratic surface on which a circle readout, a right-triangle readout, and a residual scale audit can be compared.

Theorem 9275.3 (Displayed L^q parallelogram obstruction)**.** *Let $q > 0$ and let*

$$\|(a, b)\|_q = (|a|^q + |b|^q)^{1/q}$$

on the displayed two-coordinate row. If this readout satisfies the parallelogram identity on

$$x = (1, 1), \qquad y = (1, -1),$$

then $q = 2$.

Proof. For these two displayed vectors,

$$x + y = (2, 0), \qquad x - y = (0, 2).$$

Hence

$$\|x + y\|_q^2 + \|x - y\|_q^2 = 4 + 4 = 8.$$

Also

$$\|x\|_q^2 = \|y\|_q^2 = 2^{2/q},$$

so the right side of the parallelogram identity is

$$2\|x\|_q^2 + 2\|y\|_q^2 = 4 \cdot 2^{2/q}.$$

The parallelogram identity therefore gives

$$8 = 4 \cdot 2^{2/q},$$

equivalently

$$2 = 2^{2/q}.$$

Since the displayed exponential base is greater than 1, the exponent comparison gives $2/q = 1$, hence $q = 2$. □

Principle 9275.4 (Quadratic-only primitive triangle)**.** *A primitive orthogonal triangle closure must pass through the parallelogram-compatible norm-square row. A higher-power display may be a valid arithmetic, algebraic, or analytic object, but it is not a primitive orthogonal triangle closure unless its proof ledger supplies a quadratic inner-product carrier from which the display is derived.*

9275.2 Fermat Classifiers

Definition 9275.5 (Gaussian two-square classifier row)**.** *The Gaussian two-square classifier is the specialization of the prime-classifier container of Definition 9290.7 to the norm*

$$N(a + bi) = a^2 + b^2.$$

Its inert boundary is the family of rational primes

$$p \equiv 3 \pmod 4,$$

and its finite boundary readout is

$$\partial_\square(n) := \big(v_p(n) \bmod 2\big)_{p \equiv 3 \pmod 4}.$$

The displayed closure row

$$\partial_\square(n) = 0$$

states that every inert prime class occurs with even multiplicity.

Principle 9275.6 (Fermat two-square theorem as quadratic classifier)**.** *The classical two-square theorem is the positive quadratic prototype: an integer n is a sum of two squares exactly when the inert boundary of Definition 9275.5 vanishes. For primes this says that $p = a^2 + b^2$ exactly for $p = 2$ or $p \equiv 1 \pmod 4$. BEDC reads this not merely as an equation, but as a prime-register classification of when a quadratic norm packet has no unpaired inert boundary.*

Definition 9275.7 (Higher-power pseudo-triangle row)**.** *For $n > 2$, a displayed equation*

$$x^n + y^n = z^n$$

is a higher-power pseudo-triangle row when it is offered as if it were the primitive triangle closure of Definition 9275.1. The row is accepted as a BEDC object only after its actual source ledger is exposed: cyclotomic branches, ideal factors, unit rows, class-group data, elliptic or Galois carriers, or any other arithmetic structure needed by the display. Without such a ledger it is not a primitive triangle row.

Principle 9275.8 (Fermat last theorem as high-power closure refusal)**.** *In this vocabulary, Fermat's Last Theorem says that the integer prime register has no non-trivial high-power pseudo-triangle closure:*

$$x^n + y^n = z^n, \qquad n > 2,$$

has no nonzero integer solution. The BEDC reading is narrower than the historical theorem and does not replace its proof: a higher exponent cannot silently assume the role carried by square energy in a primitive orthogonal triangle packet.

For an odd prime exponent ℓ, the algebraic display already shows the difference in carrier:

$$x^\ell + y^\ell = \prod_{k=0}^{\ell-1} (x + \zeta_\ell^k y).$$

This is a many-branch cyclotomic ledger, not the two-factor norm row

$$(a + bi)(a - bi) = a^2 + b^2.$$

The higher-power display therefore belongs to a richer arithmetic container before it belongs to any triangle-facing consumer.

9275.3 RH Radial Scale as Fermat-Type Defect

Definition 9275.9 (Fermat-type triangle obstruction)**.** *A Fermat-type triangle obstruction is a displayed closure attempt in which a non-quadratic or non-unit component is presented as if it were a primitive orthogonal triangle row. Its BEDC audit asks for the missing ledger:*

$$\text{quadratic carrier} \quad \textit{or} \quad \text{external residual row.}$$

If the quadratic carrier is absent and the residual row is omitted, the closure is not generated.

The RH route has the same shape after the Li coordinate is introduced. For a zero row ρ, write

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta}.$$

By Definition 9274.19,

$$|1 - z(\rho)^n|^2 = (e^{n\ell} - 1)^2 + 2e^{n\ell}(1 - \cos(n\theta)).$$

The second summand is the phase-facing term. The first summand is a radial scale leg. If $\ell \neq 0$, this leg is positive along suitable displayed times and is not a unit-circle phase coordinate.

Principle 9275.10 (Radial scale is not phase closure)**.** *The off-fixed-half condition $\ell \neq 0$ is the RH-facing analogue of a higher-power pseudo-triangle row. It is a syntactically visible closure attempt, but the radial factor cannot be consumed as unit phase or as a quadratic triangle invariant without displaying a scale ledger. Thus the route from Definition 9331.3 to Definition 9275.9 is:*

$$\ell \neq 0 \quad \Longrightarrow \quad \text{radial residual} \quad \Longrightarrow \quad \text{not pure unit triangle closure.}$$

Definition 9275.11 (NoFakeTriangleClosure target)**.** *The target row*

NoFakeTriangleClosure

has four clauses.

- *Every primitive orthogonal triangle closure factors through square energy and a parallelogram-compatible carrier.*
- *Every higher-power arithmetic display is either accounted for by its own branch and prime-register ledger or refused as a primitive triangle closure.*
- *Every zeta Li packet with $\ell \neq 0$ displays a radial scale row rather than a pure unit phase row.*
- *A cofinal prime classifier detects any unpaired inert boundary, radial residual, or scale ledger that a finite visible phase readout cannot erase.*

Principle 9275.12 (Fermat prototype for the RH proof-engineering route)**.** *The proof-engineering lesson is that the target is not a bare analogy between Fermat's Last Theorem and RH. The shared BEDC shape is the refusal of unledgered closure. In the Fermat prototype, square norms have a prime classifier and higher powers cannot impersonate primitive triangles. In the RH route, unit phases have triangle readouts and an off-fixed-half zero carries a radial scale leg. The common target is to turn that scale leg into a classifier-visible obstruction rather than a hidden coordinate.*

Chapter 9276

Right-Triangle Invariant System

chapter 9274 isolates the scale component of a centered active packet as a squared residual, and chapter 9273 records the global log-potential field that should forbid such residuals at the source. This chapter names the finite geometric system behind those rows. Its content is not an additional analytic object; it is the invariant discipline that makes observation order, orthogonal residuals, and positive energy one constraint.

Definition 9276.1 (Right-triangle observation system)**.** *Let A_m be a finite active packet with heights $h_a > 0$. For a centered readout*

$$s = \frac{1}{2} + r + it,$$

define the logarithmic observation row

$$L_m(s) := \big((-rh_a)_{a\in A_m},\, (-th_a)_{a\in A_m}\big) \in \mathbb{R}^{A_m} \oplus \mathbb{R}^{A_m}.$$

The first factor is the scale leg, and the second factor is the phase leg. The weight of the packet is

$$W_m := \sum_{a\in A_m} h_a^2.$$

A right-triangle observation system *is such a packet together with the source ledger that records A_m, the heights h_a, the orthogonal sum*

$$\mathbb{R}^{A_m} \oplus \mathbb{R}^{A_m},$$

and the assertion that hidden coordinates may refine compact phase or prime-register fibres but may not add an unrecorded $\mathbb{R}_{>0}$ scale fibre.

Theorem 9276.2 (Right-triangle energy identity)**.** *For the observation row of Definition 9276.1,*

$$\|L_m(s)\|^2 = r^2 W_m + t^2 W_m.$$

Its scale leg has energy

$$E_{m,\mathrm{scale}}(s) := \|(-rh_a)_{a\in A_m}\|^2 = r^2 W_m.$$

Proof. The two displayed factors of $\mathbb{R}^{A_m} \oplus \mathbb{R}^{A_m}$ are orthogonal. Hence

$$\|L_m(s)\|^2 = \sum_{a\in A_m} r^2 h_a^2 + \sum_{a\in A_m} t^2 h_a^2 = r^2 W_m + t^2 W_m.$$

The scale formula is the first summand. □

Corollary 9276.3 (Scale leg lower bound)**.** *For every finite active packet,*

$$\|L_m(s)\|^2 \geq E_{m,\mathrm{scale}}(s).$$

Consequently, phase notation cannot cancel a nonzero scale leg inside the squared observation energy.

Proof. By Definition 9276.2,

$$\|L_m(s)\|^2 - E_{m,\mathrm{scale}}(s) = t^2 W_m \geq 0.$$

□

Principle 9276.4 (Projection residual as coordinate creation)**.** *Let $\mathcal{H}_m$ be the Hilbert subspace generated by the displayed ledger rows before adding a further observation v. The projection decomposition*

$$v = P_{\mathcal{H}_m} v + (I - P_{\mathcal{H}_m})v$$

separates the explained part from the residual. The residual is orthogonal to $\mathcal{H}_m$ and therefore contributes the nonnegative energy

$$\|(I - P_{\mathcal{H}_m})v\|^2.$$

Thus an unexplained scale component must either appear as a new orthogonal coordinate or be ruled out by a source-side positivity row; it cannot be erased by changing the phase coordinate.

Definition 9276.5 (Finite invariant ledger)**.** *A finite invariant ledger for the right-triangle system consists of the following rows for every displayed observation family $v_1, \ldots, v_N$:*

$$G_N := (\langle v_i, v_j \rangle)_{1 \leq i,j \leq N} \succeq 0,$$

the Bessel row

$$\sum_{i=1}^{N} |\langle v, e_i \rangle|^2 \leq \|v\|^2$$

for every displayed orthonormal subfamily $e_1, \ldots, e_N$, and the Schur residual row

$$\Delta_N := a_N - b_N^* G_N^+ b_N \geq 0$$

whenever

$$G_{N+1} = \begin{pmatrix} G_N & b_N \\ b_N^* & a_N \end{pmatrix}$$

is the next displayed Gram extension with the required range row $b_N \in \mathrm{Range}(G_N)$.

Principle 9276.6 (Invariant ledger meaning)**.** *The rows of Definition 9276.5 are the finite Hilbert expression of BEDC ledger discipline. Positive semidefinite Gram matrices say that displayed correlations cannot exceed displayed energies. Bessel rows say that recorded coordinates cannot contain more energy than the observation. Schur rows say that a further observation has nonnegative conditional energy after projection to the previous ledger. In the RH route these are the common finite form of the Li–Weil time row, the Weil energy row, and the Nyman container row.*

Theorem 9276.7 (Schur row is residual energy)**.** *Assume that G_N is the Gram matrix of vectors $v_1, \dots, v_N$ in a Hilbert space, that v_{N+1} is another vector, and that*

$$a_N = \langle v_{N+1}, v_{N+1} \rangle, \qquad b_N = (\langle v_1, v_{N+1} \rangle, \dots, \langle v_N, v_{N+1} \rangle)^T.$$

Then the Schur residual Δ_N of Definition 9276.5 is the squared norm of the orthogonal residual of v_{N+1} modulo $\operatorname{span}\{v_1, \dots, v_N\}$.

Proof. Let P_N be the orthogonal projection onto $\operatorname{span}\{v_1, \dots, v_N\}$. The best-approximation theorem gives

$$\|v_{N+1} - P_N v_{N+1}\|^2 = \|v_{N+1}\|^2 - \|P_N v_{N+1}\|^2.$$

Writing the projection coefficients through the Gram system gives

$$\|P_N v_{N+1}\|^2 = b_N^* G_N^+ b_N$$

on the range row. Hence

$$\|v_{N+1} - P_N v_{N+1}\|^2 = a_N - b_N^* G_N^+ b_N = \Delta_N.$$

□

Principle 9276.8 (Mirror midpoint obstruction)**.** *Let*

$$z_+ = e^{\ell + i\theta}, \qquad z_- = e^{-\ell + i\theta}.$$

The midpoint after Li time n is

$$M_n := \frac{z_+^n + z_-^n}{2} = \cosh(n\ell) e^{in\theta}.$$

Thus

$$|M_n| = \cosh(n\ell).$$

If $\ell \neq 0$, the midpoint lies outside the unit circle. A reflected pair therefore does not remove the scale coordinate; it moves the center of the pair away from the legal phase boundary.

Principle 9276.9 (Parallelogram obstruction for reflected scale)**.** *For*

$$a = z_+^n, \qquad b = z_-^n,$$

the parallelogram identity gives

$$|a + b|^2 + |a - b|^2 = 2|a|^2 + 2|b|^2.$$

Since

$$|a| = e^{n\ell}, \qquad |b| = e^{-n\ell},$$

the right-hand side is

$$2e^{2n\ell} + 2e^{-2n\ell}.$$

For $\ell \neq 0$ this is strictly larger than 4. Mirror exchange can change the sign of the scale parameter, but the square-energy ledger records both sides as positive length.

Definition 9276.10 (Triangular invariant audit)**.** *Let* R *be a zero-relevant source row in the RH route. A* triangular invariant audit *of* R *is a triple*

$$\mathsf{Audit}(\mathsf{R}) := (\mathsf{T}_{\mathsf{R}}, \mathsf{U}_{\mathsf{R}}, \mathsf{P}_{\mathsf{R}})$$

together with a displayed defect readout. The row T_{R} *records the observation order or refinement order consumed by* R*. The row* U_{R} *records the unit, positive, or no-negative-energy side of* R*. The row* P_{R} *records the ledger side: which generators, test rows, certificates, or containers are allowed to carry the observation. The defect readout must factor through the same right-triangle scale leg as Definition 9276.1.*

Definition 9276.11 (Audited RH source family)**.** *The audited source family is the list of RH-route rows*

$$\mathcal{A}_{\triangle} := \{\mathsf{LiTimePositiveTower}, \mathsf{GlobalWeilPositivity}, \mathsf{NymanBeurlingExhaustion}, \mathsf{LeeYangBoundaryStability}, \mathsf{GoldenDomi}$$

Each member of $\mathcal{A}_{\triangle}$ *is to be read through Definition 9276.10, rather than as an isolated route.*

Principle 9276.12 (Li audit row)**.** *The audit of* $\mathsf{LiTimePositiveTower}$ *has* T*-side given by the discrete Li time* n *and the iteration*

$$z(\rho)^n.$$

Its U*-side is the nonnegative phase contribution*

$$2 - 2\cos(n\theta) \geq 0$$

when $z(\rho) = e^{i\theta}$*. Its* P*-side is the reflected zero ledger used in the Li–Weil coefficient row. A radial pair* $e^{\ell+i\theta}$ *and* $e^{-\ell+i\theta}$ *is audited by the factor*

$$\cosh(n\ell),$$

which exposes the same scale coordinate as the midpoint obstruction of Definition 9276.8.

Principle 9276.13 (Weil audit row)**.** *The audit of* $\mathsf{GlobalWeilPositivity}$ *has* T*-side given by the cofinal selection of test rows,* U*-side given by the nonnegativity of the Weil quadratic form, and* P*-side given by the source test space and regularization ledger of Definition 9265.2. A reflected off-fixed-half pair is audited by the finite value block*

$$\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

whose negative direction is the energy-side projection of the same scale leg that appears in Definition 9276.2.

Principle 9276.14 (Nyman audit row)**.** *The audit of* $\mathsf{NymanBeurlingExhaustion}$ *has* T*-side given by the increasing Hilbert subspaces generated by the Nyman rows,* U*-side given by the projection identity*

$$\|1 - P_{N+1}1\|^2 = \|1 - P_N 1\|^2 - \|P_{N+1}1 - P_N 1\|^2,$$

and P*-side given by the displayed generator ledger* $\rho_{1/n}$*. An off-fixed-half zero supplies a continuous Mellin functional that annihilates the displayed generators while separating the constant row; this is the container-side readout of a nonzero residual coordinate.*

Principle 9276.15 (Boundary and dominance audit rows)**.** *The audit of* LeeYangBoundaryStability *has* T*-side given by finite-volume refinement,* U*-side given by unit-boundary nonzero regions, and* P*-side given by stable operations such as polarization, Asano contraction, or a representation theoretic compactness ledger. A golden or Zeckendorf ruler can be used only as a displayed refinement scale; it is not by itself the unit container.*

The audit of GoldenDominantBranch *has* T*-side given by the finite recurrence or endpoint parameter,* U*-side given by the maximal-modulus branch condition, and* P*-side given by the exact algebraic certificates that distinguish the branch. Thus a branch may be used in a zero law only after dominance and source identity are both ledgered.*

Principle 9276.16 (Capture, Nyman–Mobius, and Schur audit rows)**.** *The audit of* ActiveCapture *has* T*-side given by certificate refinement,* U*-side given by boundary stability or transport into a positive container, and* P*-side given by the source-side construction of the container before any zero island is selected.*

The audit of GoldenNymanGramExhaustion *has* T*-side given by the Fibonacci refinement order,* U*-side given by nonnegative Hilbert residual gains, and* P*-side given by the Möbius and Nyman generator ledgers that must exhaust the constant row.*

The audit of SchurResidualSquareRepresentation *has* T*-side given by appending a test direction,* U*-side given by*

$$\Delta_N \geq 0,$$

and P*-side given by a source-side square representation of* Δ_N*, not by a posterior factorization of an already positive matrix.*

Definition 9276.17 (Triangular audit coherence)**.** *The source row*

$$\mathsf{TriangularAuditCoherence}_\zeta$$

asserts that every member of $\mathcal{A}_\triangle$ *carries a triangular invariant audit and that the audits are compatible by the following two-out-of-three transport rows:*

$$\mathsf{T} + \mathsf{U} \to \mathsf{P}, \qquad \mathsf{U} + \mathsf{P} \to \mathsf{T}, \qquad \mathsf{P} + \mathsf{T} \to \mathsf{U}.$$

The arrows are not logical shortcuts between unrelated theorems. They state that if two sides of the same finite right-triangle ledger are source-side certified, then the third side must read the same scale defect and cannot introduce a different hidden coordinate.

Principle 9276.18 (Common audit invariant)**.** *The common invariant behind every audited row is the Li-coordinate decomposition*

$$|1 - z^n|^2 = (e^{n\ell} - 1)^2 + 2e^{n\ell}(1 - \cos(n\theta)).$$

The first summand is the scale residual and the second summand is the phase residual. The audit discipline requires every named RH-route row to say where this scale residual is seen in time, where it is forbidden by positivity or unit boundary, and where it is recorded in the ledger.

Definition 9276.19 (Ontic Pythagorean closure row)**.** *The source row*

$$\mathsf{OnticPythagoreanClosure}_\zeta$$

asserts that every zero-relevant certificate tower admits finite right-triangle observation systems whose scale legs are controlled by a source-side unit-positive row:

$$E_{m,\mathrm{scale}}(s_\infty) \leq B$$

for a tower bound B independent of the refinement level, while the active weights are cofinal:

$$W_m \to \infty.$$

The row also requires that any hidden fibre accepted by the tower is a compact phase or prime-register fibre, not an unrecorded real-positive scale fibre.

Theorem 9276.20 (Ontic Pythagorean closure gives fixed-half readout)**.** *Let a zero-relevant certificate tower have limit readout*

$$s_\infty = \frac{1}{2} + r + it.$$

If the tower satisfies $\mathsf{OnticPythagoreanClosure}_\zeta$ *and its finite right-triangle systems extract the scale energy*

$$E_{m,\mathrm{scale}}(s_\infty) = r^2 W_m + o(W_m),$$

then $r = 0$.

Proof. Assume $r \neq 0$. Then $r^2 > 0$. From the extraction row there is a cofinal tail on which

$$|o(W_m)| \leq \frac{r^2}{2} W_m.$$

Therefore

$$E_{m,\mathrm{scale}}(s_\infty) \geq \frac{r^2}{2} W_m$$

on that tail. Since $W_m \to \infty$, the scale energies are unbounded along the tail, contradicting the tower bound in Definition 9276.19. Hence $r = 0$. □

Principle 9276.21 (Invariant target of the RH route)**.** *The analytic burden of the route is to supply the source-side unit-positive row used in Definition 9276.19. The Stieltjes and Herglotz rows of chapter 9270, the log-potential no-scale field of chapter 9273, the Gram and Schur rows of chapter 9279, and the Nyman square tower of chapter 9281 are different finite readouts of that single positivity demand. The right-triangle system specifies what these readouts must forbid: a nonzero scale leg carried by* e^{-rh_a}*. Definition 9276.17 records the corresponding bookkeeping demand: each named route must display its time side, its unit-positive side, and its ledger side as projections of that same scale-leg obstruction.*

Chapter 9277

Source-Side Triadic Audit Criterion

chapter 9276 records the finite scale-leg invariant, while Definition 9257.20 records the certificate-tower rows P, U, and T. The present chapter states the audit rule that every RH-facing source row must satisfy before it can be consumed by the fixed-half route. A row that occupies only one side of the triangle is a local tool. A row that is used in the route must display its source ledger, unit-positive boundary, and refinement or finite-witness order.

Definition 9277.1 (Source-side triadic audit of a route row)**.** *Let $\mathcal{Q}$ be a source row in the RH route. A source-side triadic audit of $\mathcal{Q}$ is a displayed factorization*

$$\mathcal{Q} \rightsquigarrow (\mathcal{Q}_{\mathsf{P}}, \mathcal{Q}_{\mathsf{U}}, \mathcal{Q}_{\mathsf{T}})$$

where $\mathcal{Q}_{\mathsf{P}}$ is the source-ledger and legal-hidden fibre row, $\mathcal{Q}_{\mathsf{U}}$ is the unit-boundary or positive energy row, and $\mathcal{Q}_{\mathsf{T}}$ is the refinement, cofinality, or finite-witness row. The audit is closed when the three rows read the same scale defect and no side introduces an unrecorded real-positive coordinate.

Definition 9277.2 (Triadic source transport)**.** *For an audited route row $\mathcal{Q}$, triadic source transport is the requirement that the following three transport rows are source-side valid:*

$$\mathcal{Q}_{\mathsf{P}} + \mathcal{Q}_{\mathsf{T}} \to \mathcal{Q}_{\mathsf{U}}, \qquad \mathcal{Q}_{\mathsf{P}} + \mathcal{Q}_{\mathsf{U}} \to \mathcal{Q}_{\mathsf{T}}, \qquad \mathcal{Q}_{\mathsf{U}} + \mathcal{Q}_{\mathsf{T}} \to \mathcal{Q}_{\mathsf{P}}.$$

The first row says that a legal ledger and an internal time readout force the absence of an independent radial gauge. The second says that a legal ledger and a unit boundary leave only the phase-time parameter as a free readout. The third says that a unit boundary and a refinement law select the zero-relevant modes that must be ledgered.

Definition 9277.3 (Triadic no-scale packet)**.** *Let an active packet A_m carry heights $h_a > 0$ and centered channel*

$$U_a(s) = e^{-(s-1/2)h_a} = e^{-rh_a} e^{-ith_a}.$$

The packet is triadic no-scale when its P row accepts compact phase and prime-register fibres only, its U row supplies a source-side bound for the scale energy, and its T row supplies cofinal active-weight growth or a finite negative witness whenever $r \neq 0$. In symbols the scale row is

$$d_a(s) := \log |U_a(s)| = -rh_a, \qquad E_m^{\mathrm{scale}}(s) = \sum_{a \in A_m} d_a(s)^2 = r^2 W_m,$$

where

$$W_m := \sum_{a \in A_m} h_a^2.$$

Principle 9277.4 (Stable rows already fit the audit)**.** *The BEDC history generator supplies the* T *side: finite records extend by append-only constructor rows. The phase-channel solenoid of Definition 9286.1 supplies the* P *side: hidden state may live in compact prime-register fibres, not in an external real-positive scale line. Weak eta capture of Definition 9255.7 supplies local analytic capture and part of the time side, but it does not supply the unit side. The Fibonacci path and Lee–Yang lift rows of Definition 9260.1 and Definition 9260.2 supply a finite internal ruler and a unit-boundary seed, but not by themselves a prime-compatible zeta container. The quartic endpoint model supplies the methodological load: a branch must be shown dominant by source certificates before it can carry a zero law.*

Definition 9277.5 (Audited golden bridge rows)**.** *The golden bridge targets are audited as follows.*

The row GoldenStableRoucheHomotopy *has* P *side given by the eta, Zeckendorf, and bridge ledgers,* U *side given by Lee–Yang or Herglotz stability along the bridge, and* T *side given by boundary non-vanishing and winding preservation.*

The row PrimeZeckendorfLift *has* P *side given by the transport from additive Zeckendorf data to multiplicative prime-register data,* U *side given by preservation of unit boundary under that transport, and* T *side given by cofinal refinement through the prime-compatible tower.*

The row PrimeCompatibleGoldenTower *has* P *side given by prime-register alignment at every level,* U *side given by no-scale boundary stability, and* T *side given by unbounded active-weight growth or finite-witness extraction.*

Definition 9277.6 (Audited positivity rows)**.** *The positive spectral targets are audited as follows.*

The row BalancedGoldenConstruction *has* P *side given by internally determined normalization data,* U *side given by preservation of the unit-boundary zero law after balancing, and* T *side given by compatibility of the normalization under refinement.*

The row BalancedGoldenLiCNDClosure *has* P *side given by the finite container and zero-ledger provenance,* U *side given by conditional negative definiteness of the Li kernel, and* T *side given by closure of that kernel row under the limiting process.*

The row XiStieltjesLogDerivative *has* P *side given by a positive measure constructed from source data rather than from a posterior fixed-half divisor,* U *side given by Stieltjes and Herglotz positivity, and* T *side given by a half-plane representation rather than a pointwise search.*

The row GlobalWeilPositivity *has* P *side given by the legal test space and explicit-formula ledger,* U *side given by nonnegativity of the Weil quadratic form, and* T *side given by cofinal finite test packets that detect any negative direction.*

Definition 9277.7 (Audited witness-reduction rows)**.** *The finite-witness and closure targets are audited as follows.*

The row WeilPositivityReduction *has* P *side given by a legal test packet,* U *side given by violation of a positive quadratic row, and* T *side given by finite detection of the negative witness.*

The row ObservationPythagoreanClosureForZeta *has* P *side given by heights from prime or solenoid ledgers,* U *side given by control of the scale component through unit positivity, and* T *side given by cofinal growth*

$$W_m \to \infty$$

or by finite witness extraction.

Theorem 9277.8 (Triadic no-scale criterion)**.** *Let every zero-relevant accepted certificate tower be represented by triadic no-scale packets. Assume that each such packet satisfies triadic source transport, has defect extraction*

$$E_m^{\mathrm{scale}}(s_\infty) = r^2 W_m + o(W_m),$$

has either $W_m \to \infty$ or a finite negative witness when $r \neq 0$, and carries a source-side unit-positive row excluding unbounded scale energy and negative witnesses. Then every represented readout

$$s_\infty = \frac{1}{2} + r + it$$

has $r = 0$.

Proof. Assume $r \neq 0$. If the time row supplies cofinal active-weight growth, then the defect extraction gives a cofinal tail on which

$$E_m^{\text{scale}}(s_\infty) \geq \frac{r^2}{2} W_m.$$

The energies are unbounded along that tail, contradicting the source-side unit-positive row. If instead the time row supplies a finite negative witness, that witness contradicts the same unit-positive row in its finite test form. In both cases the assumption $r \neq 0$ is impossible. Hence $r = 0$. □

Principle 9277.9 (Compressed source target)**.** *The compressed source target is to realize one positive-spectrum row whose triadic audit is source-side. The Stieltjes log-derivative target of Definition 9270.13 is the most compact form of this requirement: the measure must be generated before reading a fixed-half divisor, positivity supplies the unit side, and the representation supplies a half-plane time row. When such a source row is transported through the prime and certificate ledgers, the right-triangle scale coordinate has no legal carrier.*

Chapter 9278

Radial Scale Projection System

chapter 9274 identifies the analytic triangle as one scale defect, and chapter 9276 records its finite Hilbert form. The present chapter isolates the scalar readout shared by the Li, Weil, and Nyman projections. The scalar is the radial coordinate of the Li map; every analytic line in the route reads the same coordinate through a different finite or Hilbert witness.

Definition 9278.1 (Li radial scale coordinate)**.** *For a nontrivial completed zeta zero row ρ, let*

$$z(\rho) := 1 - \frac{1}{\rho}$$

as in Definition 9266.1. The Li radial scale coordinate is

$$\ell(\rho) := \log |z(\rho)|.$$

When $z(\rho) = e^{\ell + i\theta}$, the coordinate ℓ is the scale leg and θ is the phase angle.

Theorem 9278.2 (Radial scale reads the fixed-half surface)**.** *For a nontrivial completed zero row ρ,*

$$\ell(\rho) = 0$$

if and only if the readout of ρ lies on the fixed-half surface.

Proof. By definition, $\ell(\rho) = 0$ exactly when $|z(\rho)| = 1$. By Definition 9266.2, this is equivalent to the fixed-half readout. □

Definition 9278.3 (Critical half axis row)**.** *The critical half axis row is the recovered-carrier predicate*

$$\mathcal{C}_{1/2} := \{s : \mathrm{Re}(s) = 1/2\}$$

read inside the completed zeta zero interface. Its mirror source is the involution of Definition 9320.1,

$$\iota(s) = 1 - \overline{s},$$

its unit readout is the Li coordinate

$$z(s) = 1 - \frac{1}{s},$$

and its ledger readout is the radial scale

$$\ell(s) = \log |z(s)|.$$

Theorem 9278.4 (Critical half axis is the mirror fixed locus)**.** *For a completed zero coordinate* $s = \sigma + i\gamma$*,*

$$\iota(s) = s$$

if and only if

$$\sigma = \frac{1}{2}.$$

Proof. By Definition 9320.1,

$$\iota(s) = 1 - \overline{s} = 1 - \sigma + i\gamma.$$

The equality $\iota(s) = s$ is therefore equivalent to

$$1 - \sigma = \sigma,$$

which is equivalent to $\sigma = 1/2$. □

Definition 9278.5 (Critical half axis triple)**.** *The critical half axis carries the ontological triple*

$$\mathrm{Ont}(\mathcal{C}_{1/2}) = (\mathsf{T}_{\mathcal{C}}, \mathsf{U}_{\mathcal{C}}, \mathsf{L}_{\mathcal{C}}).$$

The time row $\mathsf{T}_{\mathcal{C}}$ *is the fixed locus of the zeta mirror involution. The unit row* $\mathsf{U}_{\mathcal{C}}$ *is the unit Li readout*

$$s \in \mathcal{C}_{1/2} \Longleftrightarrow |z(s)| = 1.$$

The ledger row $\mathsf{L}_{\mathcal{C}}$ *is the zero radial account*

$$s \in \mathcal{C}_{1/2} \Longleftrightarrow \ell(s) = 0.$$

Thus the critical half axis is not an unlicensed host line: it is the common fixed, unit, and zero-ledger row consumed by the closed zero packet route.

Theorem 9278.6 (Mirror reflection reverses the radial ledger)**.** *If* $z(s) = e^{\ell + i\theta}$ *and* $\iota(s)$ *is the mirror coordinate, then*

$$z(\iota(s)) = e^{-\ell + i\theta}.$$

Consequently the critical half axis is exactly the zero ledger locus for the mirror radial pair.

Proof. The identity is Definition 9320.2. The zero ledger locus is $\ell = 0$, which is equivalent to fixed-half readout by Definition 9278.2. □

Theorem 9278.7 (Closed radial packets lie on the critical half axis)**.** *Let a licensed zeta zero packet carry*

ZetaZeroObjectsHaveOntTriple, GlobalOffLineZeroToFiniteNPWindow, LedgerClosureRefusal.

If the packet is closed, then its Li radial scale satisfies

$$\ell(\rho) = 0,$$

and hence its readout lies on $\mathcal{C}_{1/2}$*.*

Proof. If $\ell(\rho) \neq 0$, then Definition 9278.2 says that ρ is off the fixed-half surface. The licensed triple route then gives the closed-status refusal of Definition 9310.9. This contradicts the closed-packet hypothesis. Therefore $\ell(\rho) = 0$, and Definition 9278.5 identifies the readout with the critical half axis. □

Theorem 9278.8 (Li radial Pythagorean identity)**.** *Let*

$$z = e^{\ell + i\theta}.$$

For every $n \geq 1$,

$$|1 - z^n|^2 = (e^{n\ell} - 1)^2 + 2e^{n\ell}(1 - \cos(n\theta)).$$

Proof. This is Definition 9274.19, rewritten with the notation of Definition 9278.1. □

Definition 9278.9 (Radial projection triple)**.** *The radial projection triple attached to a completed zero ledger is*

$$\mathsf{RadialProjection}_\zeta := (\mathsf{T}_\ell, \mathsf{W}_\ell, \mathsf{N}_\ell).$$

The time projection T_ℓ *is the Li-time readout of* $z(\rho)^n$*. The energy projection* W_ℓ *is the Weil-quadratic readout of reflected zero pairs. The container projection* N_ℓ *is the Nyman–Beurling readout of the Mellin separator attached to a zero in the right open half of the critical strip.*

Principle 9278.10 (Time projection of a nonzero radial scale)**.** *If a reflected zero pair has Li coordinates*

$$z_+ = e^{\ell + i\theta}, \qquad z_- = e^{-\ell + i\theta},$$

then Li time reads the radial coordinate through the factor

$$\cosh(n\ell).$$

For $\ell \neq 0$*, this factor is larger than* 1 *for* $n \geq 1$*. The finite Li–Weil witness row of Definition 9265.22 is the time-side certificate that such radial amplification cannot coexist with the global Li positivity row.*

Principle 9278.11 (Energy projection of a nonzero radial scale)**.** *A reflected off-fixed-half pair produces a Weil value block with a negative direction, as in Definition 9274.21. The sign of* ℓ *may be reversed by reflection, but the existence of a two-point reflected orbit with* $|\ell| > 0$ *is what gives the energy-side negative direction. Global Weil positivity forbids that projection when the test row and tail ledgers are source-side controlled.*

Principle 9278.12 (Container projection of a nonzero radial scale)**.** *If the reflected orbit has a representative*

$$s_0 = \sigma + i\tau, \qquad \sigma > \frac{1}{2},$$

then Definition 9281.8 supplies the continuous Mellin functional

$$L_{s_0}(f) = \int_0^1 f(x) x^{s_0 - 1}\, dx.$$

It annihilates the displayed Nyman generators and does not annihilate **1***. Thus the same radial scale coordinate that Li time reads as amplification and Weil energy reads as a negative direction is read by the Nyman container as a residual separator.*

Definition 9278.13 (Zeta radial triangular closure)**.** *The source row*

$$\mathsf{ZetaRadialTriangularClosure}$$

asserts that every accepted nontrivial completed zero ledger carries the radial projection triple of Definition 9278.9, and that the three projections are governed by one scalar

$$\ell(\rho) = \log\left|1 - \frac{1}{\rho}\right|.$$

The row further asserts that a nonzero value of this scalar must be detected by at least one of the three finite or Hilbert witnesses: Li-time negativity, Weil negative direction, or Nyman residual separation.

Theorem 9278.14 (Radial triangular closure gives fixed-half readout)**.** *Assume* ZetaRadialTriangularClosure *and assume the three projection rows*

GlobalLiWeilPositivity, GlobalWeilPositivity, NymanBeurlingExhaustion

are available with their usual reflection consumption rows. Then every accepted nontrivial completed zero has fixed-half readout.

Proof. Let ρ be an accepted nontrivial completed zero. If $\ell(\rho) \neq 0$, the closure row forces a detection in one of the three projections. A Li-time negative witness contradicts GlobalLiWeilPositivity. A Weil negative direction contradicts GlobalWeilPositivity. A Nyman residual separator contradicts NymanBeurlingExhaustion by Definition 9281.8. Hence $\ell(\rho) = 0$. By Definition 9278.2, ρ has fixed-half readout. □

Principle 9278.15 (Single radial burden)**.** *The Li, Weil, and Nyman tasks should be read as three audits of one radial coordinate, not as unrelated proof searches. Li time asks whether powers of $z(\rho)$ expose $\ell(\rho)$. Weil energy asks whether a test row can extract a negative direction from the reflected orbit. Nyman exhaustion asks whether the legal generator container leaves a residual Mellin functional. The source-side burden is to show that the BEDC triadic carrier never admits a nonzero radial coordinate without one of these witnesses.*

Definition 9278.16 (Cross-projection radial refutation packet)**.** *A cross-projection radial refutation packet for a completed zero ledger is a source-side row that starts from a displayed assumption*

$$\ell(\rho) \neq 0$$

and exports this same scalar to the three projection ledgers

$$\mathsf{T}_\ell, \qquad \mathsf{W}_\ell, \qquad \mathsf{N}_\ell$$

of Definition 9278.9. The packet is accepted only when the time ledger reads the reflected Li pair, the energy ledger reads the corresponding Weil negative direction, and the container ledger reads the Mellin separator in the open half selected by reflection. Thus the packet does not certify a contradiction inside a single projection; it certifies that a nonzero radial coordinate has the same readback in the other two projections as well.

Definition 9278.17 (Triangular burden of a radial source row)**.** *Let $\mathcal{Q}$ be a RH-facing source row whose conclusion is consumed by the fixed-half route. Its triangular radial burden is the requirement that any use of $\mathcal{Q}$ against a zero ledger with*

$$\ell(\rho) \neq 0$$

comes with a cross-projection radial refutation packet. A row that only records positivity, separation, or exhaustion in its native projection is therefore a local analytic row. It becomes a route row only after the same radial scalar has been transported to the remaining projection ledgers.

Theorem 9278.18 (Two-sided projection audit closes the third side)**.** *Assume a completed zero ledger carries a cross-projection radial refutation packet. Suppose two of the projection rows*

$$\mathsf{GlobalLiWeilPositivity}, \qquad \mathsf{GlobalWeilPositivity}, \qquad \mathsf{NymanBeurlingExhaustion}$$

are source-side closed, and suppose the remaining projection is linked to them by the triadic source transport of Definition 9277.2. Then the zero ledger cannot carry

$$\ell(\rho) \neq 0.$$

Proof. Assume $\ell(\rho) \neq 0$. The cross-projection packet exports this scalar to all three ledgers. If the time ledger supplies a finite negative Li witness, it contradicts GlobalLiWeilPositivity. If the energy ledger supplies a Weil negative direction, it contradicts GlobalWeilPositivity. If the container ledger supplies a Mellin separator, it contradicts NymanBeurlingExhaustion by Definition 9281.8. The two closed sides and the triadic source transport ensure that the remaining side cannot hide the same scalar as an unledgered real-positive coordinate. Hence the assumption $\ell(\rho) \neq 0$ is impossible. □

Principle 9278.19 (No single-projection consumption)**.** *The fixed-half route may consume a Li, Weil, or Nyman target only after its triangular radial burden is displayed. A Li square row must explain where the corresponding radial scale would appear as Weil energy and as Nyman residual separation. A Weil factorization row must explain where the same radial scale would appear in Li time and in the Nyman container. A Nyman exhaustion row must explain where its residual separator would appear in Li time and Weil energy. This is the source-side form of the rule that every off-fixed-half assumption is tested against the other two ledgers, not only against the ledger in which it was first detected.*

Chapter 9279

Golden Weil Gram Induction

chapter 9265 records the global Weil-positive tower as the non-local target of the no-scale route. The present chapter records a finite Gram-matrix form of that target. The aim is to replace an open-ended search through zero certificates by a source-side sequence of finite semidefinite tests.

Definition 9279.1 (Golden Weil test ruler)**.** *Let* $\varphi = (1+\sqrt{5})/2$ *and let*

$$\delta_m := \varphi^{-m}.$$

Choose a fixed compactly supported smooth bump ψ *on the logarithmic line. A* golden Weil test ruler *is a sequence*

$$\mathcal{B}_\varphi = (\psi_i)_{i\geq 1}$$

obtained from translated and rescaled bumps

$$\psi_{m,k}(u) := \psi\left(\frac{u-k\delta_m}{\delta_m}\right)$$

by a Zeckendorf ledger ordering. The ruler rows require that the source of each scale is recorded by the Fibonacci ledger, that

$$\operatorname{span}\{\psi_i : i \geq 1\}$$

is dense in the test space of Definition 9265.1, and that adding a later ψ_i *refines the observation ledger without deleting earlier rows.*

Definition 9279.2 (Golden Weil Gram matrix)**.** *For the finite test space*

$$\mathcal{A}_N := \operatorname{span}\{\psi_1, \ldots, \psi_N\},$$

define the golden Weil Gram matrix

$$G_N = (g_{ij})_{1\leq i,j\leq N}$$

by the sesquilinear Weil pairing

$$g_{ij} := \mathcal{W}(\psi_i, \psi_j),$$

where $\mathcal{W}(f,g)$ *denotes the polarization of the quadratic row of Definition 9265.2. Thus, for*

$$f_c = \sum_{i=1}^{N} c_i\psi_i,$$

one has

$$c^* G_N c = \mathcal{W}(f_c).$$

Theorem 9279.3 (Golden Gram reduction)**.** *Assume the golden Weil test ruler is dense and that the Weil quadratic row is continuous for the chosen test topology. If*

$$G_N \succeq 0 \qquad \text{for every } N,$$

then GlobalWeilPositivity *holds. Conversely,* GlobalWeilPositivity *implies* $G_N \succeq 0$ *for every* N*.*

Proof. Assume first that every G_N is positive semidefinite. Let f be a test row. By density, choose $f_N \in \mathcal{A}_N$ with $f_N \to f$. Since $G_N \succeq 0$,

$$\mathcal{W}(f_N) \geq 0.$$

Continuity gives

$$\mathcal{W}(f) = \lim_N \mathcal{W}(f_N) \geq 0.$$

Thus GlobalWeilPositivity holds.

Conversely, if GlobalWeilPositivity holds, then for every $c \in \mathbb{C}^N$,

$$c^* G_N c = \mathcal{W}\left(\sum_{i=1}^N c_i \psi_i\right) \geq 0.$$

Hence $G_N \succeq 0$. □

Principle 9279.4 (Finite diagonal witness)**.** *If the global Weil form has a negative direction, then the golden ruler detects it at finite resolution. Indeed, choose* f *with*

$$\mathcal{W}(f) < 0.$$

By density and continuity, some $f_N \in \mathcal{A}_N$ *still satisfies*

$$\mathcal{W}(f_N) < 0.$$

Writing $f_N = \sum_i c_i \psi_i$ *gives*

$$c^* G_N c < 0.$$

Thus a diagonal negative probe is not an infinitely postponed anomaly; it appears as a finite negative Gram direction.

Definition 9279.5 (Schur residual of the golden Weil tower)**.** *Write the next Gram matrix as*

$$G_{N+1} = \begin{pmatrix} G_N & b_N \\ b_N^* & a_N \end{pmatrix},$$

where

$$a_N := \mathcal{W}(\psi_{N+1}, \psi_{N+1})$$

and

$$b_N := \left(\mathcal{W}(\psi_1, \psi_{N+1}), \ldots, \mathcal{W}(\psi_N, \psi_{N+1})\right)^T.$$

The Schur residual *is*

$$\Delta_N := a_N - b_N^* G_N^+ b_N,$$

with G_N^+ *the Moore–Penrose inverse. The range row*

$$b_N \in \mathrm{Range}(G_N)$$

is part of the semidefinite Schur ledger.

Definition 9279.6 (Diagonal-safe Weil induction)**.** *The source row*

$$\mathsf{DiagonalSafeWeilInduction}$$

asserts that

$$G_1 \succeq 0,$$

and for every N the range row

$$b_N \in \mathrm{Range}(G_N)$$

and the conditional-energy row

$$\Delta_N \geq 0$$

hold.

Theorem 9279.7 (Schur induction gives finite Gram positivity)**.** *If* DiagonalSafeWeilInduction *holds, then*

$$G_N \succeq 0 \qquad \textit{for every } N.$$

Proof. Proceed by induction on N. The base row is $G_1 \succeq 0$. For the step, assume $G_N \succeq 0$. The semidefinite Schur complement criterion says that

$$G_{N+1} = \begin{pmatrix} G_N & b_N \\ b_N^* & a_N \end{pmatrix} \succeq 0$$

exactly when b_N lies in the range of G_N and

$$a_N - b_N^* G_N^+ b_N \geq 0.$$

These are precisely the range and conditional-energy rows of Definition 9279.6. □

Corollary 9279.8 (Diagonal-safe Weil induction gives global positivity)**.** *Assume the density and continuity rows of Definition 9279.3. If* DiagonalSafeWeilInduction *holds, then* GlobalWeilPositivity *holds.*

Proof. By Definition 9279.7, every G_N is positive semidefinite. Apply Definition 9279.3. □

Definition 9279.9 (Orthogonal residual of the added test row)**.** *When the range row holds, the residual of the added test row is the formal class*

$$\psi_{N+1}^{\perp} := \psi_{N+1} - \Pi_N \psi_{N+1},$$

where Π_N is the Weil-Gram projection onto $\mathcal{A}_N$. The Schur residual is the residual energy row

$$\Delta_N = \mathcal{W}(\psi_{N+1}^{\perp}).$$

Definition 9279.10 (Golden Weil Schur residual positivity)**.** *The source row*

$$\mathsf{GoldenWeilSchurResidualPositivity}$$

asserts that every residual row of Definition 9279.9 has nonnegative Weil energy:

$$\mathcal{W}(\psi_{N+1}^{\perp}) \geq 0.$$

It is the finite conditional-information form of the no-demon obligation.

Definition 9279.11 (Schur residual square representation)**.** *The source row*

SchurResidualSquareRepresentation

asserts that for every N there are a Hilbert space $\mathcal{H}_N$ and a source-side linear readout T_N such that

$$\Delta_N = \|T_N \psi_{N+1}^{\perp}\|_{\mathcal{H}_N}^2.$$

Theorem 9279.12 (Square representation gives diagonal-safe induction)**.** *If $G_1 \succeq 0$, the range rows hold, and* SchurResidualSquareRepresentation *holds, then* DiagonalSafeWeilInduction *holds.*

Proof. The square representation gives

$$\Delta_N = \|T_N \psi_{N+1}^{\perp}\|_{\mathcal{H}_N}^2 \geq 0$$

for every N. Together with the assumed base and range rows, this is exactly DiagonalSafeWeilInduction. □

Principle 9279.13 (Finite induction target)**.** *The finite Gram form converts the global positivity route into a sequence of Schur residuals. The active source obligation is not a universal decider for all future tests; it is the structural representation*

SchurResidualSquareRepresentation.

If each added golden resolution direction has residual Weil energy presented as a norm square, the Gram tower is positive by finite induction and the global Weil positivity row follows by density.

Chapter 9280

Diagonal Schur Square Target

chapter 9279 reduces the global Weil-positive route to finite Gram positivity and then to Schur residuals. This chapter records the diagonal obstruction behind that reduction and isolates the source-side square target: each conditional Weil energy row must be presented as a norm square before any posterior matrix factorization is invoked.

Definition 9280.1 (Finite reflected zero ledger)**.** *Let J denote the completed-zeta reflection*

$$J(\rho) := 1 - \overline{\rho}.$$

A finite zero ledger $\mathcal{Z}_T$ is reflected *when it is closed under J, with the displayed multiplicities preserved. On the finite value space*

$$V_T := \{v = (v_\rho)_{\rho \in \mathcal{Z}_T}\},$$

define the reflected Weil block

$$Q_T(v) := \sum_{\rho \in \mathcal{Z}_T} v_\rho \, \overline{v_{J\rho}}.$$

Theorem 9280.2 (Finite reflected Weil signature)**.** *Assume $\mathcal{Z}_T$ is a reflected finite zero ledger. A fixed point of J contributes a positive square to Q_T. A two-point orbit $\{\rho, J\rho\}$ with $\rho \neq J\rho$ contributes one positive and one negative direction. Consequently, Q_T is positive semidefinite exactly when the finite ledger has no two-point reflected orbit.*

Proof. If $J\rho = \rho$, then the orbit contribution is

$$v_\rho \overline{v_\rho} = |v_\rho|^2.$$

If $\rho \neq J\rho$, write the two coordinates as (x, y). The orbit contribution is

$$x\overline{y} + y\overline{x} = 2\,\mathrm{Re}(x\overline{y}).$$

In the basis (x, y) the Hermitian matrix is

$$\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

with eigenvalues 1 and -1. Summing over the finite J-orbits gives the signature statement and the stated criterion for semidefiniteness. $\square$

Corollary 9280.3 (Finite mirror negative value row)**.** *If $\mathcal{Z}_T$ contains a two-point reflected orbit*

$$\rho_+ = \frac{1}{2} + r + i\gamma, \qquad \rho_- = \frac{1}{2} - r + i\gamma, \qquad r \neq 0,$$

then there is $v \in V_T$ with

$$Q_T(v) < 0.$$

Proof. Set $v_{\rho_+} = 1$, $v_{\rho_-} = -1$, and set every other displayed coordinate to 0. Then the orbit contribution is

$$1 \cdot \overline{-1} + (-1) \cdot \overline{1} = -2.$$

All other displayed contributions vanish. □

Definition 9280.4 (Finite Mellin interpolation row)**.** *The test space $\mathcal{A}$ has the finite Mellin interpolation row when for every finite set of distinct complex points*

$$s_1, \ldots, s_M$$

and target values

$$a_1, \ldots, a_M$$

there is $f \in \mathcal{A}$ with

$$\widehat{f}(s_j) = a_j \qquad (1 \leq j \leq M).$$

In logarithmic coordinates this asks for a compactly supported smooth row ϕ with

$$\int_{-\infty}^{\infty} \phi(u) e^{s_j u}\, du = a_j.$$

Lemma 9280.5 (Translate packets give finite Mellin interpolation)**.** *Assume the logarithmic test space contains finite linear combinations of translates of a compactly supported smooth bump ψ whose Laplace transform*

$$\Psi(s) := \int_{-\infty}^{\infty} \psi(u) e^{su}\, du$$

is nonzero at $s_1, \ldots, s_M$. Then the finite Mellin interpolation row holds for these points.

Proof. Use test rows of the form

$$\phi(u) = \sum_{k=1}^{M} c_k \psi(u - T_k).$$

Their readout at s_j is

$$\int \phi(u) e^{s_j u}\, du = \Psi(s_j) \sum_{k=1}^{M} c_k e^{s_j T_k}.$$

The functions $T \mapsto e^{s_j T}$ are linearly independent for distinct s_j. Therefore one can choose $T_1, \ldots, T_M$ so that the evaluation matrix

$$\left(e^{s_j T_k}\right)_{j,k}$$

is invertible; otherwise the determinant would vanish for all choices of sample points and the displayed exponentials would be linearly dependent. The resulting finite linear system determines $c_1, \ldots, c_M$. □

Definition 9280.6 (Tail-controlled diagonal interpolation)**.** *The finite Mellin interpolation row is tail-controlled for a reflected finite zero ledger when the interpolating row can be chosen so that the regularized contribution of zeros outside the ledger is bounded by a displayed error constant. For the mirror value row of Definition 9280.3, the required bound is strictly smaller than the magnitude of the finite negative block.*

Theorem 9280.7 (Tail-controlled interpolation gives a negative Weil probe)**.** *Assume a reflected finite zero ledger contains a two-point reflected orbit and that the finite Mellin interpolation row is tail-controlled for the corresponding mirror value row. Then there exists $f \in \mathcal{A}$ with*

$$\mathcal{W}(f) < 0.$$

Proof. By Definition 9280.3, prescribe values on the finite ledger whose reflected block contribution is negative. By finite Mellin interpolation, choose a test row realizing these values. The tail-control row makes the regularized contribution from the complement smaller than the finite negative margin. Therefore the full Weil quadratic row is negative. □

Definition 9280.8 (Explicit formula Schur square)**.** *The source row*

ExplicitFormulaSchurSquare

asserts that every Schur residual of Definition 9279.9 is presented directly from the explicit-formula source rows as a norm square. In symbols, there are Hilbert spaces $\mathcal{H}_N$ and source-side linear readouts T_N such that

$$\mathcal{W}(\psi_{N+1}^{\perp}) = \|T_N \psi_{N+1}^{\perp}\|_{\mathcal{H}_N}^2.$$

The readout T_N must be constructed from the archimedean, prime, normalization, solenoid, Lee–Yang, Jensen, or trace-formula rows. It may not be obtained by first assuming the positivity of G_{N+1} and then factoring that matrix.

Theorem 9280.9 (Explicit formula Schur square gives square representation)**.** *If* ExplicitFormulaSchurSquare *holds, then*

SchurResidualSquareRepresentation

holds.

Proof. The row ExplicitFormulaSchurSquare supplies exactly the Hilbert spaces and source-side readouts required in Definition 9279.11, with

$$\Delta_N = \mathcal{W}(\psi_{N+1}^{\perp}) = \|T_N \psi_{N+1}^{\perp}\|_{\mathcal{H}_N}^2.$$

□

Corollary 9280.10 (Explicit formula Schur square gives global positivity)**.** *Assume $G_1 \succeq 0$, the Schur range rows, and the density and continuity rows of Definition 9279.3. If*

ExplicitFormulaSchurSquare

holds, then GlobalWeilPositivity *holds.*

Proof. By Definition 9280.9, the Schur residual square representation holds. Then Definition 9279.12 gives DiagonalSafeWeilInduction, and Definition 9279.8 gives GlobalWeilPositivity. □

Definition 9280.11 (Weil–Kolmogorov factorization)**.** *The source row*

$$\mathsf{WeilKolmogorovFactorization}$$

asserts the existence of a Hilbert space $\mathcal{H}$ and a linear source readout

$$\Theta : \mathcal{A} \to \mathcal{H}$$

such that the polarized Weil form satisfies

$$\mathcal{W}(f, g) = \langle \Theta f, \Theta g \rangle_{\mathcal{H}} \qquad (f, g \in \mathcal{A}).$$

The construction of Θ is source-side: it is not the operation of placing zero ordinates into a spectrum after fixed-half readout has already been obtained.

Theorem 9280.12 (Weil–Kolmogorov factorization gives Schur squares)**.** *If* WeilKolmogorovFactorization *holds, then*

$$\mathsf{SchurResidualSquareRepresentation}$$

holds for the golden Weil Gram tower.

Proof. Let Θ be the factorization map. The Gram matrix G_N is the ordinary Hilbert Gram matrix of

$$\Theta\psi_1, \ldots, \Theta\psi_N.$$

The residual row $\psi_{N+1}^{\perp}$ maps to the Hilbert residual of $\Theta\psi_{N+1}$ modulo the span of the earlier vectors. Therefore

$$\Delta_N = \mathcal{W}(\psi_{N+1}^{\perp}) = \|\Theta\psi_{N+1}^{\perp}\|_{\mathcal{H}}^2.$$

Taking T_N to be the restriction of Θ to the residual row gives the required square representation. □

Corollary 9280.13 (Weil–Kolmogorov factorization gives fixed-half readout)**.** *Assume the base, range, density, continuity, and Weil criterion consumption rows used above. If*

$$\mathsf{WeilKolmogorovFactorization}$$

holds, then the completed zeta zero ledger has fixed-half readout.

Proof. Definition 9280.12 gives SchurResidualSquareRepresentation. The square representation gives DiagonalSafeWeilInduction, hence GlobalWeilPositivity. The Weil criterion consumption row then returns fixed-half readout. □

Principle 9280.14 (Minimal diagonal-safe square target)**.** *The finite Gram route reduces the non-local obstruction to conditional energy rows:*

$$\Delta_N = a_N - b_N^* G_N^+ b_N.$$

The non-circular target is not a posterior factorization of a positive matrix. It is a source construction of the readouts T_N, or more globally of a Weil–Kolmogorov factorization. In named form the target chain is

WeilKolmogorovFactorization $\Longrightarrow$ SchurResidualSquareRepresentation $\Longrightarrow$ GlobalWeilPositivity $\Longrightarrow$ *fixed-half zero rea*

Chapter 9281

Golden Nyman Square Tower

chapter 9280 asks for a source-side square presentation of the conditional Weil energy rows. The Nyman–Beurling Hilbert container gives a more constructive square tower: finite positivity is supplied by the ambient space $L^2(0,1)$, while the remaining obligation is cofinal exhaustion of the constant row.

Definition 9281.1 (Nyman–Beurling generator)**.** *For $0 < \theta \le 1$ and $0 < x < 1$, define*

$$\rho_\theta(x) := \left\{\frac{\theta}{x}\right\} - \theta\left\{\frac{1}{x}\right\},$$

where $\{y\}$ denotes the fractional part of y. Let

$$\mathcal{H}_{\mathrm{NB}} := L^2(0,1), \qquad \mathbf{1}(x) := 1.$$

Definition 9281.2 (Finite Nyman Hilbert container)**.** *For $N \ge 1$, let*

$$V_N := \operatorname{span}\{\rho_1, \rho_{1/2}, \dots, \rho_{1/N}\} \subset \mathcal{H}_{\mathrm{NB}}.$$

Let P_N be the orthogonal projection onto V_N and define

$$d_N := \operatorname{dist}_{L^2}(\mathbf{1}, V_N) = \|\mathbf{1} - P_N\mathbf{1}\|_2.$$

Theorem 9281.3 (Finite Nyman Gram positivity)**.** *Let*

$$B_N := \Big(\langle \rho_{1/i}, \rho_{1/j}\rangle_{L^2(0,1)}\Big)_{1\le i,j\le N}.$$

Then $B_N \succeq 0$ for every N.

Proof. For $c = (c_1, \dots, c_N) \in \mathbb{C}^N$,

$$c^* B_N c = \left\|\sum_{j=1}^N c_j \rho_{1/j}\right\|_2^2 \ge 0.$$

Thus B_N is positive semidefinite. □

Definition 9281.4 (Nyman square drop)**.** *The Nth Nyman square drop is*

$$\Delta_N^{\mathrm{NB}} := d_N^2 - d_{N+1}^2.$$

Theorem 9281.5 (Nyman drops are Hilbert squares)**.** *For the nested spaces $V_N \subseteq V_{N+1}$,*

$$\Delta_N^{\mathrm{NB}} = \|P_{N+1}\mathbf{1} - P_N\mathbf{1}\|_2^2 \geq 0.$$

Proof. Since $V_N \subseteq V_{N+1}$, the projection $P_{N+1}\mathbf{1} - P_N\mathbf{1}$ is orthogonal to $\mathbf{1} - P_{N+1}\mathbf{1}$. Therefore

$$\mathbf{1} - P_N\mathbf{1} = (\mathbf{1} - P_{N+1}\mathbf{1}) + (P_{N+1}\mathbf{1} - P_N\mathbf{1})$$

is an orthogonal decomposition. Pythagoras gives

$$d_N^2 = d_{N+1}^2 + \|P_{N+1}\mathbf{1} - P_N\mathbf{1}\|_2^2,$$

which is the claimed square identity. □

Definition 9281.6 (Nyman exhaustion row)**.** *The source row*

$$\mathsf{NymanBeurlingExhaustion}$$

asserts that

$$\lim_{N\to\infty} d_N = 0.$$

Equivalently,

$$\mathbf{1} \in \overline{\operatorname{span}\{\rho_{1/n} : n \geq 1\}}^{L^2(0,1)}.$$

Definition 9281.7 (Nyman Mellin bridge row)**.** *The Nyman Mellin bridge row is the classical identity*

$$\int_0^1 \rho_\theta(x)x^{s-1}\,dx = \frac{(\theta - \theta^s)\zeta(s)}{s}, \qquad 0 < \mathrm{Re}(s) < 1.$$

It is consumed only as an analytic bridge between the Hilbert container and the zeta zero ledger.

Lemma 9281.8 (Off-half zero gives a Nyman separator)**.** *Assume the Nyman Mellin bridge row. If s_0 is a nontrivial zeta zero with $\mathrm{Re}(s_0) > 1/2$, then the functional*

$$L_{s_0}(f) := \int_0^1 f(x)x^{s_0-1}\,dx$$

is continuous on $L^2(0,1)$, vanishes on every $\rho_{1/n}$, and satisfies

$$L_{s_0}(\mathbf{1}) = \frac{1}{s_0} \neq 0.$$

Proof. Write $\sigma = \mathrm{Re}(s_0)$. Since $\sigma > 1/2$, the kernel $x^{\overline{s_0}-1}$ belongs to $L^2(0,1)$, so L_{s_0} is continuous by Cauchy–Schwarz. The Mellin bridge row and $\zeta(s_0) = 0$ give

$$L_{s_0}(\rho_{1/n}) = \frac{(n^{-1} - n^{-s_0})\zeta(s_0)}{s_0} = 0$$

for every $n \geq 1$. Direct integration gives

$$L_{s_0}(\mathbf{1}) = \int_0^1 x^{s_0-1}\,dx = \frac{1}{s_0},$$

which is nonzero for a nontrivial zero. □

Theorem 9281.9 (Nyman exhaustion gives fixed-half readout)**.** *Assume the Nyman Mellin bridge row and the usual reflection consumption row for the completed zeta zero ledger. If*

$$\mathsf{NymanBeurlingExhaustion}$$

holds, then the completed zeta zero ledger has fixed-half readout.

Proof. By Definition 9281.8, any zero with $\mathrm{Re}(s_0) > 1/2$ gives a continuous functional that annihilates each $\rho_{1/n}$ but does not annihilate $\mathbf{1}$. This contradicts

$$\mathbf{1} \in \overline{\mathrm{span}\{\rho_{1/n} : n \geq 1\}}^{L^2(0,1)}.$$

The reflection consumption row then rules out the opposite open side of the strip by reflecting it into the side already excluded. Thus the zero ledger reads through the fixed-half surface. □

Definition 9281.10 (Golden Nyman square tower)**.** *Let $(F_m)_{m\geq 1}$ be the Fibonacci scale sequence used by the golden resolution ledger. Define*

$$V_m^{\varphi} := \mathrm{span}\{\rho_{1/n} : 1 \leq n \leq F_m\}, \qquad d_m^{\varphi} := \mathrm{dist}_{L^2}(\mathbf{1}, V_m^{\varphi}).$$

The golden Nyman square drops are

$$\Delta_m^{\varphi,\mathrm{NB}} := (d_m^{\varphi})^2 - (d_{m+1}^{\varphi})^2.$$

Corollary 9281.11 (Golden Nyman drops are squares)**.** *For every m,*

$$\Delta_m^{\varphi,\mathrm{NB}} = \|P_{m+1}^{\varphi}\mathbf{1} - P_m^{\varphi}\mathbf{1}\|_2^2 \geq 0,$$

where P_m^{φ} denotes orthogonal projection onto V_m^{φ}.

Proof. Apply Definition 9281.5 to the nested subspaces

$$V_m^{\varphi} \subseteq V_{m+1}^{\varphi}.$$

□

Definition 9281.12 (Golden Nyman Gram exhaustion)**.** *Let*

$$G_m^{\varphi} := \Big(\langle \rho_{1/i}, \rho_{1/j}\rangle_{L^2(0,1)}\Big)_{1\leq i,j\leq F_m}$$

and

$$u_m := \Big(\langle \mathbf{1}, \rho_{1/i}\rangle_{L^2(0,1)}\Big)_{1\leq i\leq F_m}.$$

The source row

$$\mathsf{GoldenNymanGramExhaustion}$$

asserts the finite matrix limit

$$\lim_{m\to\infty}\Big(1 - u_m^*(G_m^{\varphi})^+ u_m\Big) = 0,$$

where $(G_m^{\varphi})^+$ is the Moore–Penrose inverse.

Theorem 9281.13 (Golden Gram row is the golden distance row)**.** *For every m,*

$$(d_m^{\varphi})^2 = 1 - u_m^*(G_m^{\varphi})^+ u_m.$$

Consequently, GoldenNymanGramExhaustion *is precisely the row $d_m^{\varphi} \to 0$.*

Proof. The vector u_m records the inner products of $\mathbf{1}$ with the finite generator list, and G_m^{φ} is the corresponding Gram matrix. The orthogonal projection of $\mathbf{1}$ onto V_m^{φ} has squared norm

$$\|P_m^{\varphi}\mathbf{1}\|_2^2 = u_m^*(G_m^{\varphi})^+ u_m,$$

with the Moore–Penrose inverse handling possible linear dependence in the displayed generator list. Since $\|\mathbf{1}\|_2^2 = 1$ and $\mathbf{1} - P_m^{\varphi}\mathbf{1}$ is orthogonal to $P_m^{\varphi}\mathbf{1}$, the displayed distance identity follows. □

Corollary 9281.14 (Golden Nyman exhaustion gives fixed-half readout)**.** *Assume the Nyman Mellin bridge row and the usual reflection consumption row for the completed zeta zero ledger. If*

GoldenNymanGramExhaustion

holds, then the completed zeta zero ledger has fixed-half readout.

Proof. By Definition 9281.13, GoldenNymanGramExhaustion gives $d_m^{\varphi} \to 0$. Since $F_m \to \infty$, the golden spaces form a cofinal reciprocal-parameter subtower of the Nyman spaces. Hence

$$\mathbf{1} \in \overline{\operatorname{span}\{\rho_{1/n} : n \geq 1\}}^{L^2(0,1)}.$$

Apply Definition 9281.9. □

Definition 9281.15 (Residue readback on reciprocal intervals)**.** *For $n \geq 1$ and $k \geq 1$, write*

$$r_n(k) := k - n\left\lfloor \frac{k}{n} \right\rfloor.$$

Thus $0 \leq r_n(k) < n$ and $r_n(k)$ is the residue of k modulo n.

Theorem 9281.16 (Nyman generators have residue normal form)**.** *If*

$$\frac{1}{x} = k + t, \qquad k \in \mathbb{N}_{\geq 1}, \qquad 0 \leq t < 1,$$

then

$$\rho_{1/n}(x) = \frac{r_n(k)}{n}.$$

Proof. Write $k = qn + r_n(k)$. Since $0 \leq r_n(k) + t < n$, one has

$$\left\{\frac{k+t}{n}\right\} = \frac{r_n(k) + t}{n}.$$

Also $\{1/x\} = t$. Therefore

$$\rho_{1/n}(x) = \left\{\frac{k+t}{n}\right\} - \frac{1}{n}\{k+t\} = \frac{r_n(k)+t}{n} - \frac{t}{n} = \frac{r_n(k)}{n}.$$

□

Theorem 9281.17 (Explicit Nyman Gram readback)**.** *For $i, j \geq 1$, the finite Nyman Gram entries and constant-vector entries are*

$$\langle \rho_{1/i}, \rho_{1/j} \rangle = \frac{1}{ij} \sum_{k=1}^{\infty} r_i(k) r_j(k) \left(\frac{1}{k} - \frac{1}{k+1} \right),$$

and

$$\langle \mathbf{1}, \rho_{1/j} \rangle = \frac{\log j}{j}.$$

Proof. Use the change of variables $y = 1/x$. Then $dx = y^{-2}\, dy$, and the interval $y \in [k, k+1)$ corresponds to

$$x \in \left(\frac{1}{k+1}, \frac{1}{k} \right].$$

By Definition 9281.16, the product $\rho_{1/i}\rho_{1/j}$ is constant on that interval with value $r_i(k)r_j(k)/(ij)$. Hence

$$\int_{1/(k+1)}^{1/k} \rho_{1/i}(x)\rho_{1/j}(x)\, dx = \frac{r_i(k)r_j(k)}{ij} \int_k^{k+1} \frac{dy}{y^2}.$$

Since

$$\int_k^{k+1} \frac{dy}{y^2} = \frac{1}{k} - \frac{1}{k+1},$$

the Gram formula follows by summing over k. The formula for $\langle \mathbf{1}, \rho_{1/j} \rangle$ is the removable $s \to 1$ limit of the Mellin bridge row

$$\frac{(j^{-1} - j^{-s})\zeta(s)}{s},$$

namely $j^{-1} \log j$. □

Definition 9281.18 (Explicit Nyman Gram exhaustion)**.** *Let G_N^{res} be the matrix with entries given by Definition 9281.17, and let*

$$u_N^{\mathrm{res}} := \left(\frac{\log 1}{1}, \frac{\log 2}{2}, \ldots, \frac{\log N}{N} \right)^T.$$

The row

$$\mathsf{ExplicitNymanGramExhaustion}$$

asserts

$$\lim_{N \to \infty} \left(1 - (u_N^{\mathrm{res}})^* (G_N^{\mathrm{res}})^+ u_N^{\mathrm{res}} \right) = 0.$$

Theorem 9281.19 (Explicit Nyman Gram exhaustion gives Nyman exhaustion)**.** *If* ExplicitNymanGramExhaustion *holds, then*

$$\mathsf{NymanBeurlingExhaustion}$$

holds.

Proof. Definition 9281.17 identifies G_N^{res} and u_N^{res} with the Gram matrix and constant-vector row of the finite space V_N. The same projection calculation used in Definition 9281.13 gives

$$d_N^2 = 1 - (u_N^{\mathrm{res}})^* (G_N^{\mathrm{res}})^+ u_N^{\mathrm{res}}.$$

The displayed limit is therefore exactly $d_N \to 0$. □

Definition 9281.20 (Damped Mobius Nyman exhaustion)**.** *Let μ denote the Mobius function. A damped Mobius Nyman row is a finite family of weights*

$$\omega_m : \{1, \dots, F_m\} \to \mathbb{C}$$

and the associated vector

$$A_m^{\varphi}(x) := -\sum_{n=1}^{F_m} \mu(n)\omega_m(n)\rho_{1/n}(x) \in V_m^{\varphi}.$$

The source row

$$\mathsf{DampedMobiusNymanExhaustion}$$

asserts that such weights can be chosen with

$$\|A_m^{\varphi} - \mathbf{1}\|_2 \to 0.$$

Theorem 9281.21 (Damped Mobius exhaustion gives golden Gram exhaustion)**.** *If* DampedMobiusNymanExhausti *holds, then*

$$\mathsf{GoldenNymanGramExhaustion}$$

holds.

Proof. Since $A_m^{\varphi} \in V_m^{\varphi}$,

$$d_m^{\varphi} \le \|A_m^{\varphi} - \mathbf{1}\|_2.$$

The right side tends to 0, so $d_m^{\varphi} \to 0$. By Definition 9281.13, this is GoldenNymanGramExhaustion. □

Principle 9281.22 (Mobius truncation as obstruction detector)**.** *The undamped choice $\omega_m(n) = 1$ exposes the arithmetic load hidden inside the Hilbert exhaustion row. On intervals with $1/x \in [k, k+1)$ and $k \le N$, the raw sum*

$$-\sum_{n=1}^{N} \mu(n)\rho_{1/n}(x)$$

differs from $\mathbf{1}$ by the scalar

$$-k\sum_{n=1}^{N} \frac{\mu(n)}{n}.$$

Thus the low reciprocal blocks already demand cancellation in the weighted Mobius average. The damped row is therefore not an external shortcut; it is a finite Hilbert-space target that keeps the tail ledger visible.

Principle 9281.23 (Constructive square target)**.** *The Nyman square tower relocates the non-circular part of the finite positive-container route. Finite positive semidefiniteness is no longer the active burden: it is the ordinary Hilbert Gram fact Definition 9281.3. The active burden is the cofinality row*

$$\mathsf{GoldenNymanGramExhaustion}.$$

Thus the target chain is

$$\mathsf{DampedMobiusNymanExhaustion} \Longrightarrow \mathsf{GoldenNymanGramExhaustion} \Longrightarrow \mathsf{NymanBeurlingExhaustion} \Longrightarrow \textit{fixed-half ze}$$

with the Mellin bridge and reflection consumption rows displayed as analytic interfaces rather than hidden positivity assumptions.

Chapter 9282

Mobius Nyman Mollifier Bounds

chapter 9281 reduces the Hilbert container route to the finite row

$$\mathsf{DampedMobiusNymanExhaustion}.$$

The present chapter records a more inspectable sufficient package for that row. It separates the reciprocal interval computation into a low block controlled by a smoothed Mobius average and a tail block governed by weighted residue orthogonality.

Definition 9282.1 (Dirichlet mollifier readout)**.** *Let μ denote the Mobius function. For a finite damping row*

$$w_X : \mathbb{N}_{\geq 1} \to \mathbb{C}$$

with finite support, define the Dirichlet mollifier

$$A_X(s) := \sum_{n\geq 1} \mu(n) w_X(n) n^{-s}$$

and its Nyman readout

$$M_X(x) := -\sum_{n\geq 1} \mu(n) w_X(n) \rho_{1/n}(x).$$

The support condition makes M_X a finite Nyman vector.

Definition 9282.2 (Mellin mollifier error row)**.** *For $0 < \mathrm{Re}(s) < 1$, the Mellin bridge of Definition 9281.7 gives*

$$\int_0^1 M_X(x) x^{s-1}\, dx = -\frac{\zeta(s)}{s} \sum_{n\geq 1} \mu(n) w_X(n)(n^{-1} - n^{-s}).$$

Thus the error against $\mathbf{1}$ has Mellin readout

$$\int_0^1 (M_X(x) - \mathbf{1}) x^{s-1}\, dx = -\frac{1}{s} - \frac{\zeta(s)}{s} \sum_{n\geq 1} \mu(n) w_X(n)(n^{-1} - n^{-s}).$$

This row is only an analytic diagnostic; the Hilbert proof obligations below are stated directly in $L^2(0,1)$.

Definition 9282.3 (Golden damped Mobius readout)**.** *For the Fibonacci scale F_m, a golden damping row is a finitely supported weight*

$$w_m : \mathbb{N}_{\geq 1} \to \mathbb{C}$$

whose support is contained in a displayed finite multiple of F_m. It defines

$$M_m^{\varphi}(x) := -\sum_{n\geq 1} \mu(n) w_m(n) \rho_{1/n}(x).$$

The row

GoldenDampedMobiusExhaustion

asserts

$$\|M_m^{\varphi} - \mathbf{1}\|_2 \to 0.$$

Theorem 9282.4 (Golden damped Mobius exhaustion gives golden Nyman exhaustion)**.** *If* GoldenDampedMobiusE *holds and each M_m^{φ} belongs to V_m^{φ}, then*

GoldenNymanGramExhaustion

holds.

Proof. The distance from $\mathbf{1}$ to V_m^{φ} is bounded by the error of any displayed vector in V_m^{φ}. Hence

$$d_m^{\varphi} \leq \|M_m^{\varphi} - \mathbf{1}\|_2.$$

The right side tends to 0. Apply Definition 9281.13. □

Definition 9282.5 (Golden Mobius low block)**.** *For a golden damping row w_m, define*

$$S_m := \sum_{n\geq 1} \frac{\mu(n) w_m(n)}{n}.$$

The low-block bound is

$$F_m |S_m|^2 \to 0.$$

Definition 9282.6 (Golden residue tail block)**.** *Using $r_n(k)$ from Definition 9281.15, define the tail error*

$$T_m := \sum_{k>F_m} \left| 1 + \sum_{n\geq 1} \mu(n) w_m(n) \frac{r_n(k)}{n} \right|^2 \left(\frac{1}{k} - \frac{1}{k+1} \right).$$

The residue tail bound is

$$T_m \to 0.$$

Definition 9282.7 (Golden Mobius low-tail bounds)**.** *The source row*

GoldenMobiusLowTailBounds

asserts the existence of golden damping rows w_m such that the low-block bound of Definition 9282.5 and the tail bound of Definition 9282.6 both hold.

Lemma 9282.8 (Low block bound controls the displayed low intervals)**.** *Assume $w_m(n) = 1$ for $1 \le n \le F_m$. On reciprocal intervals with $1/x \in [k, k+1)$ and $k \le F_m$, the low-block contribution to $M_m^{\varphi}(x) - \mathbf{1}$ is*

$$-kS_m.$$

Consequently, its L^2 contribution is bounded by

$$F_m|S_m|^2.$$

Proof. By Definition 9281.16,

$$\rho_{1/n}(x) = \frac{r_n(k)}{n}.$$

For $k \le F_m$ and $n \le F_m$,

$$r_n(k) = k - n\left\lfloor \frac{k}{n} \right\rfloor.$$

Therefore the raw low block reads

$$-\sum_{n \le F_m} \mu(n)\frac{r_n(k)}{n} = -k \sum_{n \le F_m} \frac{\mu(n)}{n} + \sum_{n \le k} \mu(n)\left\lfloor \frac{k}{n} \right\rfloor.$$

The divisor identity gives

$$\sum_{n \le k} \mu(n)\left\lfloor \frac{k}{n} \right\rfloor = 1.$$

After subtracting $\mathbf{1}$, the displayed low error is $-kS_m$. The interval weight is

$$\int_k^{k+1} \frac{dy}{y^2} = \frac{1}{k} - \frac{1}{k+1},$$

so

$$\sum_{k \le F_m} k^2|S_m|^2\left(\frac{1}{k} - \frac{1}{k+1}\right) \le F_m|S_m|^2.$$

□

Theorem 9282.9 (Low-tail bounds give golden damped Mobius exhaustion)**.** *If* GoldenMobiusLowTailBounds *holds and the damping rows have unit low block $w_m(n) = 1$ for $n \le F_m$, then*

GoldenDampedMobiusExhaustion

holds.

Proof. Split the L^2 norm of $M_m^{\varphi} - \mathbf{1}$ along the reciprocal intervals $1/x \in [k, k+1)$. The part with $k \le F_m$ tends to 0 by Definition 9282.8 and the low-block bound. The part with $k > F_m$ is exactly the tail quantity T_m, hence tends to 0 by the residue tail bound. Therefore

$$\|M_m^{\varphi} - \mathbf{1}\|_2 \to 0.$$

□

Corollary 9282.10 (Low-tail bounds give fixed-half readout)**.** *Assume* GoldenMobiusLowTailBounds*, unit low blocks, and the Mellin and reflection consumption rows of Definition 9281.9. Then the completed zeta zero ledger has fixed-half readout.*

Proof. Definition 9282.9 gives GoldenDampedMobiusExhaustion. The vectors lie in the golden Nyman spaces, so Definition 9282.4 gives GoldenNymanGramExhaustion. Finally apply Definition 9281.14. □

Principle 9282.11 (Mobius residue orthogonality target)**.** *The low-tail package isolates the remaining analytic burden. The low row asks for sufficient cancellation of the smoothed Mobius average*

$$\sum_{n\geq 1} \frac{\mu(n)w_m(n)}{n},$$

while the tail row asks for weighted orthogonality between $\mu(n)w_m(n)$ and the residue readbacks $r_n(k)/n$ on the reciprocal tail. In named form the target chain is

GoldenMobiusLowTailBounds $\Longrightarrow$ GoldenDampedMobiusExhaustion $\Longrightarrow$ GoldenNymanGramExhaustion $\Longrightarrow$ *fixed-half*

Chapter 9283

BEDC–Golden–Zeta Generation Machine

chapter 9351 supplies the raw mark-history kernel, chapter 9255 supplies the RH-free zero-generation interface, chapter 9259 supplies the golden resolution tower, and chapter 9260 isolates the Lee–Yang bridge. The present chapter records the composite machine obtained by placing those rows in one source order. It is a conditional interface: the fixed-half readout is produced only after the source rows listed below have been supplied.

Definition 9283.1 (BEDC–Golden–Zeta generation machine)**.** *A* BEDC–Golden–Zeta generation machine *is a finite-to-limit source packet*

$$\mathfrak{M}_\zeta$$

with the following displayed rows.

The kernel row is the raw mark and history spine

$$\mathsf{b0}, \mathsf{b1} \longrightarrow \mathsf{BHist}$$

of Definition 9351.1, equipped with the one-step time row of Definition 9361.15. Thus time is constructor-tail generation over histories rather than an ambient parameter.

The zero row is an RH-free generated zero carrier

$$Z = \mu F_Z$$

with a realization

$$\varepsilon : Z \to \mathcal{Z}_\zeta$$

as in Definition 9255.2. Its source completeness row is the essential coverage component

$$\prod_{u:\mathcal{Z}_\zeta} \sum_{z:Z} \varepsilon(z) \sim u.$$

The arithmetic row assigns active heights

$$h_a > 0$$

from the logarithmic prime or integer ledger, so that centered zeta channels have the form

$$U_a(s) := e^{-(s-1/2)h_a}.$$

The resolution row is a golden resolution ruler

$$\delta_m = \varphi^{-m}, \qquad N_m = F_{Lm},$$

with Zeckendorf truncation ledgers, as in Definition 9259.10 and Definition 9259.11.

The certificate row is a compatible resolution certificate tower in the sense of Definition 9259.5, carrying the triadic invariant of Definition 9257.20 at every displayed level.

The bridge row is a cofinal family of golden Lee–Yang bridge witnesses in the sense of Definition 9260.3. This row connects the weak eta capture packet to a lifted Fibonacci path packet with the same zero-island readout.

The defect row is the scale-energy extraction

$$E_m(s) = r^2 W_m + o(W_m), \qquad W_m \to \infty,$$

for readouts

$$s = \frac{1}{2} + r + it.$$

Definition 9283.2 (Constructive layer witness)**.** *A* constructive layer witness *for a machine level is a quadruple*

$$(O, G, I, F).$$

Here O is the displayed object row, G is the generator row producing that object from the previous layer, I is the invariant transported by the generator, and F is the projection-loss row recording what the current layer forgets when read by the next visible observer. The loss row is a ledger, not a license to introduce hidden structure.

Definition 9283.3 (Constructive BEDC–Golden–Zeta machine)**.** *A* constructive BEDC–Golden–Zeta machine *is a BEDC–Golden–Zeta generation machine together with constructive layer witnesses for the source chain*

$$\mathsf{BMark} \to \mathsf{BHist} \to \mathsf{Time} \to \mathsf{PrimeLedger} \to \mathsf{Hamiltonian} \to \mathsf{GoldenResolution} \to \mathsf{EtaPacket} \to \mathsf{ZeckendorfPacket} \to \mathsf{S}$$

Each transition must be generated from the preceding object and the triadic invariant rows. A later layer may inspect the projection loss of an earlier layer only through the displayed ledger F; it may not repair that loss by importing an ungenerated coordinate.

Definition 9283.4 (Machine legality)**.** *The machine $\mathfrak{M}_\zeta$ is* legal *when its hidden coordinates are confined to the compact phase row and finite prime-register fibres:*

$$\mathbb{T}, \qquad \prod_{p \in S} \mathbb{Z}_p,$$

and when no constructor, bridge comparison, tail row, or limit socket imports an independent real positive closure coordinate

$$\mathbb{R}_{>0}.$$

Equivalently, the only admissible readback of

$$U_a(s) = e^{-rh_a} e^{-ith_a}$$

inside the closed machine treats e^{-ith_a} as phase data and requires e^{-rh_a} to be accounted for by the defect ledger rather than absorbed as gauge.

Principle 9283.5 (No downstream smuggling)**.** *In a constructive BEDC–Golden–Zeta machine, no layer after a projection may supply data that the previous generator did not produce. Thus a Lee–Yang boundary row may stabilize an eta zero island only through a displayed same-island bridge; it may not choose a stable packet after the zero is known. A solenoid row may hide only phase and prime-register fibres; it may not supply a real positive scale coordinate. A limit row may read a compatible tower; it may not add an external zero presentation. This is the layerwise form of machine legality.*

Definition 9283.6 (Internal golden ruler)**.** *An* internal golden ruler *at level m is the row*

$$\mathcal{R}_m := (\delta_m, N_m, Z_m)$$

where

$$\delta_m = \varphi^{-m}, \qquad N_m = F_{Lm},$$

and Z_m is the Zeckendorf resolution ledger of Definition 9259.11 for N_m. It is internal when the following three rows are generated inside the same BEDC packet.

The P *row is Zeckendorf source uniqueness: the Fibonacci-block address of N_m is not replaceable by another unledgered truncation source.*

The U *row is the no-adjacent path boundary: the digits of Z_m lie in the stable Zeckendorf window, hence in the path carrier used by Definition 9260.1. This supplies the unit-boundary source for the later Lee–Yang lift; it does not by itself prove zeta boundary stability.*

The T *row is Fibonacci refinement:*

$$\mathcal{R}_m \rightsquigarrow \mathcal{R}_{m+1},$$

read as another level of the same generated ruler rather than as a change of external measurement.

Definition 9283.7 (Triadic ruler invariance)**.** *A family of internal golden rulers*

$$(\mathcal{R}_m)_{m\geq 0}$$

satisfies triadic ruler invariance *when every ruler level carries the* P, U, *and* T *rows of Definition 9283.6, and every refinement map*

$$\mathcal{R}_m \rightsquigarrow \mathcal{R}_{m+1}$$

transports those rows. The ruler is then part of the generated system: it is not an outside observer, and it cannot supply an outside $\mathbb{R}_{>0}$ scale ledger.

Principle 9283.8 (Machine source order)**.** *The source order of Definition 9283.1 is strict. Raw marks generate histories. Histories provide the time row. The generated zero carrier supplies the zero-presentation surface. The prime ledger supplies logarithmic heights. The golden ruler supplies finite resolution. Weak eta capture supplies local zero islands. The Lee–Yang bridge supplies boundary stability for the same islands. The defect-energy row then turns any off-half radial coordinate into an unbounded normal-energy readout. No later row may be used as an unledgered source for an earlier row.*

Theorem 9283.9 (Constructive layer discipline preserves legality)**.** *Let a constructive BEDC–Golden–Zeta machine have legal first layer, and assume every generator row transports the triadic invariant and obeys Definition 9283.5. Then every displayed layer of the machine is legal in the sense needed by Definition 9283.4.*

Proof. Proceed by induction along the displayed source chain of Definition 9283.3. The base layer is legal by hypothesis. For the induction step, assume the preceding layer is legal. The generator row transports the source, unit-boundary, and time invariants to the next layer. The projection-loss ledger records exactly what becomes invisible at that transition, while Definition 9283.5 forbids the next layer from replacing that loss by an ungenerated coordinate. Hence the compact phase and prime-register boundaries remain the only hidden gauges, and no $\mathbb{R}_{>0}$ closure coordinate is introduced. This is precisely the legality condition for the next layer. □

Principle 9283.10 (Internal rulers remove the measurement escape)**.** *If the golden ruler is external, a failure of the route could be hidden in the choice of resolution, truncation, or refinement schedule. If the ruler is internal and satisfies Definition 9283.7, the measuring rows themselves are subject to the same source, boundary, and time invariants as the zero certificate tower. Thus an off-half radial factor cannot be reclassified as a feature of measurement; it must appear in the defect ledger of the same closed machine.*

Theorem 9283.11 (Legal generation machines exclude radial limits)**.** *Let a legal BEDC–Golden–Zeta generation machine produce a completed zero certificate tower with limit readout*

$$s_\infty = \frac{1}{2} + r + it.$$

If its bridge witnesses supply zero-compatible boundary bounds and its defect row satisfies

$$E_m(s_\infty) = r^2 W_m + o(W_m), \qquad W_m \to \infty,$$

then $r = 0$.

Proof. The certificate row of the machine is a resolution certificate tower. The bridge row supplies the boundary-stability component by Definition 9260.17; the legality row supplies the refusal of hidden real-positive scale gauge; the defect row supplies cofinal growth and scale-energy extraction. Thus the tower is legal boundary-stable in the sense of Definition 9257.22. Applying Definition 9257.23 gives $r = 0$. □

Theorem 9283.12 (Internal ruler invariance excludes measurement exceptions)**.** *Let a BEDC–Golden–Zeta generation machine be legal, and assume its golden ruler family satisfies triadic ruler invariance. If each zero certificate level is generated from the corresponding internal ruler level and the tower satisfies the defect extraction and boundary-bound rows of Definition 9283.11, then its limit readout has* $r = 0$.

Proof. By triadic ruler invariance, every refinement level of the ruler carries the P, U, and T rows and transports them to the next level. Since each certificate level is generated from the corresponding ruler level, the certificate tower cannot appeal to an external resolution row, external truncation row, or external scale row. The only visible off-half component of

$$e^{-(s-1/2)h_a} = e^{-rh_a} e^{-ith_a}$$

is therefore the defect term e^{-rh_a} recorded by the same machine. The hypotheses then reduce exactly to the legal generation-machine exclusion of Definition 9283.11, which gives $r = 0$. □

Definition 9283.13 (BEDC–Golden–Zeta source row)**.** *The source row*

$$\mathsf{BEDCGoldenZetaMachine}_\zeta$$

asserts that every accepted non-trivial completed zeta zero is presented by a legal BEDC–Golden–Zeta generation machine whose sufficiently fine levels carry compatible golden Lee–Yang bridge witnesses.

Definition 9283.14 (Constructive machine source row)**.** *The source row*

$$\mathsf{ConstructiveBEDCGoldenZetaMachine}_\zeta$$

asserts that every accepted non-trivial completed zeta zero is presented by a constructive BEDC–Golden–Zeta machine whose layer witnesses obey Definition 9283.5, whose golden ruler satisfies triadic ruler invariance, and whose sufficiently fine levels carry compatible golden Lee–Yang bridge witnesses.

Definition 9283.15 (Zeta constraint container)**.** *Let Λ be the ledger of a compatible golden zero-certificate tower. A* zeta constraint container *is the specialization of Definition 9462.991 to the RH-facing candidate class*

$$\mathcal{G}_{\zeta,\varphi}$$

whose visible candidates include the critical container

$$\Gamma_{\mathrm{crit}} := \{s : \Re(s) = 1/2\}$$

and the radial containers

$$\Gamma_r := \{s : \Re(s) = 1/2 + r\}, \qquad r \neq 0.$$

Its probe row reads zero-island capture, Rouché or winding data, phase, prime-register fibres, Zeckendorf resolution ledgers, boundary stability, and defect energy. Its gauge row may contain only compact phase, finite prime-register, and Zeckendorf-ledger freedoms already displayed by the machine. The container is therefore a stabilized closure of ledger constraints, not a prior host line into which zeros are placed.

Definition 9283.16 (Zeta critical-container forcing)**.** *For the limit ledger Λ_∞ of a compatible golden zero-certificate tower, write*

$$\Lambda_\infty \Vdash_{\zeta,\varphi} [\Gamma_{\mathrm{crit}}]$$

when Γ_{crit} realizes the ledger and every candidate

$$\Delta \in \mathcal{G}_{\zeta,\varphi}$$

realizing the same ledger has the same probe readout as Γ_{crit} across the probe row of Definition 9283.15, modulo only the displayed compact phase, prime-register, and Zeckendorf gauge rows. Equivalence at the completed-zero readout means that every presentation carried by Δ has $r = 0$ in

$$s = \frac{1}{2} + r + it.$$

Theorem 9283.17 (Constructive source rows imply machine source rows)**.** *If*

$$\mathsf{ConstructiveBEDCGoldenZetaMachine}_\zeta$$

holds, then

$$\mathsf{BEDCGoldenZetaMachine}_\zeta$$

holds.

Proof. The constructive source row supplies, for every accepted non-trivial completed zeta zero, a constructive BEDC–Golden–Zeta machine. By Definition 9283.9, its layers are legal. The same source row also supplies triadic ruler invariance and compatible golden Lee–Yang bridge witnesses. Forgetting the displayed layer-witness quadruples leaves exactly the legal BEDC–Golden–Zeta generation machine required by Definition 9283.13. □

Corollary 9283.18 (The machine source row gives fixed-half readout)**.** *If*

$$\mathsf{BEDCGoldenZetaMachine}_\zeta$$

holds, then every accepted non-trivial completed zeta zero has fixed-half readout.

Proof. Let an accepted non-trivial completed zeta zero be given. The source row supplies a legal generation machine presenting it. By Definition 9283.11, its limit readout has $r = 0$ in the decomposition

$$s_\infty = \frac{1}{2} + r + it.$$

Therefore $\Re(s_\infty) = 1/2$. □

Corollary 9283.19 (Constructive machine source rows give fixed-half readout)**.** *If*

$$\mathsf{ConstructiveBEDCGoldenZetaMachine}_\zeta$$

holds, then every accepted non-trivial completed zeta zero has fixed-half readout.

Proof. Apply Definition 9283.17, then Definition 9283.18. □

Theorem 9283.20 (Constructive machines force the critical container)**.** *If*

$$\mathsf{ConstructiveBEDCGoldenZetaMachine}_\zeta$$

holds, then the limit ledger of every accepted non-trivial completed zeta zero satisfies

$$\Lambda_\infty \Vdash_{\zeta,\varphi} [\Gamma_{\mathrm{crit}}].$$

Proof. Fix an accepted non-trivial completed zeta zero and its limit ledger. The constructive source row supplies a constructive BEDC–Golden–Zeta machine for this zero. By Definition 9283.9, all displayed layers are legal, and by Definition 9283.17 the underlying legal generation-machine source row is present.

Let $\Delta \in \mathcal{G}_{\zeta,\varphi}$ realize the same limit ledger. If the readout of Δ has

$$s = \frac{1}{2} + r + it$$

with $r \neq 0$, then the defect row of the machine gives the radial energy extraction

$$E_m(s) = r^2 W_m + o(W_m), \qquad W_m \to \infty,$$

while the compatible golden Lee–Yang bridge witnesses supply the zero-compatible boundary bound. Since Δ realizes the same ledger, it must realize these rows with the same legal gauge restrictions. Thus the Δ-readout satisfies the hypotheses of Definition 9283.11, which forces $r = 0$, a contradiction. Hence every surviving candidate has fixed-half readout. The remaining invisible rows are exactly the displayed compact phase, prime-register, and Zeckendorf gauge rows, so all surviving candidates have the same probe readout as Γ_{crit} on the probes of Definition 9283.15. This is the forcing judgment of Definition 9283.16. □

Principle 9283.21 (Machine proof load)**.** *The machine formulation separates the proof load into source rows. The kernel and history rows are supplied by the BEDC spine. The golden resolution and weak eta capture rows are supplied by the local Rouché construction of Definition 9259.14. The strong source content has three coupled parts: constructive layer witnesses with no downstream smuggling, triadic ruler invariance for the golden resolution row, and compatible golden Lee–Yang bridge witnesses for the same zero islands, including dominance, same-island transfer, radial purity, and far-end energy control. Those rows are the mathematical content of*

$$\mathsf{BEDCGoldenZetaMachine}_{\zeta}.$$

Under those rows, the public geometric readout is the derived constraint container judgment

$$\Lambda_{\infty} \Vdash_{\zeta,\varphi} [\Gamma_{\mathrm{crit}}],$$

not an initial assumption that zero certificates already live on the critical line.

Chapter 9284

Internal Ruler Constraint Container

chapter 9283 packages the BEDC–Golden–Zeta machine, while Definition 9462.991 supplies the general constraint-container interface. The present chapter records the common source row in which the golden ruler is itself part of the generated container. The point is not to place zero certificates inside a prior critical-line host; the point is to make the internal ruler, the zero-certificate tower, and the surviving candidate container use the same source, boundary, and time ledgers.

Definition 9284.1 (Container-mature internal ruler)**.** *Let*

$$(\mathcal{R}_m)_{m\geq 0}$$

be an internal golden ruler family in the sense of Definition 9283.6. It is container-mature for a zero-certificate tower *when the following rows are present.*

The source row is triadic ruler invariance:

$$\mathcal{R}_m \rightsquigarrow \mathcal{R}_{m+1}$$

transports the P, U, *and* T *rows of Definition 9283.7.*

The weak capture row is a cofinal family of golden eta packets

$$\mathcal{G}_m(\rho) = (D_m, P_m, R_m, \Gamma_m)$$

as in Definition 9259.13, with the Rouché boundary gap supplied by Definition 9259.14 where its hypotheses apply.

The boundary row is a cofinal family of golden Lee–Yang bridge witnesses in the sense of Definition 9260.3. Thus the same zero-island ledger has a lifted path packet, a Lee–Yang unit-boundary certificate, same-island transfer, radial purity, and dominance.

The audit row records projection loss through the displayed Zeckendorf, prime-register, phase, tail, boundary, and defect ledgers. It does not allow the ruler to supply an independent real-positive scale coordinate.

Definition 9284.2 (Internal-ruler constraint container package)**.** *An* internal-ruler constraint container package *for a completed zeta zero readout consists of:*

- *a constructive BEDC–Golden–Zeta machine in the sense of Definition 9283.3;*
- *a container-mature internal ruler family* $(\mathcal{R}_m)_{m\geq 0}$*;*
- *a compatible zero-certificate tower generated levelwise from* $\mathcal{R}_m$*;*

- *the zeta constraint container of Definition 9283.15 for the limit ledger Λ_∞;*
- *the defect extraction and cofinal active-height rows*

$$E_m(s) = r^2 W_m + o(W_m), \qquad W_m \to \infty,$$

for readouts

$$s = \frac{1}{2} + r + it.$$

Principle 9284.3 (The ruler cannot be the scale reservoir)**.** *In an internal-ruler constraint container package, the ruler is part of the audited container rather than an outside measurement device. Hence an off-half factor*

$$e^{-rh_a} \in \mathbb{R}_{>0}$$

cannot be reclassified as a choice of resolution, truncation schedule, Zeckendorf address, or path-model lift. The only admissible hidden rows are the displayed compact phase row, the finite prime-register fibres, and the Zeckendorf ledger rows. Any real-positive radial factor must therefore appear in the defect-energy ledger.

Theorem 9284.4 (Internal-ruler containers exclude radial readouts)**.** *Let an internal-ruler constraint container package have limit readout*

$$s_\infty = \frac{1}{2} + r + it.$$

Then $r = 0$.

Proof. The package contains a constructive BEDC–Golden–Zeta machine and a container-mature internal ruler family. By Definition 9283.9, the displayed layers are legal. By Definition 9284.1, the ruler transports the triadic rows and does not supply an independent $\mathbb{R}_{>0}$ gauge. Thus Definition 9284.3 forces any off-half factor to be read through the defect ledger.

The same package supplies the golden Lee–Yang bridge witnesses, hence the zero-compatible boundary bound, and it also supplies

$$E_m(s_\infty) = r^2 W_m + o(W_m), \qquad W_m \to \infty.$$

These are exactly the hypotheses of Definition 9283.11. Therefore $r = 0$. □

Definition 9284.5 (Internal-ruler constraint-container source row)**.** *The source row*

$$\mathsf{InternalRulerConstraintContainer}_{\zeta,\varphi}$$

asserts that every accepted non-trivial completed zeta zero is presented by an internal-ruler constraint container package.

Definition 9284.6 (Internal golden ruler zeta certificate)**.** *The source row*

$$\mathsf{InternalGoldenRulerZetaCertificate}_{\zeta,\varphi}$$

asserts that every accepted non-trivial completed zeta zero has a cofinal golden eta certificate tower whose ruler family is internal and container-mature, whose Zeckendorf truncation ledgers are unique under refinement, and whose sufficiently fine levels carry golden Lee–Yang bridge witnesses compatible with the same zero island.

Definition 9284.7 (Golden zeta constraint-container route)**.** *The named route*

$$\mathrm{ConstraintContainer}^{\uparrow}_{\zeta,\varphi}$$

is the conjunction of the following source rows:

$$\mathsf{GoldenCoverage}_{\zeta,\varphi}, \qquad \mathsf{InternalGoldenRuler}_{\varphi}, \qquad \mathsf{ZetaGoldenLeeYangBridge}, \qquad \mathsf{CofinalGrowth}_{\zeta,\varphi}.$$

Here $\mathsf{GoldenCoverage}_{\zeta,\varphi}$ *means that accepted non-trivial completed zeta zeros enter golden BEDC certificate towers;* $\mathsf{InternalGoldenRuler}_{\varphi}$ *means that the ruler family is generated internally and transports the triadic rows; the bridge row is the same-island Lee–Yang source row; and the growth row is the cofinal active-height condition*

$$W_m \to \infty.$$

Definition 9284.8 (Golden bridge analytic subrows)**.** *The analytic content of* $\mathsf{ZetaGoldenLeeYangBridge}$ *is the source package of Definition 9260.16. The dominance-facing part is the row*

$$\mathsf{GoldenDominantBranchTheorem}$$

which is supplied only after a golden spectral expansion and spectral gap have selected the Zeckendorf–Fibonacci path packet as the zero-relevant branch by source, dominance, and tail ledgers. The boundary-facing part is the row

$$\mathsf{GoldenStableRoucheHomotopy}$$

which supplies a boundary-nonvanishing homotopy from the golden eta packet to the lifted path packet on the same zero island, while also preserving the strict inside and strict outside Lee–Yang zero-free regions. These rows are source obligations; none follows from the existence of a golden ruler alone.

Definition 9284.9 (Window-six finite audit anchor)**.** *The source row*

$$\mathsf{WindowSixFiniteAnchor}_{\zeta,\varphi}$$

admits the Window-six finite audit laboratory of Definition 9349.10 as the finite anchor for the golden zeta container route. It consists of the following finite records.

The visible-address record is

$$|X_6| = F_8 = 21,$$

with X_6 *the sixth no-adjacent Zeckendorf window of Definition 9347.1. The ambient fold record is*

$$\Omega_6 = \{0,1\}^6 \longrightarrow X_6, \qquad |\Omega_6| = 64.$$

The hidden-fibre histogram record is

$$d_6(x) \in \{2,3,4\},$$

with

$$\#\{x : d_6(x) = 2\} = 8, \qquad \#\{x : d_6(x) = 3\} = 4, \qquad \#\{x : d_6(x) = 4\} = 9,$$

so that

$$8 \cdot 2 + 4 \cdot 3 + 9 \cdot 4 = 64.$$

The visible-insufficiency record is the strict inequality

$$\dim_{\mathbb{C}} Z_6^{(3)} \leq 12 < 21 = |X_6|.$$

The oriented-boundary record keeps boundary-sheet parity as an integral or mod-2 ledger row, not as data visible in the rational continuous envelope. The moment-audit record requires signed moments for the phase-character sectors to reconstruct the displayed hidden-fibre histogram without exposing every ambient microstate.

The scope record is part of the source row: this finite anchor supplies a visible-insufficiency, hidden-fibre, parity, and signed-moment audit model. It does not supply zeta zero coverage, golden propagation, same-island Lee–Yang transport, cofinal growth, or an infinite boundary-stability theorem.

Definition 9284.10 (Golden propagation source row)**.** *The source row*

$$\mathsf{GoldenPropagation}_{\zeta,\varphi}$$

asserts that the finite audit structure displayed by $\mathsf{WindowSixFiniteAnchor}_{\zeta,\varphi}$ *is transported to the cofinal golden certificate tower used by the zeta route. It contains the internal-ruler row*

$$\mathsf{InternalGoldenRuler}_{\varphi},$$

preserves Zeckendorf ledger uniqueness under refinement, keeps hidden-fibre audit data through the tower, transports oriented boundary parity by discrete ledger rows, and refuses any replacement of these rows by a real-positive radial scale coordinate. This row is not a consequence of Window six alone; it is the propagation obligation that connects the finite anchor to cofinal golden resolution.

Theorem 9284.11 (Window-six anchored rows supply the golden container route)**.** *If*

$$\mathsf{WindowSixFiniteAnchor}_{\zeta,\varphi}, \quad \mathsf{GoldenPropagation}_{\zeta,\varphi}, \quad \mathsf{GoldenCoverage}_{\zeta,\varphi}, \quad \mathsf{ZetaGoldenLeeYangBridge}, \quad \mathsf{C}$$

hold, then

$$\mathrm{ConstraintContainer}^{\uparrow}_{\zeta,\varphi}$$

holds.

Proof. By Definition 9284.10, the propagation row contains

$$\mathsf{InternalGoldenRuler}_{\varphi}.$$

Together with the displayed golden coverage, golden Lee–Yang bridge, and cofinal growth rows, this is exactly the conjunction defining

$$\mathrm{ConstraintContainer}^{\uparrow}_{\zeta,\varphi}$$

in Definition 9284.7. The Window-six row supplies the finite audit anchor for that propagation obligation, while the infinite route is supplied only by the listed cofinal and bridge rows. □

Corollary 9284.12 (Window-six anchored rows force the critical container)**.** *Under the hypotheses of Definition 9284.11, the limit ledger of every accepted non-trivial completed zeta zero satisfies*

$$\Lambda_\infty \Vdash_{\zeta,\varphi} [\Gamma_{\mathrm{crit}}].$$

Proof. Apply Definition 9284.11 and then Definition 9284.18. □

Theorem 9284.13 (Internal golden certificates supply container packages)**.** *If*

$$\mathsf{InternalGoldenRulerZetaCertificate}_{\zeta,\varphi}$$

holds, then

$$\mathsf{InternalRulerConstraintContainer}_{\zeta,\varphi}$$

holds.

Proof. Fix an accepted non-trivial completed zeta zero. The internal golden certificate row supplies a cofinal golden eta certificate tower and an internal container-mature ruler family. The unique Zeckendorf truncation ledgers provide the source-address part of the ruler, while the compatible golden Lee–Yang bridge witnesses provide the boundary, same-island transfer, radial-purity, and dominance rows. Together with the constructive BEDC–Golden–Zeta machine rows of Definition 9283.3, these are exactly the components listed in Definition 9284.2. Hence the zero is presented by an internal-ruler constraint container package. □

Theorem 9284.14 (Golden zeta container route supplies internal golden certificates)**.** *If*

$$\mathrm{ConstraintContainer}^{\uparrow}_{\zeta,\varphi}$$

holds, then

$$\mathsf{InternalGoldenRulerZetaCertificate}_{\zeta,\varphi}$$

holds.

Proof. The golden coverage row supplies golden BEDC certificate towers for accepted non-trivial completed zeta zeros. The internal ruler row makes the corresponding golden ruler family internal and triadic under refinement. The bridge row supplies cofinal golden Lee–Yang bridge witnesses on the same zero islands, while the cofinal growth row supplies the active-height growth required by the defect ledger. These are precisely the components required by Definition 9284.6. □

Theorem 9284.15 (Internal-ruler containers supply constructive machines)**.** *If*

$$\mathsf{InternalRulerConstraintContainer}_{\zeta,\varphi}$$

holds, then

$$\mathsf{ConstructiveBEDCGoldenZetaMachine}_{\zeta}$$

holds.

Proof. For each accepted non-trivial completed zeta zero, the internal-ruler source row supplies an internal-ruler constraint container package. Its first component is a constructive BEDC–Golden–Zeta machine, and its remaining components supply the container-mature internal ruler, compatible certificate tower, bridge witnesses, and defect rows. Forgetting those additional container rows leaves the source row required by Definition 9283.14. □

Corollary 9284.16 (Internal-ruler containers force the critical container)**.** *If*

$$\mathsf{InternalRulerConstraintContainer}_{\zeta,\varphi}$$

holds, then the limit ledger of every accepted non-trivial completed zeta zero satisfies

$$\Lambda_\infty \Vdash_{\zeta,\varphi} [\Gamma_{\mathrm{crit}}].$$

Proof. Apply Definition 9284.15 and then Definition 9283.20. □

Corollary 9284.17 (Internal golden certificates force the critical container)**.** *If*

$$\mathsf{InternalGoldenRulerZetaCertificate}_{\zeta,\varphi}$$

holds, then the limit ledger of every accepted non-trivial completed zeta zero satisfies

$$\Lambda_\infty \Vdash_{\zeta,\varphi} [\Gamma_{\mathrm{crit}}].$$

Proof. Apply Definition 9284.13 and then Definition 9284.16. □

Corollary 9284.18 (Golden zeta containers force the critical container)**.** *If*

$$\mathrm{ConstraintContainer}^{\uparrow}_{\zeta,\varphi}$$

holds, then the limit ledger of every accepted non-trivial completed zeta zero satisfies

$$\Lambda_\infty \Vdash_{\zeta,\varphi} [\Gamma_{\mathrm{crit}}].$$

Proof. Apply Definition 9284.14 and then Definition 9284.17. □

Principle 9284.19 (Proof load of the internal-ruler container)**.** *The internal-ruler container formulation separates four rows. The general constraint-container interface is supplied by Definition 9462.991. The golden ruler and Zeckendorf address rows are supplied by Definition 9259.10 and Definition 9259.11. The weak analytic capture row is supplied by Definition 9259.14. The strong source row is the same-island Lee–Yang bridge of Definition 9260.18. The container package closes only when these rows are displayed together with radial purity, dominance, cofinal active-height growth, and no external scale-gauge row.*

Principle 9284.20 (Bridge reduction for the internal golden certificate)**.** *The internal golden certificate row does not add a second analytic route beyond the golden bridge. The weak eta capture row supplies finite zero-island capture; the internal ruler row supplies source, refinement, and Zeckendorf address control; the constraint-container row records the surviving candidate class and admissible gauge. The only strong zeta-specific row is the same-island Lee–Yang bridge, namely a cofinal supply of the witnesses of Definition 9260.3. Thus failure of that bridge leaves the package at weak capture, while success of that bridge upgrades the package to the internal-ruler container source row. Definition 9284.8 records the analytic subrows of this bridge: spectral expansion and spectral gap for the selected path branch, and stable Rouché homotopy to the analytic packet on the same boundary.*

Chapter 9285

Arithmetic Spectral String Route

Definition 9255.11 reads the eta packet as a many-oscillator phase sum, while Definition 9257.13 reads a completed zero through a compatible tower of finite certificates. The present chapter records the same row in string-like spectral language. The word "string" here is a mode-organization term: one oscillator displays one mode, a finite packet displays finitely many modes, and the arithmetic spectral carrier organizes the compatible tower of logarithmic modes. No spacetime target, quantized physical spectrum, or imported physical formalism is assumed.

Definition 9285.1 (Arithmetic spectral string carrier)**.** *An* arithmetic spectral string carrier *is a displayed normal-mode readout*

$$X(t) = \sum_{n\geq 1} a_n e^{-ith_n}$$

on a licensed summability or certificate window, with logarithmic heights

$$h_n = \log n.$$

The eta critical-line carrier is the instance

$$a_n = (-1)^{n-1} n^{-1/2}, \qquad X_\eta(t) = \sum_{n\geq 1} (-1)^{n-1} n^{-1/2} e^{-it\log n}.$$

The prime ledger is the factorization row

$$\log n = \sum_p v_p(n) \log p,$$

so the displayed modes are arithmetic normal modes generated by prime frequency registers. The carrier is therefore string-like because it organizes a compatible normal-mode family, not because it imports an external physical string formalism.

Principle 9285.2 (String nodes are phase cancellations)**.** *A node of the conservative arithmetic spectral string is a zero readout of the phase carrier:*

$$X(t) = 0.$$

For the eta instance this is the critical-line cancellation

$$\eta(1/2 + it) = 0$$

whenever the displayed readout is licensed. A projected cancellation of an amplitude-biased readout is not yet a conservative string node. The certificate must also show that the active channels close by phase inside the unit boundary.

Definition 9285.3 (Centered string channel)**.** *For*

$$s = \frac{1}{2} + r + it$$

and an active logarithmic height $h_a > 0$, the centered string channel is

$$U_a(s) := e^{-(s-1/2)h_a} = e^{-rh_a} e^{-ith_a}.$$

The factor e^{-ith_a} is the conservative phase mode. The factor e^{-rh_a} is a real positive radial scale mode. Thus an off-half readout carries a second nonunitary coordinate unless the certificate supplies a legal scale ledger, which the closed arithmetic string row does not permit.

Definition 9285.4 (Unitary arithmetic string flow)**.** *A* unitary arithmetic string flow *is a phase evolution*

$$U(t) = e^{-itH}$$

on a displayed normal-mode carrier with

$$He_n = (\log n)e_n$$

on the mode basis under consideration, and with

$$U(t)^* U(t) = I.$$

The same Hamiltonian readout gives every active logarithmic mode the single time parameter t. A radial factor e^{-rH} is not part of this unitary flow; it is a damping or gain row.

Theorem 9285.5 (Unitary string admissibility excludes radial scale)**.** *Let a string certificate have limit readout*

$$s_\infty = \frac{1}{2} + r + it.$$

If some active height $h_a > 0$ satisfies the unit-boundary row

$$|e^{-(s_\infty - 1/2)h_a}| = 1,$$

then $r = 0$.

Proof. The centered channel factorization gives

$$|e^{-(s_\infty - 1/2)h_a}| = e^{-rh_a}.$$

The unit-boundary row therefore says

$$e^{-rh_a} = 1.$$

Since the real exponential is injective and $h_a > 0$, this implies $r = 0$. □

Definition 9285.6 (Closed arithmetic string certificate)**.** *A* closed arithmetic string certificate *for an accepted non-trivial completed zeta zero is a legal boundary-stable zero certificate tower in the sense of Definition 9257.22, together with the following mode interpretation:*

$$h_n = \log n, \qquad \log n = \sum_p v_p(n) \log p,$$

finite certificate levels are finite normal-mode packets, the time row is the unitary arithmetic string flow of Definition 9285.4, the boundary row is the unit-channel condition of Definition 9285.5, and the far-end row is the no-absorption discipline required by Definition 9257.22. Thus a zero is certified as a node of a closed conservative arithmetic spectral system, not as a cancellation produced by unledgered radial amplitude change.

Principle 9285.7 (Zeta closed arithmetic string target)**.** *The target*

$$\mathsf{ZetaClosedArithmeticString}$$

asserts that every accepted non-trivial completed zeta zero admits a closed arithmetic string certificate. Its source load has the following rows:

$$\mathsf{ZetaStringRealization},$$

$$\mathsf{StrongActiveCapture},$$

$$\mathsf{BoundaryStability},$$

$$\mathsf{NoFarEndAbsorption}_{\zeta},$$

and

$$\mathsf{ZeroPresentationCompleteness}.$$

The first row identifies the logarithmic normal-mode carrier; the second turns a zero into a canonical finite packet tower; the third supplies the unitary boundary row; the fourth prevents the infinite tail from serving as a radial scale reservoir; the fifth supplies coverage of all accepted non-trivial zero readouts.

Corollary 9285.8 (Closed arithmetic string coverage gives fixed-half readout)**.** *If* ZetaClosedArithmeticString *holds, then every accepted non-trivial completed zeta zero has real part* $1/2$*.*

Proof. Let u be an accepted non-trivial completed zeta zero. The target ZetaClosedArithmeticString supplies a closed arithmetic string certificate for u, hence a legal boundary-stable certificate tower by Definition 9285.6. Applying Definition 9257.24 gives the fixed-half readout. □

Principle 9285.9 (String language does not change the proof boundary)**.** *The arithmetic string language reorganizes the conservative oscillator route; it does not remove any source obligation. Weak eta capture still only supplies local analytic boxes. The closed string claim requires the strong certificate rows of Definition 9285.7. In particular, unitary normal-mode language does not by itself prove that every zeta zero is represented by a closed arithmetic string certificate, and it does not by itself prove boundary stability for the canonical packets.*

Concretized in §9139: Arithmetic spectral string certificate as finite normal-mode, prime-ledger, and unit-boundary NameCert data.

Chapter 9286

Thermodynamic No-Scale Route

chapter 9257 separates compact phase recurrence from radial scale time, while chapter 9285 reads the same distinction as a conservative normal-mode condition. The present chapter records the information-thermodynamic reading of that row. It treats an off-half real part as a Boltzmann tilt of the active mode distribution. The chapter supplies a no-scale implication under explicit stability and growth hypotheses; it does not supply the golden Lee–Yang bridge, strong active capture, or zero-presentation completeness.

Definition 9286.1 (Phase channel with hidden prime fibre)**.** *Fix a finite displayed prime family S. A phase channel with hidden prime fibre is a readout*

$$\pi_S : \Sigma_S \to \mathbb{T}$$

from the S-solenoid of Definition 9413.779, together with its invisible fibre

$$K_S := \ker(\pi_S).$$

The visible output is the unit phase row in $\mathbb{T}$. The hidden state is the compact prime-register fibre row carried by K_S. A consumer that receives only $\pi_S(x)$ has a phase output, not the full solenoid state x.

Principle 9286.2 (Kernel blindness of the phase channel)**.** *The phase channel of Definition 9286.1 is a coarse-graining row. Equality of visible outputs,*

$$\pi_S(x) = \pi_S(x'),$$

does not recover equality of solenoid states unless the prime-register fibre ledger is also present. In finite quotients this hidden part may be read as a fibre-size or fibre-volume entropy. Thus the channel has a nontrivial conditional-information row

$$\mathsf{HiddenInfo}(x \mid \pi_S(x)),$$

which is ledgered by compact prime-register data, not by a real-positive scale coordinate.

Definition 9286.3 (Solenoid legal fibre row)**.** *For a finite prime family S, the legal hidden fibre of the phase channel is the compact row*

$$K_S = \ker(\pi_S)$$

from Definition 9286.1. A zero-relevant packet is solenoid-legal when every hidden coordinate used to refine its phase readout factors through compact phase data or through this prime-register fibre. No coordinate of type $\mathbb{R}_{>0}$ is part of the solenoid-legal fibre row.

Theorem 9286.4 (Solenoid fibres exclude radial gauges)**.** *Let a centered active packet be solenoid-legal in the sense of Definition 9286.3. If a local channel has the form*

$$U_a(s) = e^{-rh_a} e^{-ith_a}, \qquad h_a > 0,$$

and its modulus row is supplied by the solenoid fibre, then $r = 0$.

Proof. The solenoid fibre is compact. A modulus row supplied by it is therefore a continuous positive real character of a compact phase carrier. By Definition 9413.781, such a character is trivial. Hence

$$|U_a(s)| = e^{-rh_a} = 1.$$

Since $h_a > 0$, taking logarithms gives $r = 0$. □

Principle 9286.5 (Solenoid–Pick conditional route)**.** *The solenoid row and the Pick row play distinct roles in the same triadic obstruction. The solenoid row determines the legal fibre of the observation cord: it permits visible unit phase and hidden compact prime-register data, but not a radial $\mathbb{R}_{>0}$ gauge. The Pick row of Definition 9271.2 determines whether the same observation cord embeds into a Hilbert space with nonnegative squared length. Consequently, an off-half zero has two incompatible readings: it requires a nontrivial radial factor e^{-rh_a}, while Definition 9286.4 refuses such a factor as hidden fibre and Definition 9271.13 turns the same radial defect into a finite negative Pick witness. Thus the conditional route is*

$$\mathsf{SolenoidLegalFibre} \times \mathsf{TriadicPickPositivity}_\xi \Longrightarrow \textit{fixed-half readout.}$$

Principle 9286.6 (No recovery by mirror scale)**.** *For a centered active channel*

$$U_a(s) = e^{-rh_a} e^{-ith_a},$$

the mirror row sends r to $-r$ and therefore exchanges damping with gain:

$$e^{-rh_a} \longleftrightarrow e^{rh_a}.$$

This creates the mirror amplitude row; it does not reconstruct the hidden solenoid fibre erased by π_S, and it does not return a single packet to the unit boundary. A recovery of hidden prime-register data requires the compact ledger of Definition 9286.2; a recovery of a radial factor requires an external $\mathbb{R}_{>0}$ ledger, which is excluded from closed phase packets.

Definition 9286.7 (Finite thermodynamic mode packet)**.** *A finite thermodynamic mode packet at level m consists of a finite active set A_m, positive heights*

$$h_a > 0 \qquad (a \in A_m),$$

and nonnegative weights w_a whose total weight is positive. The pure phase state is

$$\Psi_m(t) := \sum_{a \in A_m} c_a e^{-ith_a} e_a.$$

For a readout

$$s = \frac{1}{2} + r + it,$$

the amplitude-biased state is

$$\Psi_m(r,t) := \sum_{a \in A_m} c_a e^{-rh_a} e^{-ith_a} e_a.$$

The factor e^{-ith_a} is a reversible phase row. The factor e^{-rh_a} is a real-positive thermal tilt row.

Definition 9286.8 (Relative scale-defect energy)**.** *For a finite thermodynamic mode packet, let*

$$\bar{h}_m := \frac{\sum_{a\in A_m} w_a h_a}{\sum_{a\in A_m} w_a}.$$

The relative log-scale defect of $s = 1/2 + r + it$ at a is

$$\widetilde{d}_a(r) := -r(h_a - \bar{h}_m).$$

The relative scale-defect energy is

$$E_m^{\mathrm{rel}}(r) := \sum_{a\in A_m} w_a \widetilde{d}_a(r)^2.$$

Equivalently,

$$E_m^{\mathrm{rel}}(r) = r^2 V_m, \qquad V_m := \sum_{a\in A_m} w_a (h_a - \bar{h}_m)^2.$$

This relative form ignores a common normalization factor and records only mode-to-mode scale distortion.

Definition 9286.9 (Boltzmann tilt of an active packet)**.** *The normalized baseline distribution of a finite thermodynamic mode packet is*

$$p_a^{(0)} := \frac{w_a}{\sum_{b\in A_m} w_b}.$$

The off-half parameter r tilts it to

$$p_a^{(r)} := \frac{w_a e^{-2rh_a}}{Z_m(r)}, \qquad Z_m(r) := \sum_{b\in A_m} w_b e^{-2rh_b}.$$

Thus r is not a phase coordinate. It changes the relative distribution of active modes by an exponential-family row.

Principle 9286.10 (Relative entropy detects radial tilt)**.** *In the packet of Definition 9286.9, the free-energy row*

$$F_m(r) := -\log Z_m(r)$$

and the relative entropy

$$D_{\mathrm{KL}}(p^{(r)} \| p^{(0)})$$

read the same radial phenomenon as the scale-defect ledger. Near $r = 0$, the Fisher-information row is governed by the active-height variance:

$$I_m(0) = 4\,\mathrm{Var}_{p^{(0)}}(h).$$

Accordingly, a nonzero r is a relative-information cost, not a bounded phase error on $\mathbb{T}$.

Definition 9286.11 (Thermodynamically stable zero packet tower)**.** *A zero certificate tower is thermodynamically stable when each sufficiently fine level carries a finite thermodynamic mode packet, the only legal closed dynamics are the unit phase rows*

$$e^{-ith_a} \in \mathbb{T},$$

there is no unledgered $\mathbb{R}_{>0}$ reservoir, the relative variance row is cofinal,

$$V_m \to \infty,$$

and the relative scale-defect energy is bounded:

$$E_m^{\mathrm{rel}}(r) \le B$$

for a finite B independent of m.

Definition 9286.12 (No unledgered selector row)**.** *The source row*

$$\mathsf{NoMaxwellDemonZeta}_\zeta$$

asserts that a zeta zero packet tower has no unledgered information selector capable of changing active-mode weights. Concretely, the row forbids an external selector of the form

$$a \longmapsto e^{-rh_a}$$

unless the corresponding real-positive scale ledger is displayed inside the tower. Compact phase rows and compact prime-register fibres may carry legal hidden data; an unrecorded $\mathbb{R}_{>0}$ selector may not be used to make an amplitude-biased packet appear to be unit-phase closed.

Definition 9286.13 (Radial compensation selector)**.** *Let*

$$s = \frac{1}{2} + r + it$$

and let $h_a > 0$ be an active height. A radial compensation selector for the centered channel

$$U_a(s) = e^{-rh_a} e^{-ith_a}$$

is a displayed family

$$C_a(s) \in \mathbb{R}_{>0}$$

such that

$$|C_a(s)U_a(s)| = 1.$$

For $r \neq 0$, this condition forces

$$C_a(s) = e^{rh_a}.$$

Thus a radial compensation selector is precisely a real-positive scale ledger indexed by the active heights.

Lemma 9286.14 (Unit boundary local channel test)**.** *Let*

$$s = \frac{1}{2} + r + it$$

and let $h_a > 0$. For the centered channel

$$U_a(s) = e^{-(s-1/2)h_a},$$

the unit-boundary condition

$$|U_a(s)| = 1$$

forces $r = 0$.

Proof. The centered channel decomposes as

$$U_a(s) = e^{-rh_a} e^{-ith_a}.$$

Hence

$$|U_a(s)| = e^{-rh_a}.$$

If this modulus is one, then $e^{-rh_a} = 1$. Taking real logarithms gives $-rh_a = 0$. Since $h_a > 0$, one has $r = 0$. □

Theorem 9286.15 (No-demon scale compensation)**.** *Assume a packet admits only compact phase rows, compact prime-register fibre rows, Zeckendorf ledger rows, and explicitly measured defect rows as legal gauges. If $r \neq 0$ and $h_a > 0$, no legal gauge supplies a radial compensation selector for*

$$U_a(s) = e^{-rh_a} e^{-ith_a}.$$

Proof. By Definition 9286.13, unit modulus after compensation requires

$$C_a(s) = e^{rh_a} \in \mathbb{R}_{>0}.$$

Compact phase rows change only the phase of $U_a(s)$ and do not change its modulus. Compact prime-register fibre rows and Zeckendorf ledger rows carry discrete or compact source information; they do not supply an unmeasured continuous real-positive scale factor. The remaining allowed case is an explicitly measured defect row, which records the radial defect rather than hiding it as a gauge. Hence no legal gauge supplies the displayed compensation factor. □

Principle 9286.16 (No free entropy lowering)**.** *Definition 9286.12 is the thermodynamic reading of ledger discipline. A selector that sorts, damps, or amplifies modes according to their heights has information cost. If that cost is not carried by the source, tail, prime-register, boundary, or scale-defect ledger, then the selector is outside the closed packet. Thus finite phase recurrence may provide unit-phase return candidates, but it cannot provide a free entropy-lowering operation that cancels the radial Boltzmann tilt of Definition 9286.9. The local obstruction is Definition 9286.15: the compensation factor is real-positive scale data, not phase or compact fibre data.*

Definition 9286.17 (Demon-free thermodynamic zero tower)**.** *A zero packet tower is demon-free thermodynamic when it is thermodynamically stable in the sense of Definition 9286.11 and carries the row*

$$\mathsf{NoMaxwellDemonZeta}_\zeta.$$

Equivalently, every information selector used by the tower is either a compact phase row, a compact prime-register fibre row, a Zeckendorf ledger row, or an explicitly measured defect row.

Definition 9286.18 (No-demon zeta certificate)**.** *The source row*

$$\mathsf{NoDemonZetaCertificate}_\zeta$$

asserts that every accepted non-trivial completed zeta zero is represented by a demon-free thermodynamic zero tower whose relative variance row is cofinal and whose scale-defect extraction is the displayed ledger of Definition 9286.8. This row is a coverage hypothesis: it packages the no-unledgered-selector condition together with the analytic tower needed to apply the thermodynamic no-scale theorem.

Theorem 9286.19 (Thermodynamic no-scale theorem)**.** *Let a thermodynamically stable zero packet tower have limit readout*

$$s_\infty = \frac{1}{2} + r + it.$$

Then $r = 0$.

Proof. By Definition 9286.8,

$$E_m^{\mathrm{rel}}(r) = r^2 V_m.$$

If $r \neq 0$, then $r^2 > 0$. Since $V_m \to \infty$, the displayed energy is unbounded:

$$E_m^{\mathrm{rel}}(r) \to \infty.$$

This contradicts the thermodynamic stability bound

$$E_m^{\mathrm{rel}}(r) \leq B.$$

Therefore $r = 0$. □

Corollary 9286.20 (Thermodynamic stability gives fixed-half readout)**.** *If every accepted non-trivial completed zeta zero is represented by a thermodynamically stable zero packet tower, then every such readout has real part* $1/2$.

Proof. Apply Definition 9286.19 to the tower representing the accepted zero. □

Corollary 9286.21 (Demon-free towers have fixed-half readout)**.** *If every accepted non-trivial completed zeta zero is represented by a demon-free thermodynamic zero tower, then every such readout has real part* $1/2$.

Proof. A demon-free thermodynamic zero tower is thermodynamically stable by Definition 9286.17. Apply Definition 9286.20. □

Corollary 9286.22 (No-demon certificates give fixed-half readouts)**.** *If*

$$\mathsf{NoDemonZetaCertificate}_\zeta$$

holds, then every accepted non-trivial completed zeta zero has real part $1/2$.

Proof. The source row of Definition 9286.18 supplies a demon-free thermodynamic zero tower for each accepted non-trivial completed zeta zero. Apply Definition 9286.21. □

Definition 9286.23 (No-demon internal golden zeta certificate)**.** *The source row*

$$\mathsf{NoDemonInternalGoldenZetaCertificate}_{\zeta,\varphi}$$

asserts that every accepted non-trivial completed zeta zero is presented by a cofinal golden certificate tower satisfying four compatible rows. The internal-ruler row is

$$\mathsf{InternalGoldenRulerZetaCertificate}_{\zeta,\varphi}$$

from Definition 9284.6. The same-island boundary row is

$$\mathsf{ZetaGoldenLeeYangBridge}$$

from Definition 9260.18. The information-thermodynamic row is

$$\mathsf{NoDemonZetaCertificate}_{\zeta}$$

from Definition 9286.18. The compatibility row requires that these three presentations use the same zero island, the same Zeckendorf address ledger, the same active-height refinement, and the same scale-defect extraction. Thus the row is a source package, not an additional analytic theorem: it records that the internal golden ruler, the Lee–Yang bridge, and the no-unledgered-selector discipline are present on one certificate tower.

Theorem 9286.24 (No-demon internal golden certificates supply thermodynamic certificates)**.** *If*

$$\mathsf{NoDemonInternalGoldenZetaCertificate}_{\zeta,\varphi}$$

holds, then

$$\mathsf{NoDemonZetaCertificate}_{\zeta}$$

holds.

Proof. Fix an accepted non-trivial completed zeta zero. The source row of Definition 9286.23 supplies a single cofinal golden certificate tower carrying the no-demon zeta row, with the scale-defect extraction and active-height refinement displayed on that same tower. Forgetting the internal-ruler and Lee–Yang bridge rows leaves exactly the demon-free thermodynamic tower required by Definition 9286.18. □

Corollary 9286.25 (No-demon internal golden certificates give fixed-half readout)**.** *If*

$$\mathsf{NoDemonInternalGoldenZetaCertificate}_{\zeta,\varphi}$$

holds, then every accepted non-trivial completed zeta zero has real part $1/2$*.*

Proof. Apply Definition 9286.24 and then Definition 9286.22. □

Principle 9286.26 (No-demon internal golden source load)**.** *The row*

$$\mathsf{NoDemonInternalGoldenZetaCertificate}_{\zeta,\varphi}$$

does not replace the analytic bridge obligations. Its internal golden ruler component still depends on the source package of Definition 9284.6; its boundary component still depends on the bridge source row of Definition 9260.18; and the bridge source row still carries the dominant-branch and Rouché homotopy obligations isolated in Definition 9284.8. The contribution of the no-demon row is orthogonal: once those same-island rows are supplied, no unledgered information selector may turn the radial factor

$$e^{-rh_a}$$

into a legal phase or compact prime-register gauge.

Principle 9286.27 (Thermodynamic wording preserves the proof boundary)**.** *The information-thermodynamic language identifies the off-half coordinate with entropy production, free-energy cost, or thermal tilt only after a canonical packet tower has been supplied. It does not construct that tower. The remaining source load is the same as in the golden route: strong active capture, same-island Lee–Yang boundary stability, cofinal relative-variance growth, no unledgered selector, no far-end scale reservoir, and zero-presentation completeness. Without those rows, the chapter gives a conditional no-scale implication rather than a zeta-zero coverage theorem.*

Chapter 9287

Copenhagen Boundary Route Audit

The Copenhagen no-scale route is a route-audit chapter, not a proof of RH. Its purpose is to keep three attractive reformulations on the honest side of the boundary. A completed-xi route may speak in Copenhagen tower energy, in diagonal Jensen hyperbolicity, or in Gomboc–Stieltjes positivity; none of these languages supplies the missing source-side positivity by being renamed. A closed proof still needs an independent global row that is cofinal in all visible cutoffs and is constructed before the zero divisor is read.

9287.1 Faithful Reformulations and Leverage

Principle 9287.1 (Faithful reformulations are not leverage)**.** *The following rows are faithful reformulations of the same completed-xi barrier unless an independent source-side positivity or uniform-estimate row is supplied:*

$$\mathsf{NoFarEndAbsorption}, \quad \mathsf{LiPositivity}, \quad \mathsf{WeilPositivity},$$
$$\mathsf{StieltjesHerglotzPositivity}, \quad \mathsf{FullJensenHyperbolicity}.$$

They may be excellent coordinates for the proof obligation. They do not decrease the proof obligation merely by translating it into a positivity, moment, hyperbolicity, or no-scale dialect.

The distinction is between a source row and a posterior readback. If a positive spectral measure is built from an already fixed-half divisor, it records what RH would make visible; it does not generate RH. If Li, Weil, Herglotz, Stieltjes, or Jensen data are proved from prime-side or operator-side rows without consuming the zero-placement conclusion, then the route has leverage. The audit question is therefore not whether these formulations are equivalent to the target. The question is whether their positive object is produced on the source side.

9287.2 The Three Projections of the Same Wall

Principle 9287.2 (Copenhagen boundary)**.** *At the completed-xi level, the Copenhagen energy tower, the diagonal-Jensen row, and the Gomboc row are three projections of the same global positivity wall. In schematic form the closed target is*

$$\begin{aligned} &\forall D, n\ \mathsf{JensenHyperbolic}(D, n) \\ \iff\quad &\exists \nu \geq 0\ \mathsf{StieltjesXi}(\nu) \\ \iff\quad &\forall \varphi\ \mathsf{WeilPSD}(\varphi). \end{aligned}$$

The Copenhagen energy expression is the no-scale face of the same wall: an off-half real scale r creates a positive factor r^2 multiplying a cofinal weight. Bounded energy can then rule out positive apartness of r^2, but only after the cofinal bounded-energy capture has been supplied.

The bridge just stated is a boundary principle, not a new theorem of this chapter. Its force is negative: it prevents a proof from treating one projection as a free source for another. A finite table of Jensen polynomials, a finite Weil Gram table, a finite spectral measure approximation, or a finite Copenhagen tower prefix sees only a bounded window. A global result must be cofinal in degree, truncation, support, height, and packet depth.

Principle 9287.3 (Finite visibility is incomplete)**.** *Finite phase data, finite Jensen radius data, finite spectral data, and finite positive-semidefinite tables do not determine the complete zero set. A finite window may be matched while additional zeros are inserted outside the visible radius by a Blaschke-type outer-window modification. Therefore finite success cannot be promoted to completed-xi closure unless there is a cofinal uniform theorem or an independent source-side construction that controls every later window.*

The consequence is operational. If the argument asks to check all degrees D, all Jensen levels n, all spectral cutoffs K, or all compact supports one by one, then it has become an enumeration protocol rather than a proof. A proof needs a row whose statement is uniform before the enumeration starts.

9287.3 Checked Finite Brick

Theorem 9287.4 (Bounded energy excludes positive scale apartness)**.** *Let r be a rational scale parameter, let $W : \mathbb{N} \to \mathbb{Q}$ be nonnegative and unbounded, and let B be a rational bound. If*

$$\forall n, \qquad r^2 W_n \le B,$$

then $0 < r^2$ is impossible.

Lean4✓ `BEDC.Derived.RHRoute.CopenhagenNoScale.boundedEnergy apart absurd`

Proof. The formal proof chooses, by unboundedness of W, an index n with

$$W_n > B/r^2$$

under the temporary assumption $0 < r^2$. Multiplication by the positive rational r^2 gives

$$B < r^2 W_n,$$

contradicting the assumed bound $r^2 W_n \le B$. This is the abstract Archimedean no-scale brick. It is checked in Lean with no additional axiom. □

Theorem 9287.5 (Finite jets underdetermine the polynomial)**.** *For every polynomial p over the rationals and every N, there is an infinite injective family of polynomials, each sharing the first $N+1$ coefficients, the degree-N jet, with p, obtained by adding a single high-degree monomial beyond the visible window. Hence a finite jet does not determine the polynomial.*

Lean4✓ `BEDC.Derived.RHRoute.FiniteVisibility.fvFamily injective`

↪ variant `BEDC.Derived.RHRoute.FiniteVisibility.fvFamily shares jet`

↪ variant `BEDC.Derived.RHRoute.FiniteVisibility.jet extendAt invisible`

Proof. This checked brick is the additive core of Definition 9287.3. The family changes only a coefficient beyond the visible degree-N jet, so the finite window still reads the same polynomial data while the resulting polynomials are pairwise different. The Blaschke-type outer-window modification in Definition 9287.3, where one keeps the disk window fixed while inserting a zero outside it, is the multiplicative and geometric version of the same boundary principle. That version remains a paper-level principle here and is not claimed as Lean checked. □

Theorem 9287.6 (Degree-two Turan certificate for Jensen positivity)**.** *Let $P(X) = a+2bX+cX^2$ be the degree-two Jensen polynomial with $c > 0$. Then P takes a nonpositive value for some rational X if and only if the Turan inequality $b^2 \geq ac$ holds. The proof completes the square,*

$$c\,P(X) = (cX + b)^2 + (ac - b^2),$$

and uses the witness $X = -b/c$.

Lean4✓ `BEDC.Derived.RHRoute.JensenTuranDegree2.jensen2 dips iff turan`

↪ variant `BEDC.Derived.RHRoute.JensenTuranDegree2.jensen2 complete square`

↪ variant `BEDC.Derived.RHRoute.JensenTuranDegree2.jensen2 nonpos forces turan`

Proof. This is an unconditional finite algebraic certificate over the rational carrier used by the Lean packet. It isolates the structural core of the Turan inequality

$$\gamma_{n+1}^2 \geq \gamma_n \gamma_{n+2}$$

for the Taylor coefficients that would feed the degree-two Jensen polynomial of ξ. The certificate is strictly weaker than RH: only Jensen hyperbolicity for all degrees d and all levels n is the Pólya–RH equivalent statement. It does not constrain ξ zeros without the coefficient-enclosure obligation; turning the rational certificate into a statement about ξ would also require certified rational enclosures for the relevant Taylor coefficients $\gamma_0, \gamma_1, \gamma_2$. □

Theorem 9287.7 (Cubic discriminant identity and the higher-Turan condition)**.** *Let $J(X) = g_0+3g_1X+3g_2X^2+g_3X^3$ be the degree-three Jensen polynomial and set $A = g_1^2-g_0g_2$, $B = g_2^2-g_1g_3$, $C = g_1g_2 - g_0g_3$, and $T_3 = 4AB - C^2$. Then the discriminant of J satisfies the pure ring identity*

$$\Delta(J) = 27\,T_3,$$

and, over the ordered rationals, $T_3 \geq 0$ if and only if $A \geq 0$, $B \geq 0$, and $C^2 \leq 4AB$.

Lean4✓ `BEDC.Derived.RHRoute.JensenTuranDegree3.cubic discriminant eq 27 T3`

↪ variant `BEDC.Derived.RHRoute.JensenTuranDegree3.T3 nonneg iff`

↪ variant `BEDC.Derived.RHRoute.JensenTuranDegree3.subdiscriminant A`

Proof. The Lean certificate is finite, unconditional, and algebraic over the rational carrier. The discriminant formula is a pure ring identity, and the subdiscriminant layer supplies the SOS-type identity

$$4A^3 = H_A^2 + g_0^2 T_3$$

with the corresponding B-side relation used by the ordered-rational corollary. Thus the nontrivial direction from $T_3 \geq 0$ to $A \geq 0$ and $B \geq 0$ is obtained without real closure.

This is not the real-root bridge. The implication

$$\Delta \geq 0 \iff J \text{ has three real roots}$$

is a separate real-closure or Sturm obligation, and is not part of this certificate. Over the ordered rationals, nonnegative discriminant does not even supply rational roots: $X^3 - 3X + 1$ has discriminant $81 > 0$ and no rational root. Nor is T_3 an unconditional coefficient-SOS polynomial: at $(g_0, g_1, g_2, g_3) = (1, 0, 0, 1)$ one has $T_3 = -1$.

The fixed degree-three certificate is strictly weaker than RH and is not RH-equivalent. Pólya equivalence requires Jensen hyperbolicity in every degree and every level. Applying this finite algebraic brick to ξ would still require certified enclosures for $\gamma_0, \gamma_1, \gamma_2, \gamma_3$, and the brick alone does not constrain the zero set of ξ. □

The conditional tower interface is also encoded:

Lean4 (definition) `BEDC.Derived.RHRoute.CopenhagenNoScale.CopenhagenTowerData`

and

Lean4 (definition) `BEDC.Derived.RHRoute.CopenhagenNoScale.CopenhagenCaptureObligation`

. The field

$$\mathsf{energy_bounded} : \exists B,\ \forall n,\ r^2 W_n \le B$$

inside CopenhagenTowerData is a capture input. It is not inhabited here for completed zeta zeros. The checked conditional theorem

$$\mathsf{CopenhagenTowerData}(r) \Longrightarrow \neg(0 < r^2)$$

is recorded as

Lean4 ✓ `BEDC.Derived.RHRoute.CopenhagenNoScale.copenhagenTower forces not apart`

. Thus the Lean contribution is a true finite brick plus a conditional handoff. It does not assert $r = 0$ by trichotomy, does not construct the xi tower, and does not prove RH.

9287.4 GAG One-Step Certificate

The GAG one-step packet is another finite brick in the same audit discipline. For a fixed degree parameter D, a certificate records rational root isolation intervals $[r_i^-, r_i^+]$, a rational level interval $[\lambda^-, \lambda^+]$, and rational signed-lobe intervals $[S_i^-, S_i^+]$. Its overshoot interval is computed by the finite recursion

$$m_0^- = \lambda^-, \qquad m_0^+ = \lambda^+,$$
$$m_{i+1}^- = S_i^- - m_i^+, \qquad m_{i+1}^+ = S_i^+ - m_i^-.$$

The checked part is entirely finite and rational: if the true level and true signed-lobe values lie in the recorded intervals, then the true overshoot lies in the computed overshoot interval at every step. If in addition $\lambda^- > 0$ and every lower overshoot bound m_i^- is positive through the finite range, the true overshoots are positive.

Lean4 ✓ `BEDC.Derived.RHRoute.GAGCertificate.GAGCert.gag true overshoot in interval`

Lean4 ✓ `BEDC.Derived.RHRoute.GAGCertificate.GAGCert.gag true overshoot pos`

Theorem 9287.8 (Finite GAG alternation soundness)**.** *For one fixed finite GAG certificate, positive true overshoot at a signed-lobe step forces the signed-lobe value to cross the level λ in the parity prescribed by the certificate: odd lobes are strictly above λ, and even lobes are strictly below λ.*

Lean4 ✓ `BEDC.Derived.RHRoute.GAGCertificate.GAGCert.gag signed lobe alternation`

Proof. The formal statement is the rational one-step calculation. In odd parity the signed-lobe relation is $v = \lambda + m$; in even parity it is $\lambda = v + m$. The hypothesis $m > 0$ gives the corresponding strict inequality. The interval theorem above supplies the positive overshoot input when the recorded finite certificate passes its lower-bound tests. □

This theorem is not a root-count theorem. The root intervals are included in the packet because they are the intended handoff surface for a later constructive located-IVT bridge. The finite Lean theorem checks the rational alternation soundness only: interval inclusion gives positive overshoot, and positive overshoot gives strict alternation across the level.

Principle 9287.9 (Nonvacuous one-step witness)**.** *The certificate layer is not an empty shell. The encoded $D = 1$ instance uses $\lambda = 1/2$, a root ledger at -1, and the single signed-lobe value 1. It passes because $1/2 > 0$ and $1 - 1/2 = 1/2 > 0$.*
Lean4✓ `BEDC.Derived.RHRoute.GAGCertificate.GAGCert.gagCert D1 passes`

This is the formal analogue of the hand calculation behind $I_1 = 1 + X$ and the one-step hyperbolic successor I_2 in the toy oracle case. It shows that the certificate format has an inhabited finite example. It does not by itself prove a general Jensen–Pólya step.

Principle 9287.10 (Located-IVT root count is an obligation)**.** *Passing finite GAG alternation is not yet the assertion that I_{D+1} has $D + 1$ located negative real roots. That conclusion needs a constructive located-IVT root-count bridge: monotone crossing, located root existence, and endpoint sign crossing have to be supplied as located-real witnesses. In Lean this bridge is deliberately recorded as an obligation structure, not as an inhabited theorem:*
Lean4 (definition) `BEDC.Derived.RHRoute.GAGCertificate.GAGCert.GAGRootCountObligation`
. The conditional handoff
Lean4 (definition) `BEDC.Derived.RHRoute.GAGCertificate.GAGCert.gag onestep hyperbolic of rootcount`
only packages the conclusion after those obligation witnesses and the root-count function have already been supplied.

Thus the checked GAG contribution is exactly the finite rational certificate soundness plus a nonvacuous $D = 1$ witness. It does not prove the located-IVT bridge, does not count roots of I_{D+1}, and does not assert unconditional hyperbolicity for any completed Jensen–Pólya family.

Principle 9287.11 (Uniform GAG generator is the frontier)**.** *For each fixed D, the GAG format gives a finite certificate target: one may provide rational isolating intervals, a rational level interval, signed-lobe bounds, and finite lower-bound checks for the overshoot recursion. Closing all degrees would require a* UniformGAGCertificateGenerator *producing the certificates uniformly in D and proving*

$$\forall D\ \forall i \le D, \qquad m_i^-(D) > 0.$$

The natural decomposition is a finite-part lower-bound proof, a tail upper-bound proof such as a prolate or Hilbert–Schmidt estimate, and a stability proof for the overshoot recursion. If such a uniform generator were attached to the full Jensen–Pólya family, it would cross the RH *boundary. It is therefore recorded here as an* RH*-level frontier, not as a theorem and not as evidence that the all-D problem is already closed.*

9287.5 Gomboc Conditional Comparison

The Gomboc route has the same logical shape. Its encoded xi-facing container
Lean4 (definition) `BEDC.Derived.RHRoute.AnalyticGombocForXi.AnalyticGombocForXi`
contains Pick, Herglotz, Stieltjes, equivalence, handoff, and no-hidden-ballast data. The handoff theorem
Lean4✓ `BEDC.Derived.RHRoute.AnalyticGombocForXi.rh via analytic gomboc`
is conditional on such a container. The source-side spectral positivity field

Lean4 (definition) `BEDC.Derived.RHRoute.AnalyticGombocForXi.StieltjesPositiveSpectral.positive spectral measure`

is part of the supplied structure, not a theorem generated in this paper chapter.

This is the intended comparison. Copenhagen says that bounded cofinal energy plus unbounded weights forbid positive scale apartness. Gomboc says that a supplied Pick–Herglotz–Stieltjes positive package gives the constructive RH readout. Both routes are useful boundary normal forms. Neither route claims that the required xi-facing package has been constructed.

9287.6 Bad Examples as First-Class Boundary Data

Principle 9287.12 (Two-term resonance is off-line)**.** *For two exponential terms with distinct heights $h_1 \neq h_2$ and coefficients $a \neq b$, phase cancellation occurs at a shifted line*

$$\delta = \frac{\log(b/a)}{h_2 - h_1} \neq 0$$

in general. Verdict: phase cancellation alone is not enough; exact balance or a Lee–Yang stability row is required before a resonance may be used as fixed-half evidence.

Principle 9287.13 (Positive kernels do not imply Laguerre–Polya)**.** *Let*

$$\mu = \delta_{-1} + a\delta_0 + \delta_1 \qquad (a > 2).$$

The Fourier transform is

$$\widehat{\mu}(z) = a + 2\cos z.$$

Its zeros need not be real. Verdict: positivity of a kernel or measure row does not by itself place an entire function in the Laguerre–Polya class; a separate real-rootedness-preserving mechanism is needed.

Principle 9287.14 (Mellin projection need not preserve Lee–Yang)**.** *The finite Mellin projection*

$$P_2(s) = 1 - 2^{-s}$$

has zeros on $\mathrm{Re}(s) = 0$*, not on the line* $\mathrm{Re}(s) = 1/2$*. Verdict: a projection that is natural for Mellin or prime-window bookkeeping need not preserve the Lee–Yang unit circle or the fixed-half target.*

Principle 9287.15 (All-cutoff dyadic LP is not a reliable premise)**.** *The all-K dyadic Laguerre–Polya premise is not a stable bridge. Low corrected Jensen levels for small cutoffs such as $K = 2, 3$ already exhibit non-hyperbolic behaviour in the intended finite tests. Verdict: a cutoff-by-cutoff Laguerre–Polya route should be treated as a refuted or unreliable premise unless it supplies a separate uniform preservation theorem.*

Principle 9287.16 (Finite visibility cannot certify the tail)**.** *Any finite table of phases, Jensen coefficients, spectral atoms, Gram entries, or Copenhagen tower levels leaves an outer region unseen. Additional zeros or defects may be placed beyond that region without changing the visible data. Verdict: finite visibility is evidence about a window, not a certificate for the completed zero set.*

Principle 9287.17 (Boundary verdict)**.** *The honest output of the Copenhagen audit is the following separation. The checked no-scale brick is real: bounded cofinal energy contradicts positive rational scale apartness. The capture rows that would attach that brick to completed zeta zeros are not inhabited here. The diagonal Jensen, Weil, Stieltjes–Herglotz, and Gomboc formulations describe the same global wall. A proof must add source-side positivity or a cofinal uniform theorem; otherwise the route remains a boundary normal form and does not become a proof of* RH.

Chapter 9288

Unitary Scale Closure Route for RH

chapter 9255 isolates a pre-RH zero-generation route, and chapter 9243 identifies the critical line with unit-amplitude prime-channel readouts. The present chapter records the scale-normalized reduction suggested by the chapter 9250 carrier and the no-independent-real-scale ledger in the ZetaCosmosClosure route. It is a conditional reduction, not a proof of RH: the mathematical load is the obligation that a certified critical-strip zero packet has no independent real scale ledger and therefore lands on a unitary scale surface.

Definition 9288.1 (Golden scale eigenvalue)**.** *Let*

$$w := s - \frac{1}{2}, \qquad \varphi := \frac{1+\sqrt{5}}{2}, \qquad q := \varphi^w.$$

The golden scale eigenvalue of s is the centered scale readout q. It is located only as a scale-coordinate packet over the centered critical-strip route; it is not an independent zero generator, a branch choice for ζ, or a replacement for the zeta zero ledger.

Principle 9288.2 (Unitary scale closure reduction)**.** *For a critical-strip zero packet s, write $w = s - 1/2$ and $q = \varphi^w$. Since $\varphi > 1$,*

$$|q| = |\varphi^w| = \varphi^{\Re(w)}.$$

Therefore

$$\Re(s) = \frac{1}{2} \iff \Re(w) = 0 \iff |q| = 1.$$

The unitary scale closure route is the conditional reduction

$$\mathsf{NoIndependentRealScaleLedger}(s) \Longrightarrow \mathsf{UnitaryScale}(q) \Longrightarrow |q| = 1 \Longrightarrow \mathsf{OnCritLine}(s).$$

If every certified non-trivial zeta zero in the critical strip satisfies the displayed no-scale-to-unitary obligation, then the BEDC-RH witness function of Definition 9333.1 is inhabited.

Lean4 (statement) `BEDC.Derived.RHRoute.ZetaUnitaryScaleClosure.ZetaUnitaryScaleClosure`
Lean4 (statement) `BEDC.Derived.RHRoute.ZetaUnitaryScaleClosure.rh via unitary scale closure`

Principle 9288.3 (Argument-principle bypass is only a route choice)**.** *This route does not count zeros by contour integration, does not use the argument principle as a zero-enumeration engine, and does not require a classical winding-number decision over an unbounded contour family. It instead asks for a scale-closure certificate on already certified zero packets. The bypass is methodological: it avoids the constructive obstruction of turning global argument variation into a total zero ledger, but it does not remove the need to prove the scale-closure obligation.*

Remark 9288.4 (Connes–Consani half-density reading)**.** *The centered coordinate $w = s - 1/2$ matches the half-density normalization in scale-action readings of the zeta symmetry: the real half-shift is absorbed into the carrier before the residual scale action is inspected. In this language, the nontrivial part of the scale action is the phase row φ^{it} when $w = it$. The BEDC route uses that analogy only as a scale-normalized readout of the ZetaCosmosClosure ledger; it does not import an external spectral triple, trace formula, or classical cohomology theorem as a proof object.*

Principle 9288.5 (Symmetry alone is not enough)**.** *The functional equation, conjugation symmetry, and the mirror fixed surface do not by themselves prove* RH*. An even real polynomial can have a symmetric zero set with off-axis real scale, so symmetry alone cannot force all zeros onto a unit circle after centering. The no-independent-real scale ledger is the genuine extra input in this route. Without the obligation*

$$\mathsf{NoIndependentRealScaleLedger} \Longrightarrow \mathsf{UnitaryScale},$$

the identity $|\varphi^w| = \varphi^{\Re(w)}$ is only a readout of the critical line, not a proof that zero packets land there.

Definition 9288.6 (Gömböc-style homogeneous container row)**.** *A Gömböc-style homogeneous container row for the completed zeta carrier is a source-side packet*

$$\mathsf{ZetaGombocContainer}_\zeta$$

with three displayed fields. The homogeneity field says that the zero packet carries no hidden mass, weight, or density parameter beyond the source, prime, phase, tail, and defect ledgers already present in the carrier. In the centered channel this forbids an unrecorded $\mathbb{R}_{>0}$ factor acting as a radial counterweight. The equilibrium field says that the legal balance surface of the container is the unit scale surface

$$|q| = 1.$$

The source-field says that the balance is produced by the internal container rows themselves, not by selecting a zero and then attaching a compensating scale ledger to it. In particular, the row is global: it is a constraint on the completed zeta carrier as a shape, not a family of local supports built separately around individual zero packets.

Principle 9288.7 (Analytic Gömböc reading)**.** *The Gömböc-style reading is a geometric discipline for the no-scale obligation in Definition 9288.2. A homogeneous convex body with a single stable balance point represents, at the level of analogy, a container whose righting behaviour is carried by shape rather than by hidden weights. The zeta translation is the row*

$$\mathsf{ZetaGombocContainer}_\zeta \Longrightarrow \mathsf{NoIndependentRealScaleLedger} \Longrightarrow \mathsf{UnitaryScale}(q).$$

Thus an off-half readout is not interpreted as a second equilibrium of the same homogeneous container. It is interpreted as a demand for a radial counterweight, namely an extra real-positive scale ledger. The row is still conditional: it names the geometric content of the no-scale-to-unitary implication, but it does not prove that every zeta zero packet carries such a container.

Definition 9288.8 (Analytic Gömböc source shape)**.** *An analytic Gömböc source shape for ξ is a source-side global presentation of the completed zeta carrier in one of the following positive forms:*

$$K_\xi(z, w) = \langle \Phi_\xi(z), \Phi_\xi(w) \rangle_{\mathcal{H}}$$

as in Definition 9271.8, the positive real row

$$\operatorname{Re}\frac{\xi'(s)}{\xi(s)} \geq 0 \qquad \left(\operatorname{Re}(s) > \frac{1}{2}\right)$$

of Definition 9270.2, or a positive spectral representation of the same log-derivative as in Definition 9270.6. The representation must be constructed before zero locations are consumed. A representation assembled around the already-read zero divisor is not an analytic Gömböc source shape.

Principle 9288.9 (Source-shape proof form)**.** *The Gömböc row changes the proof burden from local repair to global shape. A local container placed around a candidate zero would be a supporting device for that readout; it would not certify that the completed carrier itself is homogeneous. By contrast, a source-side Pick factorization, Herglotz positive-real row, or positive spectral measure is a shape theorem for ξ as a whole. In that form an off-half zero cannot be hidden as a local exception: by Definition 9271.13 and Definition 9270.5, it becomes a finite negative Pick witness or a negative scale-flow witness against the same global positive structure.*

Theorem 9288.10 (Gömböc container gives the unitary scale reduction)**.** *Assume that every certified non-trivial zeta zero in the critical strip carries* $\mathsf{ZetaGombocContainer}_\zeta$ *and that the container row supplies the implication*

$$\mathsf{ZetaGombocContainer}_\zeta \to \mathsf{UnitaryScale}(q)$$

for the centered golden scale readout $q = \varphi^{s-1/2}$. Then every certified non-trivial zeta zero in the critical strip satisfies the critical-line readout.

Proof. Fix a certified non-trivial zeta zero s in the critical strip and set

$$q = \varphi^{s-1/2}.$$

The assumed container row gives $\mathsf{UnitaryScale}(q)$, hence $|q| = 1$. By Definition 9288.2, the identity

$$|q| = \varphi^{\Re(s-1/2)}$$

then forces $\Re(s) = 1/2$. This is precisely the ordinary $\mathsf{OnCritLine}(s)$ readout. □

Definition 9288.11 (Route obligations)**.** *The unitary scale closure route has five obligations.*

1. *The centered coordinate $w = s - 1/2$ must be carried by the same critical-strip zero packet as s.*
2. *The golden scale eigenvalue $q = \varphi^w$ must be a located scale-readout with the modulus identity*

$$|q| = \varphi^{\Re(w)}.$$

3. *The ZetaCosmosClosure no-independent-real-scale ledger must imply unitarity of the scale readout for every certified non-trivial zero packet.*
4. *The optional Gömböc-style container row, when used, must be source-side and homogeneous: it may package the no-scale-to-unitary implication through a Pick, Herglotz, or positive spectral source shape, but it may not be built by adding a compensating radial ledger after a zero has been selected.*

5. *The unitary readout must transport back to the ordinary* OnCritLine(s) *witness used by the BEDC-RH statement.*

Closure status for NameCert$_{ZetaUnitaryScaleClosureUp}$.

Origin: ai

Constructive story: The route is generated from a certified zeta zero packet, the centered coordinate $w = s - 1/2$, the golden scale readout $q = \varphi^w$, the no-independent-real-scale ledger, the optional Gömböc-style homogeneous container row, the unitary scale obligation, and transport back to the ordinary critical-line predicate.

Theory closure: TheoryGate(NameCert$_{ZetaUnitaryScaleClosureUp}$, obligation)

Scope closed: The chapter states the conditional unitary-scale reduction, the homogeneous-container reading of the no-scale obligation, the source-shape proof form, and the exact proof obligations; it does not discharge the no-scale-to-unitary implication.

Formal verification: FormalStatus(NameCert$_{ZetaUnitaryScaleClosureUp}$, formalTarget)

Bridge status: none

Not claimed: This route does not prove RH, does not count zeros, does not construct a Gömböc-style container for all zeta zero packets, and does not derive the no-independent-real-scale ledger from the functional equation or symmetry alone.

Upgrade path: Scoped closure requires a checked modulus identity for $|\varphi^w| = \varphi^{\Re(w)}$, a no-independent-real-scale to unitary-scale theorem for certified zeta zero packets, an optional source-side homogeneous-container theorem expressed through Pick, Herglotz, or positive spectral structure, and transport from unitary scale back to OnCritLine.

Chapter 9289

Phase, Orthogonal Readout, and Prime Register Residue

section 9413.6 records the Pythagorean carrier as a shape-scale decomposition, and section 9413.17 reads the same discipline through circle phase, Fourier phase, Laplace damping, and zeta. The present chapter isolates the RH-facing readout principle behind that ladder. A unit circle row is a visible phase surface; a right-triangle row is the orthogonal coordinate read of that phase; a prime register is the residual source ledger not absorbed by the visible phase projection. The point is structural. It is not a physical Heisenberg inequality and not a proof of RH.

9289.1 Unit Phase and Orthogonal Readout

Definition 9289.1 (Unit phase readout)**.** *A unit phase row is a circle-valued coordinate*

$$u(\theta) = e^{i\theta} \in \mathbb{T}.$$

Its orthogonal coordinate readout is

$$\rho_{\perp}(u(\theta)) := (\cos\theta, \sin\theta),$$

with invariant

$$\cos^2\theta + \sin^2\theta = 1.$$

The coordinate pair is therefore a finite visible vector event on the unit-circle surface, not a duplicate of every source row that produced the phase.

Principle 9289.2 (Triangle readout preserves norm and hides provenance)**.** *The passage*

$$e^{i\theta} \mapsto (\cos\theta, \sin\theta)$$

preserves the quadratic norm row and exposes an orthogonal two-coordinate event. It does not by itself expose winding history, cover data, branch choice, prime-local provenance, or any hidden fiber attached to the phase row. Those rows must be carried by separate ledgers if a later consumer is allowed to recover them.

Definition 9289.3 (Phase-triangle event)**.** *A phase-triangle event is a readout packet*

$$T_\theta := (x, y, h_\theta), \qquad x = \cos\theta, \quad y = \sin\theta,$$

where

$$h_\theta : x^2 + y^2 = 1.$$

It is the visible orthogonal slice of the phase row $e^{i\theta}$. In BEDC terms, it is an output surface with a quadratic invariant, not the full source carrier.

9289.2 Prime Register Residue

Definition 9289.4 (Solenoid phase register)**.** *In the notation of Definition 9413.779, the solenoid phase-register readout is the visible projection*

$$\Sigma_S \to \mathbb{T}$$

with fiber $K_S = \ker(\pi_S)$. For finite S, this fiber is the prime-register residue behind the circle phase: it records the prime-adic source distinctions that are not visible in the circle coordinate.

Principle 9289.5 (Prime registers are not phase coordinates)**.** *The projection $\Sigma_S \to \mathbb{T}$ licenses a visible phase readout, but it does not erase the source ledger. Two source rows in Σ_S may share the same visible phase while differing by an element of K_S. Thus a solenoid is a phase quotient with a profinite prime fiber, not a bare circle and not an ambient real-scale container.*

Definition 9289.6 (Projection residue)**.** *For a displayed readout*

$$\pi : E \to V,$$

the residue over a visible row $v : V$ is the fiber

$$\mathrm{Res}_\pi(v) := \sum_{e:E} (\pi(e) \sim_V v).$$

A visible coordinate is lossless only when the packet also supplies a certified section or classifier-faithful reconstruction row for this residue. Otherwise the readout has exposed a surface while retaining the unread distinctions as fiber or ledger data.

Principle 9289.7 (Projection-residue uncertainty)**.** *A single low-dimensional visible readout cannot, without additional ledger rows, be simultaneously the full continuous phase, the full prime-register residue, and an independent radial scale coordinate. A readout may expose one surface and preserve a stated invariant, but every unexposed source distinction must remain in a fiber, a transport ledger, or an explicit obstruction row. This is the BEDC projection-residue form of uncertainty.*

9289.3 Constructive Source Chain

Definition 9289.8 (Distinction-to-phase source chain)**.** *The source-side chain used by this chapter is the ledgered route*

$$\mathsf{BMark} \to \mathsf{BHist} \to \mathsf{Cont} \to \mathsf{OrthogonalReadout} \to \mathbb{T} \to \mathsf{PrimeLedger} \to \Sigma_S.$$

The first three entries are the kernel spine of chapter 9351. The orthogonal and unit-phase entries are the readouts of Definition 9289.1 and Definition 9289.3. The prime-ledger entry is read through the complementary normal forms of Definition 9414.204. The final entry is the solenoid phase register of Definition 9289.4.

Principle 9289.9 (Observation time is continuation growth)**.** *At this level, time is not an external real parameter added before the source is generated. A finite observation ledger is a generated history row, and a later ledger is read through displayed* Cont *growth. Thus the time arrow relevant to the phase-prime readout is append-only ledger growth over* BHist*, not a hidden background clock.*

Definition 9289.10 (Zeckendorf–prime ledger interface)**.** *A Zeckendorf–prime ledger interface for a finite binary history is a displayed sequence of rows:*

$$\mathsf{BHist} \to \mathsf{NoAdjacentWord} \to \mathsf{ZeckendorfValue} \to \mathsf{PrimeExponentLedger}.$$

The no-adjacent word is governed by the recursive additive normal form of Definition 9414.203; the prime exponent ledger is governed by the multiplicative atom normal form of Definition 9414.202. The interface is legal only when the block-code row, no-adjacent normal-form row, value-readback row, and prime-factorization row are all displayed.

Theorem 9289.11 (Finite binary histories admit a prime-ledger readout)**.** *Every finite binary history admitted by the kernel spine has a Zeckendorf–prime ledger readout after a displayed no-adjacent block-code row is chosen.*

Proof. By Definition 9351.16, a generated BHist row has a finite binary word readout. Apply the displayed block code

$$\mathsf{b0} \mapsto 10, \qquad \mathsf{b1} \mapsto 100.$$

Concatenating these blocks never creates adjacent 1 entries, so the result is a finite no-adjacent word. The Zeckendorf normal-form row reads that word as a recursive additive address, and the prime-factorization row sends the displayed address positions to prime exponents. Uniqueness is not supplied by the block code alone; it is the joint effect of the displayed block-code inverse, the no-adjacent normal-form classifier, and the multiplicative prime-factorization classifier. □

Principle 9289.12 (Constructive chain is a proof obligation route)**.** *The chain from raw distinction to solenoid phase is a route for locating the source of a zeta readout. It does not assert that the completed zeta carrier has already been generated by those rows. It identifies the rows that a later discharge must expose: finite histories, continuation growth, orthogonal readout, phase projection, recursive additive normalization, multiplicative prime accounting, solenoid fiber compatibility, and zero-ledger transport.*

9289.4 Centered Zeta Modes

Definition 9289.13 (Centered phase-scale mode)**.** *Let h_a be a displayed positive frequency or prime-ledger height, and write*

$$s = \frac{1}{2} + r + it, \qquad r, t \in \mathsf{Real}^{\uparrow}.$$

The centered zeta mode attached to a is

$$U_a(s) := e^{-(s-\frac{1}{2})h_a} = e^{-rh_a} e^{-ith_a}.$$

The factor e^{-ith_a} is the unit-circle phase read. The factor e^{-rh_a} is a positive real radial-scale read. The source of h_a is the arithmetic or prime-ledger row that determines which frequency has been inspected.

Principle 9289.14 (Unit phase closure excludes radial scale)**.** *If a zero-relevant zeta packet is licensed as a pure unit phase closure, then every centered mode must have no independent positive real scale factor. In the notation of Definition 9289.13, that means the mode is read as*

$$U_a(s) = e^{-ith_a} \in \mathbb{T}$$

rather than as

$$e^{-rh_a} e^{-ith_a}$$

with an extra radial register. This is the same proof role as the no-independent-real-scale obligation in chapter 9288.

Definition 9289.15 (Orthogonal scale-phase energy readout)**.** *For a finite active packet A_m, define*

$$v_a := (-rh_a, -th_a), \qquad W_m := \sum_{a \in A_m} h_a^2.$$

The orthogonal energy readout is

$$|v_a|^2 = r^2 h_a^2 + t^2 h_a^2,$$

and its scale component is

$$E_m^{\text{scale}} := r^2 W_m.$$

Definition 9289.16 (Scale-defect positivity packet)**.** *A scale-defect positivity packet for the active family (A_m) consists of a displayed defect readout $D_m^{\text{scale}}(s)$ and a bound row B such that*

$$D_m^{\text{scale}}(s) = r^2 W_m + \varepsilon_m, \qquad \varepsilon_m = o(W_m),$$

and

$$D_m^{\text{scale}}(s) \leq B$$

for every displayed window m. The notation records an asymptotic obligation inside the chosen analytic interface; it is not an automatic consequence of the centered-mode definition.

Theorem 9289.17 (Cofinal scale energy is incompatible with pure phase closure)**.** *Assume a cofinal family of active packets satisfies $W_m \to \infty$. If $r \# 0$, then*

$$E_m^{\text{scale}} \to \infty.$$

Consequently any zero-relevant closure theorem that supplies pure unit phase closure together with a bounded or absent radial-scale ledger must force $r = 0$.

Proof. By Definition 9289.15,

$$E_m^{\text{scale}} = r^2 W_m.$$

If $r \# 0$, then $r^2 > 0$, so the cofinal divergence of W_m gives $E_m^{\text{scale}} \to \infty$. A pure unit phase closure has no independent positive real scale row. Therefore a bounded or absent scale-ledger condition is incompatible with $r \# 0$, and the centered coordinate must satisfy $r = 0$. □

Theorem 9289.18 (Positive scale-defect criterion)**.** *Assume $W_m \to \infty$ and a scale-defect positivity packet in the sense of Definition 9289.16. Then r is not apart from 0. In any located real readback that collapses absence of apartness to equality at the stated resolution, the centered coordinate satisfies $r = 0$.*

Proof. Assume $r\#0$. Then $r^2 > 0$. Since $\varepsilon_m = o(W_m)$, there is a cofinal tail on which

$$|\varepsilon_m| \le \frac{r^2}{2} W_m.$$

Hence on that tail

$$D_m^{\mathrm{scale}}(s) \ge \frac{r^2}{2} W_m.$$

Because $W_m \to \infty$, the right side is unbounded. This contradicts the displayed bound row $D_m^{\mathrm{scale}}(s) \le B$. Therefore the apartness row $r\#0$ is impossible. A located real readback then gives the displayed equality row $r = 0$ at the resolution licensed by the packet. □

9289.5 RH-Facing Proof Load

Principle 9289.19 (RH as phase-prime-triangle closure)**.** *Under the recovered-carrier reading of chapter 9250, the RH-facing geometric assertion is that every non-trivial completed zeta zero is a legal phase-prime-triangle closure: the visible component is a unit-circle phase readout, the orthogonal coordinate event preserves the quadratic invariant, the prime source remains in the displayed ledger or solenoid fiber, and no extra radial scale register is needed to close the zero packet. In that form the conclusion is*

$$r = 0, \qquad \Re(s) = \frac{1}{2}.$$

Definition 9289.20 (BEDC-legal zeta phase object)**.** *The statement*

$$\mathsf{ZetaIsBEDCLegalPhaseObject}$$

names a certificate-bearing existence obligation in the sense of Definition 9352.18. It requires the completed zeta zero surface to supply the source-chain rows of Definition 9289.8, the centered-mode rows of Definition 9289.13, a cofinal active family, a scale-defect positivity packet, continuation and completion transport, and zero-ledger soundness, with no unledgered radial scale escape. It is an obligation row, not an axiom and not a hidden definition of RH.

Definition 9289.21 (RH problem object)**.** *The RH problem object is the certificate request*

$$\mathsf{RH}^{\uparrow} := (\mathsf{CompletedZetaSource}, \mathsf{ZeroLedger}, \mathsf{ScaleDefect}, \mathsf{PositiveWitness}, \mathsf{ClosureTransport}).$$

The source row names the completed zeta carrier; the zero ledger names the candidate non-trivial zero packet; the scale-defect row records $r = \Re(s) - 1/2$ *in the centered coordinate; the positive witness row names the analytic positivity mechanism; and the closure-transport row records how the positivity witness descends to the zero-ledger classifier. The object is admitted only through a construction certificate for these rows.*

Theorem 9289.22 (Legal zeta phase objects are conditionally RH-sufficient)**.** *If every completed non-trivial zeta zero packet carries a* $\mathsf{ZetaIsBEDCLegalPhaseObject}$ *witness, then the BEDC RH section target is inhabited.*

Proof. Let a completed non-trivial zero packet have centered coordinate

$$s = \frac{1}{2} + r + it.$$

The legal phase-object witness supplies the cofinal active family and the scale-defect positivity packet. By Definition 9289.18, the radial coordinate has no apartness from zero, and the located readback carried by the packet gives $r = 0$. Therefore the same zero packet lies on the critical line,

$$\Re(s) = \frac{1}{2}.$$

Transporting this row through the zero-ledger classifier gives the required value of the RH section for the chosen zero packet. Since the argument used only the arbitrary zero packet and its legal phase-object witness, it yields the conditional section. □

Principle 9289.23 (Pick–Herglotz positivity as analytic discharge)**.** *One analytic route for discharging Definition 9289.20 is a certificate-bearing positive-kernel factorization for the completed zeta carrier. With*

$$f(z) := 2\frac{\xi'}{\xi}\left(\frac{1}{1-z}\right),$$

the target kernel is

$$K_f(z,w) := \frac{f(z) + \overline{f(w)}}{1 - z\overline{w}}.$$

A construction

$$K_f(z,w) = \langle \Phi(z), \Phi(w) \rangle$$

would supply the orthogonal information geometry required by the phase-prime-triangle reading only if the Hilbert carrier and the map Φ themselves enter through source-side construction certificates. This chapter records that target as the analytic proof load; it does not claim the factorization.

Definition 9289.24 (Source Hilbert positivity object)**.** *The source Hilbert positivity object for the completed zeta carrier is the certificate request*

$$\mathsf{SourceHilbert}^{\uparrow}(\xi) := \sum_{\mathcal{H}} \sum_{\Phi:\mathbb{D}\to\mathcal{H}} \left(\prod_{z,w\in\mathbb{D}} K_f(z,w) = \langle \Phi(z), \Phi(w) \rangle \right) \times \mathsf{SourceCert}(\mathcal{H}, \Phi).$$

The final row asserts that $\mathcal{H}$ and Φ are constructed from the prime side, Gamma side, continuation rows, completion rows, and BEDC ledger, not from a posteriori knowledge of zero locations.

Principle 9289.25 (Source Hilbert positivity is the remaining discharge)**.** *If Definition 9289.24 is constructed, it supplies the positive witness component of Definition 9289.21. The remaining transport is then the standard Herglotz-to-zero-exclusion route: positivity of the Pick kernel gives nonnegative real part for the logarithmic derivative on the right-half critical domain, while an off-line zero would force a negative local real-part read near its pole. This principle records the analytic discharge route; the source Hilbert construction remains the open certificate.*

Principle 9289.26 (Status of the readout principle)**.** *The assertion that the unit circle is the phase surface and the right triangle is its orthogonal readout is valid only in this ledgered sense. The circle exposes phase, the triangle exposes a quadratic coordinate event, the solenoid fiber retains prime-register residue, and the centered zeta mode separates unit phase from radial scale. The remaining mathematics is the construction showing that completed zeta zero packets are confined to that legal phase-prime closure surface.*

Chapter 9290

Circle-Triangle Generation and Hidden Scale Refusal

chapter 9289 separates unit phase, orthogonal readout, and prime-register residue. The present chapter records the corresponding generation discipline at the level of zero-relevant observations. A legal phase object is not a bare complex number. It is a certificate-bearing packet whose visible component is a unit-circle phase or an orthogonal readout of that phase, and whose unread distinctions are retained by an explicit ledger. The radial scale row is therefore not free background structure. If it participates in a closure, it must be displayed as a ledgered residual; if it is not displayed, it is not available to the object.

9290.1 Generated Time and Orthogonal Readout

Definition 9290.1 (Circle-triangle generation packet)**.** *A circle-triangle generation packet is a certificate row*

$$\mathcal{G} := (B, \mathsf{Hist}_{\mathcal{G}}, \mathsf{Cont}_{\mathcal{G}}, \mathbb{T}_{\mathcal{G}}, \rho_{\perp,\mathcal{G}}, \Lambda_{\mathcal{G}})$$

with the following data. The distinction row contains two apart marks

$$B_0 \# B_1.$$

The history row $\mathsf{Hist}_{\mathcal{G}}$ *is generated by finite append of those marks, and* $\mathsf{Cont}_{\mathcal{G}}$ *records continuation of such histories. The phase row is a unit-circle readout*

$$u(\theta) = e^{i\theta} \in \mathbb{T}_{\mathcal{G}},$$

and the orthogonal observation row is

$$\rho_{\perp,\mathcal{G}}(u(\theta)) = (\cos\theta, \sin\theta).$$

The ledger $\Lambda_{\mathcal{G}}$ *records distinctions not visible in the circle or triangle readout.*

Principle 9290.2 (Observation time is append order)**.** *The time row in a circle-triangle generation packet is the order in which finite marks are appended and continued. A later observation is a longer or transported history row, not an independent real-time coordinate inserted before the finite kernel. Thus every residual that must be kept for later recovery has a ledger position in the append-and-continuation surface.*

Definition 9290.3 (Orthogonal observation event)**.** *For a phase row $u(\theta)$ in $\mathcal{G}$, the associated orthogonal observation event is the finite vector packet*

$$O_\theta := (\cos\theta, \sin\theta, h_\theta),$$

where

$$h_\theta : \cos^2\theta + \sin^2\theta = 1.$$

It exposes the quadratic invariant of the unit phase. It does not expose the complete source history, winding route, prime provenance, or solenoid fiber unless these are separately present in $\Lambda_{\mathcal{G}}$.

Principle 9290.4 (Circle and triangle are readout surfaces)**.** *The circle row is the continuous unit-phase surface. The triangle row is one orthogonal coordinate read of that phase. Neither row is licensed to erase source distinctions. Every unread distinction must be retained as a fiber, a ledger entry, a transport witness, or an obstruction row.*

9290.2 Prime Registers and Addressed Residue

Definition 9290.5 (Zeta prime-register readout)**.** *For a positive integer n, the prime-register readout is the finite support vector*

$$\upsilon(n) := (v_p(n))_p, \qquad n = \prod_p p^{v_p(n)}.$$

The corresponding frequency row is

$$\log n = \sum_p v_p(n) \log p.$$

Thus the oscillatory zeta mode

$$e^{-it\log n}$$

has visible phase behavior, while the finite exponent vector $\upsilon(n)$ records the irreducible arithmetic source ledger behind that behavior.

Principle 9290.6 (Finite addressability is not free hiding)**.** *Definition 9289.10 supplies an internal route from a finite binary history to a Zeckendorf address and then to a prime-exponent ledger. This addressability licenses finite residual data only when the relevant address row is displayed. It does not license a consumer to use residual scale, branch, phase-source, or prime-fiber information while omitting the ledger that carries it.*

Definition 9290.7 (Prime-classifier container)**.** *A prime-classifier container $\mathcal{C}$ consists of a finite prime-register window $P_{\mathcal{C}}$, a unit or normalized phase row $U_{\mathcal{C}}$, a triangular norm row $N_{\mathcal{C}}$, a boundary row $B_{\mathcal{C}}$, and a type read*

$$\tau_{\mathcal{C}} : P_{\mathcal{C}} \to \{\mathsf{split}_{\mathcal{C}}, \mathsf{inert}_{\mathcal{C}}, \mathsf{ramified}_{\mathcal{C}}\}.$$

The type names are relative to the container. A split prime is a register row whose container supplies a factor pair and hence a possible unit-phase resource. An inert prime is a register row whose unpaired occurrence contributes to the triangular norm boundary. A ramified prime is a branch or degeneracy row whose contribution must be recorded as boundary data rather than erased into phase.

Principle 9290.8 (Prime type is container-relative)**.** *A rational prime is not an undifferentiated particle in the RH-facing ledger. It acquires its proof role only after a container $\mathcal{C}$ has supplied the classifier $\tau_{\mathcal{C}}$ of Definition 9290.7. In the Gaussian two-square container this read is the familiar split, inert, and ramified trichotomy. In a Frobenius, character, solenoid, or finite-window Euler container the same discipline says that the prime row must be read through the displayed register, phase, and tower rows before it may be used as a triangle leg, a unit-phase resource, or a boundary obstruction.*

Definition 9290.9 (Triangle parity boundary)**.** *A triangle classifier container $\mathcal{C}$ is a prime-classifier container whose inert subfamily*

$$I_{\mathcal{C}} := \tau_{\mathcal{C}}^{-1}(\mathsf{inert}_{\mathcal{C}})$$

is displayed as a finite obstruction window. Its parity boundary on a finite register row $n = \prod_p p^{v_p(n)}$ is

$$\partial_{\mathcal{C}}(n) := \big(v_p(n) \bmod 2\big)_{p \in I_{\mathcal{C}}}.$$

The row

$$\partial_{\mathcal{C}}(n) = 0$$

states that every inert obstruction class visible to $\mathcal{C}$ occurs with even multiplicity.

Principle 9290.10 (Even parity is triangle-norm closure)**.** *The role of Definition 9290.9 is the same as the classical two-square classifier over the Gaussian integer container: primes split by the container may supply phase resources, while inert classes must be paired before they contribute to a quadratic norm row. Thus*

$$\partial_{\mathcal{C}}(n) = 0$$

is a triangle-norm admissibility row. It says that the visible inert boundary has no unpaired class. It does not say that the resulting norm row has already been normalized to a unit-circle phase.

Definition 9290.11 (Norm-phase separation row)**.** *For a triangle classifier container $\mathcal{C}$, the norm-phase separation row is the refusal*

$$\mathsf{TriangleNormClosed}_{\mathcal{C}}(n) \not\Rightarrow \mathsf{UnitPhaseClosed}(n).$$

The left side records parity closure and quadratic norm admissibility. The right side requires a further normalization row eliminating radial scale. In a complex readout this is the difference between a norm block and a unit quotient

$$u = \frac{\alpha}{\overline{\alpha}}, \qquad |u| = 1.$$

Principle 9290.12 (Mirror pairing is not unit-circle closure)**.** *For a Li coordinate row*

$$z_\rho = e^{\ell + i\theta},$$

and a displayed positive observation index n, the mirror pair with radial coordinates ℓ and $-\ell$ is an even scale packet, but its averaged phase-aligned readout is

$$\frac{e^{n\ell}e^{in\theta} + e^{-n\ell}e^{in\theta}}{2} = \cosh(n\ell)e^{in\theta}.$$

When $\ell \# 0$, the positivity of n gives modulus $\cosh(n\ell) > 1$. It is therefore a norm-bearing paired packet, not a pure unit-circle phase. Consequently the RH-facing route must prove not only triangle parity closure, but the stronger radial-scale elimination row $\ell = 0$.

Definition 9290.13 (No hidden scale row)**.** *For a circle-triangle generation packet $\mathcal{G}$, the row*

$$\mathsf{NoHiddenScaleFromBEDC}(\mathcal{G})$$

states the following refusal. If a radial factor

$$e^{\ell}, \qquad \ell \# 0,$$

participates in a proposed closure, then either the factor is displayed in $\Lambda_{\mathcal{G}}$ as a residual scale ledger, or the closure is not admitted as a BEDC object. If the factor is displayed, the closure is not a pure unit-phase closure. If the factor is omitted, the closure has an unledgered residual and is not legal.

Principle 9290.14 (Pure phase closure has no radial leg)**.** *In a generation packet satisfying* $\mathsf{NoHiddenScaleFromBEDC}(\mathcal{G})$*, a pure phase closure cannot use a nonzero radial scale leg. Such a leg is either a recorded residual, which changes the object from pure phase closure to scale-ledgered closure, or an unrecorded residual, which violates ledger completeness.*

9290.3 Li Coordinates as Circle-Triangle Reads

Definition 9290.15 (Li zero coordinate)**.** *For a zero packet with complex coordinate $\rho \neq 0$, the Li coordinate is*

$$z_\rho := 1 - \frac{1}{\rho}.$$

When $z_\rho \neq 0$, a located scale-phase read is a representation

$$z_\rho = e^{\ell + i\theta}, \qquad \ell, \theta \in \mathsf{Real}^{\uparrow}.$$

The row $\ell = 0$ is exactly the unit-circle readout $z_\rho \in \mathbb{T}$.

Theorem 9290.16 (Li circle criterion)**.** *Let*

$$\rho = \sigma + i\gamma, \qquad \rho \neq 0.$$

Then

$$\left|1 - \frac{1}{\rho}\right| = 1 \quad \Longleftrightarrow \quad \sigma = \frac{1}{2}.$$

Proof. Write

$$z_\rho = 1 - \frac{1}{\rho} = \frac{\rho - 1}{\rho}.$$

The equality $|z_\rho| = 1$ is equivalent to

$$|\rho - 1| = |\rho|.$$

With $\rho = \sigma + i\gamma$, this is

$$(\sigma - 1)^2 + \gamma^2 = \sigma^2 + \gamma^2.$$

Cancelling the common term gives

$$-2\sigma + 1 = 0,$$

hence $\sigma = 1/2$. The same calculation read backwards gives the converse. □

Theorem 9290.17 (Li observation defect splits into scale and phase legs)**.** *If*

$$z_\rho = e^{\ell+i\theta},$$

then for every displayed $n \in \mathbb{N}_{>0}$*,*

$$|1 - z_\rho^n|^2 = (e^{n\ell} - 1)^2 + 2e^{n\ell}(1 - \cos(n\theta)).$$

Proof. Since

$$z_\rho^n = e^{n\ell}e^{in\theta},$$

we have

$$|1 - z_\rho^n|^2 = 1 + e^{2n\ell} - 2e^{n\ell}\cos(n\theta).$$

The right side rewrites as

$$e^{2n\ell} - 2e^{n\ell} + 1 + 2e^{n\ell} - 2e^{n\ell}\cos(n\theta),$$

which is the displayed decomposition. □

Principle 9290.18 (Scale leg is the radial obstruction)**.** *In the decomposition of Definition 9290.17, the term*

$$(e^{n\ell} - 1)^2$$

is the radial scale leg, while

$$2e^{n\ell}(1 - \cos(n\theta))$$

is the phase-observation leg. A pure unit-phase closure can use the second leg as an orthogonal readout of phase, but it cannot absorb a nonzero first leg without either recording radial scale or leaving a residual unrecorded.

9290.4 Conditional RH Route

Definition 9290.19 (Zeta BEDC circle-triangle embedding)**.** *For a completed non-trivial zeta zero packet* ρ*, the statement*

$$\mathsf{ZetaBEDCEmbedding}^{\circ\triangle}(\rho)$$

names a certificate-bearing existence obligation in the sense of Definition 9352.18. It requires a circle-triangle generation packet $\mathcal{G}$*, the prime-register readout of Definition 9290.5, the Li coordinate row of Definition 9290.15, the scale-phase defect row of Definition 9290.17, zero-ledger transport, and a* $\mathsf{NoHiddenScaleFromBEDC}(\mathcal{G})$ *row. It is a proof obligation, not an additional axiom and not a definition of* RH*.*

Theorem 9290.20 (Circle-triangle embedding is conditionally RH-sufficient)**.** *If every completed non-trivial zeta zero packet* ρ *carries a* $\mathsf{ZetaBEDCEmbedding}^{\circ\triangle}(\rho)$ *certificate, and if the associated located scale readback converts absence of apartness from zero into equality for the radial coordinate, then the BEDC RH section target is inhabited.*

Proof. Let ρ be a completed non-trivial zero packet and let

$$z_\rho = e^{\ell+i\theta}$$

be the scale-phase read supplied by its embedding certificate. The certificate carries $\mathsf{NoHiddenScaleFromBEDC}(\mathcal{G})$ and classifies the zero packet as a pure phase-prime-triangle closure. If $\ell\#0$, then for any displayed positive observation n the radial leg

$$(e^{n\ell}-1)^2$$

in Definition 9290.17 is nonzero. By Definition 9290.13, that leg must either be displayed as a residual scale ledger or remain unavailable. The first case is not a pure phase closure, and the second case is not a legal BEDC object. Both contradict the embedding certificate. Hence ℓ is not apart from 0. The located readback in the theorem hypothesis gives

$$\ell = 0.$$

Therefore

$$|z_\rho| = 1.$$

By Definition 9290.16, the coordinate of the zero packet satisfies

$$\Re(\rho) = \frac{1}{2}.$$

Since ρ was arbitrary, the section target is inhabited. □

Principle 9290.21 (Cofinal mechanism rather than pointwise repair)**.** *The embedding obligation is not a zero-by-zero repair rule. It asks for a single source mechanism whose finite observation windows grow cofinally: generated histories, unit phase reads, orthogonal observation events, prime-register ledgers, Li-coordinate scale reads, and no-hidden-scale refusal must be supplied by the same certificate family. The finite Pick-tower route of chapter 9325 is one analytic candidate for producing the required positive source mechanism.*

Principle 9290.22 (Status of the circle-triangle generation route)**.** *The circle-triangle generation route reduces the geometric part of the RH-facing argument to two explicit obligations:*

$$\mathsf{ZetaBEDCEmbedding}^{\circ\triangle} \qquad \textit{and} \qquad \mathsf{NoHiddenScaleFromBEDC}.$$

The algebraic identities for the Li coordinate and for the scale-phase defect are displayed above. The remaining mathematical content is the construction showing that completed zeta zero packets are indeed admitted through this generation mechanism and that radial scale cannot be silently supplied outside the ledger.

Chapter 9291

Memory Filtration and Prime–Zeckendorf Registers

chapter 9290 records the circle-triangle generation packet and the refusal to hide radial scale. The present chapter isolates the intermediate memory principle needed by that route. A later observation may contain the earlier certificate as ledger history, while the readable residue of that later observation is orthogonal to the transported earlier readout. The two statements live on different rows: append-only containment belongs to the history ledger, and orthogonality belongs to the residual Hilbert readout.

9291.1 Orthogonal Memory Filtration

Definition 9291.1 (Self-similar orthogonal filtration)**.** *A self-similar orthogonal filtration is a tower of certificate-bearing Hilbert readout rows*

$$\mathcal{H}_0 \longrightarrow \mathcal{H}_1 \longrightarrow \mathcal{H}_2 \longrightarrow \cdots$$

together with similarity transports

$$\sigma_m : \mathcal{H}_m \to \mathcal{H}_{m+1}$$

and residual rows E_{m+1} such that

$$\mathcal{H}_{m+1} = \sigma_m(\mathcal{H}_m) \oplus E_{m+1}, \qquad E_{m+1} \perp \sigma_m(\mathcal{H}_m).$$

The ledger row records the inclusion of histories

$$\mathsf{Hist}_m \subseteq \mathsf{Hist}_{m+1},$$

while the Hilbert row records only the orthogonal decomposition of the readable residual. Thus the notation

$$B_{m+1} \supseteq B_m$$

belongs to the append-only ledger surface, whereas the notation

$$E_{m+1} \perp \sigma_m(B_m)$$

belongs to the residual readout surface.

Principle 9291.2 (Containment and orthogonality occupy different rows)**.** *A generated observation state may retain the prior state as history and still expose only an orthogonal residual in the readout row. The licensed statement is therefore not $B_{m+1} \perp B_m$. It is the split*

$$B_{m+1} \cong \sigma_m(B_m) \oplus E_{m+1}, \qquad E_{m+1} \perp \sigma_m(B_m).$$

Containment says that the ledger has not discarded the earlier certificate. Orthogonality says that the residual read by the next coordinate carries no component in the transported prior readout.

Theorem 9291.3 (Pythagorean innovation law)**.** *Let*

$$v_{m+1} = \sigma_m(v_m) + \eta_{m+1}$$

be a vector readout in a self-similar orthogonal filtration, with

$$\eta_{m+1} \in E_{m+1}.$$

Then

$$\|v_{m+1}\|^2 = \|\sigma_m(v_m)\|^2 + \|\eta_{m+1}\|^2.$$

If the similarity row has scale α_m on the displayed vector,

$$\|\sigma_m(v_m)\| = \alpha_m \|v_m\|,$$

then

$$\|v_{m+1}\|^2 = \alpha_m^2 \|v_m\|^2 + \|\eta_{m+1}\|^2.$$

Proof. The defining split gives

$$\eta_{m+1} \perp \sigma_m(v_m).$$

The norm identity is therefore the ordinary Pythagorean identity in the readout row. Substituting the displayed similarity scale gives the final formula. □

Definition 9291.4 (Orthogonal history tower)**.** *An orthogonal history tower is a filtration of Hilbert readout rows*

$$\mathcal{H}_0 \subseteq \mathcal{H}_1 \subseteq \mathcal{H}_2 \subseteq \cdots$$

whose residual rows are

$$E_{m+1} := \mathcal{H}_{m+1} \ominus \mathcal{H}_m$$

and whose ledger row records the append-only containment of histories. Equivalently, every finite stage has the displayed orthogonal split

$$\mathcal{H}_N = \mathcal{H}_0 \oplus E_1 \oplus \cdots \oplus E_N.$$

This is the tower-level form of the containment-plus-residual split: history is retained by the filtration, while readable residuals occupy orthogonal summands.

Theorem 9291.5 (Pythagorean formula for an orthogonal history tower)**.** *Let*

$$v_N \in \mathcal{H}_N$$

be displayed in the orthogonal history tower of Definition 9291.4 as

$$v_N = v_0 + \eta_1 + \cdots + \eta_N, \qquad v_0 \in \mathcal{H}_0, \qquad \eta_j \in E_j.$$

Then

$$\|v_N\|^2 = \|v_0\|^2 + \sum_{j=1}^{N} \|\eta_j\|^2.$$

Proof. By Definition 9291.4, the stage $\mathcal{H}_N$ is the orthogonal direct sum

$$\mathcal{H}_0 \oplus E_1 \oplus \cdots \oplus E_N.$$

Therefore

$$\langle v_0, \eta_j \rangle = 0 \qquad \text{and} \qquad \langle \eta_i, \eta_j \rangle = 0 \quad (i \neq j).$$

Expanding the inner product of $v_0 + \eta_1 + \cdots + \eta_N$ with itself leaves only the diagonal norm terms, which gives the displayed identity. □

Principle 9291.6 (Observation time as residual accumulation)**.** *In an orthogonal history tower, the observation order is visible as append-only history together with accumulated orthogonal residuals. If a stage transition has residual $\eta_{m+1} \neq 0$, then the readout energy changes by*

$$\|v_{m+1}\|^2 = \|v_m\|^2 + \|\eta_{m+1}\|^2$$

at that stage resolution. Thus the tower's time row is not an external clock inserted into the object; it is the generated direction along which residual square-norm entries are ledgered.

Principle 9291.7 (Creation-like growth is ledgered residual growth)**.** *The filtration is creation-like only at the level of certified generation: a later observation contains the earlier history, transports that history into the later readout space, and records the residual in an orthogonal row. The residual is not hidden by the inclusion $\mathsf{Hist}_m \subseteq \mathsf{Hist}_{m+1}$; it is exactly the part that must remain auditable as a ledger row. Binary growth, Fibonacci-normal growth, and prime-exponent growth are legal only after their own normal-form classifiers and residual ledgers are displayed.*

9291.2 Prime–Zeckendorf–Goedel Register

Definition 9291.8 (Prime–Zeckendorf–Goedel register)**.** *Let F_k be the Fibonacci scale used by the displayed Zeckendorf normal-form classifier. The Prime–Zeckendorf–Goedel register of a positive integer n is the finite-support binary array*

$$Z_{\mathsf{PZG}}(n) := (z_{p,k})_{p,k}$$

defined by the two-stage normal form

$$n = \prod_p p^{v_p(n)}, \qquad v_p(n) = \sum_k z_{p,k} F_k,$$

where

$$z_{p,k} \in \{0,1\}, \qquad z_{p,k} z_{p,k+1} = 0$$

for every fixed prime p. Equivalently,

$$n = \prod_{p,k} \left(p^{F_k}\right)^{z_{p,k}}.$$

The prime coordinate supplies multiplicative Goedel addressability; the Zeckendorf coordinate supplies additive self-similar resolution inside each prime exponent.

Theorem 9291.9 (Prime–Zeckendorf–Goedel uniqueness)**.** *Every positive integer n determines a unique finite-support binary array $Z_{\mathsf{PZG}}(n) = (z_{p,k})_{p,k}$ satisfying the no-adjacent condition in each prime row and*

$$n = \prod_{p,k} \left(p^{F_k}\right)^{z_{p,k}}.$$

Proof. Unique factorization gives the unique finite-support exponent family $(v_p(n))_p$ with

$$n = \prod_p p^{v_p(n)}.$$

For each displayed exponent $v_p(n)$, the Zeckendorf normal-form classifier gives a unique binary row $(z_{p,k})_k$ satisfying

$$z_{p,k} z_{p,k+1} = 0$$

and

$$v_p(n) = \sum_k z_{p,k} F_k.$$

Substituting these rows into the prime factorization gives the displayed product. Uniqueness follows from the uniqueness of the prime exponent row together with the uniqueness of the Zeckendorf row for each exponent. □

Definition 9291.10 (Prime–Zeckendorf–Goedel Hilbert readout)**.** *Let*

$$\mathcal{H}_{\mathsf{PZG}} := \ell^2(\mathsf{Prime}^{\uparrow} \times \mathbb{N})$$

with standard orthonormal basis $e_{p,k}$*. The Hilbert readout of* n *is the finite vector*

$$\nu_{\mathsf{PZG}}(n) := \sum_{p,k} z_{p,k} e_{p,k}.$$

Thus

$$\langle e_{p,k}, e_{q,\ell} \rangle = \delta_{p,q} \delta_{k,\ell}.$$

Theorem 9291.11 (Register extensions give orthogonal innovations)**.** *Let* $S_0 \subseteq S_1$ *be two finite supports in* $\mathsf{Prime}^{\uparrow} \times \mathbb{N}$*, and let*

$$v_i := \sum_{(p,k) \in S_i} e_{p,k} \qquad (i = 0, 1).$$

For

$$R_1 := S_1 \setminus S_0, \qquad \eta_1 := \sum_{(p,k) \in R_1} e_{p,k},$$

one has

$$v_1 = v_0 + \eta_1, \qquad \eta_1 \perp v_0,$$

and hence

$$\|v_1\|^2 = \|v_0\|^2 + \|\eta_1\|^2.$$

Proof. The basis vectors indexed by R_1 are disjoint from those indexed by S_0. Orthonormality in Definition 9291.10 therefore gives $\eta_1 \perp v_0$. The displayed vector decomposition follows from $S_1 = S_0 \sqcup R_1$, and the norm identity follows from the Pythagorean identity. □

Definition 9291.12 (Primality-supported layer)**.** *A layer* $\mathcal{L}_m$ *is* primality-supported *when it carries a displayed atom set* Π_m*, a Hilbert readout*

$$\mathcal{H}_m := \ell^2(\Pi_m),$$

with orthonormal basis $(e_\pi)_{\pi\in\Pi_m}$*, and a unique register map*

$$\nu_m : \mathcal{L}_m \to \mathcal{H}_m$$

of the form

$$\nu_m(X) = \sum_{\pi\in\Pi_m} v_\pi(X) e_\pi.$$

The atoms π *may be ordinary primes, prime ideals, irreducible branch rows, irreducible register bits, or irreducible observation residuals, provided the displayed layer supplies unique coordinates and source provenance for them.*

Theorem 9291.13 (Primality-supported layers produce stable triangles)**.** *Let* $\mathcal{L}_m$ *and* $\mathcal{L}_{m+1}$ *be primality-supported layers with*

$$\Pi_m \subseteq \Pi_{m+1}.$$

For any displayed vector $v \in \ell^2(\Pi_{m+1})$*, write*

$$P_m v := \sum_{\pi\in\Pi_m} v_\pi e_\pi, \qquad \eta_{m+1} := \sum_{\pi\in\Pi_{m+1}\setminus\Pi_m} v_\pi e_\pi.$$

Then

$$v = P_m v + \eta_{m+1}, \qquad \eta_{m+1} \perp P_m v,$$

and therefore

$$\|v\|^2 = \|P_m v\|^2 + \|\eta_{m+1}\|^2.$$

Proof. The basis vectors indexed by Π_m and by $\Pi_{m+1} \setminus \Pi_m$ are disjoint members of the displayed orthonormal basis of $\ell^2(\Pi_{m+1})$. Hence the two displayed sums are orthogonal and add to v. The norm identity is the Pythagorean identity in the Hilbert readout row. □

Principle 9291.14 (Primality is coordinate support for stable triangles)**.** *The stable triangle row is not prior geometry. It is the orthogonal readout of a layer whose atoms have unique source coordinates. If a stage has no atom set, or if an apparent residual has no unique primality-supported coordinate, then its squared norm is not a stable object-level triangle invariant. Thus primality support is the coordinate condition behind the Pythagorean rows of Definition 9291.3 and Definition 9291.5.*

Definition 9291.15 (PZG-supported residual row)**.** *Let* $S_m \subseteq S_{m+1}$ *be finite supports in* $\mathsf{Prime}^{\uparrow} \times \mathbb{N}$*, and set*

$$R_{m+1} := S_{m+1} \setminus S_m.$$

A residual row over this stage is PZG-supported *when it has the displayed form*

$$\eta_{m+1} = \sum_{(p,k)\in R_{m+1}} c_{p,k} e_{p,k},$$

with finite coefficient rows and with every basis vector $e_{p,k}$ *coming from the Prime–Zeckendorf–Goedel atom indexed by* (p,k)*. It is degenerate when all displayed coefficients are zero. It is unledgered when no finite support row* R_{m+1} *is supplied.*

Principle 9291.16 (PZG support is the nondegenerate triangle-leg criterion)**.** *A stage of an orthogonal history tower can be read as a nondegenerate triangle-producing stage only through a PZG-supported residual row. If R_{m+1} is empty, or if every coefficient in Definition 9291.15 is zero, the stage has no separate orthogonal leg and the squared norm does not gain a residual term. If a residual is present but no finite PZG support row is displayed, the stage is not a BEDC object-level triangle row, because the source ledger of the leg is absent.*

Theorem 9291.17 (PZG-supported stages give norm-square growth)**.** *Let $\mathcal{H}_m$ be spanned by $\{e_{p,k} : (p,k) \in S_m\}$, and let η_{m+1} be a PZG-supported residual over $R_{m+1} = S_{m+1} \setminus S_m$. For every $v_m \in \mathcal{H}_m$,*

$$v_{m+1} := v_m + \eta_{m+1}$$

satisfies

$$\|v_{m+1}\|^2 = \|v_m\|^2 + \sum_{(p,k)\in R_{m+1}} |c_{p,k}|^2.$$

Proof. The support R_{m+1} is disjoint from S_m. Therefore every basis vector appearing in η_{m+1} is orthogonal to every basis vector spanning $\mathcal{H}_m$ by Definition 9291.10. Hence $\eta_{m+1} \perp v_m$. Expanding the norm of $v_m + \eta_{m+1}$ leaves the norm of v_m and the diagonal coefficient sum of η_{m+1}, giving the displayed identity. □

Principle 9291.18 (Prime–Zeckendorf–Goedel readout as particle ledger)**.** *The phase*

$$e^{-it\log n}$$

is continuous on the unit circle, but its frequency source is the finite register

$$\log n = \sum_p v_p(n)\log p = \sum_{p,k} z_{p,k} F_k \log p.$$

Thus the same zeta mode has a wave row, read as unit phase, and a particle-ledger row, read as a finite Prime–Zeckendorf–Goedel support vector. A radial scale coordinate is not supplied by either row.

Theorem 9291.19 (Single-mode continuous-discrete bridge)**.** *Let $n \in \mathbb{N}_{>0}$ and let*

$$Z_{\mathsf{PZG}}(n) = (z_{p,k})_{p,k}$$

be its Prime–Zeckendorf–Goedel register. Then for every $t \in \mathsf{Real}^{\uparrow}$,

$$e^{-it\log n} = \exp\left(-it\sum_{p,k} z_{p,k} F_k \log p\right).$$

Proof. By Definition 9291.9,

$$n = \prod_{p,k} \left(p^{F_k}\right)^{z_{p,k}}.$$

Taking logarithms gives

$$\log n = \sum_{p,k} z_{p,k} F_k \log p.$$

Substitution into $e^{-it\log n}$ gives the displayed identity. □

Chapter 9292

PZG Phase Readback and Log Energy

chapter 9291 defines the Prime–Zeckendorf–Goedel register and the single-mode continuous-discrete bridge. The present chapter records the associated readback distinction. The finite PZG register is unique. The complete Dirichlet-monomial character reads its frequency faithfully. A visible unit-circle projection of a solenoid state does not, by itself, recover the prime-register fibre behind that phase.

9292.1 Log-Energy Readout

Definition 9292.1 (Log-energy PZG readout)**.** *The log-energy Prime–Zeckendorf–Goedel readout replaces the standard orthonormal basis by a weighted orthogonal basis* $(\varepsilon_{p,k})_{p,k}$ *with*

$$\|\varepsilon_{p,k}\|^2 = F_k \log p, \qquad \langle \varepsilon_{p,k}, \varepsilon_{q,\ell} \rangle = 0 \quad ((p,k) \neq (q,\ell)).$$

For a positive integer n*, set*

$$R_{\mathsf{PZG}}(n) := \sum_{p,k} z_{p,k} \varepsilon_{p,k}.$$

Theorem 9292.2 (Log-energy reads logarithmic height)**.** *For every positive integer* n*,*

$$\|R_{\mathsf{PZG}}(n)\|^2 = \log n.$$

Consequently, for every $t \in \mathsf{Real}^{\uparrow}$*,*

$$n^{-it} = e^{-it\|R_{\mathsf{PZG}}(n)\|^2}.$$

Proof. By Definition 9292.1 and orthogonality,

$$\|R_{\mathsf{PZG}}(n)\|^2 = \sum_{p,k} z_{p,k} F_k \log p.$$

The last sum is $\log n$ by the PZG expansion in Definition 9291.9. Substitution into $n^{-it} = e^{-it \log n}$ gives the phase identity. □

Principle 9292.3 (Zeckendorf carries preserve log energy)**.** *Inside a fixed prime row, the Zeckendorf carry*

$$\varepsilon_{p,k} + \varepsilon_{p,k+1} \rightsquigarrow \varepsilon_{p,k+2}$$

preserves the displayed log-energy because

$$F_k \log p + F_{k+1} \log p = F_{k+2} \log p.$$

Thus the no-adjacent normal form is not merely a coding convention. It is the register normal form compatible with the triangular square-norm row used by the PZG Hilbert readout.

9292.2 Finite Self-Description and Residual Ledgers

Definition 9292.4 (PZG finite description row)**.** *For a certificate-bearing packet $\mathcal{C}$, a PZG finite description row is a displayed triple*

$$(d_{\mathcal{C}}, \ulcorner d_{\mathcal{C}} \urcorner, Z_{\mathsf{PZG}}(\ulcorner d_{\mathcal{C}} \urcorner)).$$

Here $d_{\mathcal{C}}$ is a finite syntactic description of the source rows, generator rows, readout rows, ledger rows, and local NameCert *boundary of $\mathcal{C}$; the code $\ulcorner d_{\mathcal{C}} \urcorner$ is its positive integer address; and $Z_{\mathsf{PZG}}(\ulcorner d_{\mathcal{C}} \urcorner)$ is the unique Prime–Zeckendorf–Goedel register of that address.*

Principle 9292.5 (Finite self-description is syntactic)**.** *A PZG finite description row may describe the packet in which it occurs, but only as finite syntax. It records which source, generator, readout, ledger, and naming rows are displayed. It is not the packet itself, not a semantic truth predicate for the packet, and not a replacement for any* NameCert *field used by downstream consumers.*

Theorem 9292.6 (Finite descriptions have unique PZG addresses)**.** *Every PZG finite description row has a unique register address.*

Proof. The displayed description $d_{\mathcal{C}}$ is finite, hence it has a positive integer code $\ulcorner d_{\mathcal{C}} \urcorner$. The uniqueness theorem Definition 9291.9 assigns to that integer one Prime–Zeckendorf–Goedel register and no other. Therefore the finite description row has a unique register address. □

Definition 9292.7 (Total PZG identity code)**.** *For a PZG-facing object X, its total PZG identity code is the PZG-addressed packet*

$$\mathsf{Code}_{\mathcal{K}}(X) := Z_{\mathsf{PZG}}\big(\mathsf{data}(X), \mathsf{rules}(X), \mathsf{ledger}(X)\big).$$

The row $\mathsf{data}(X)$ records source and generator data. The row $\mathsf{rules}(X)$ records formation, normalization, readout, and transport rules. The row $\mathsf{ledger}(X)$ records residual, tail, boundary, completion, and semantic rows not closed by the public readout.

Principle 9292.8 (PZG identity principle)**.** *For PZG-facing objects X and Y, kernel identity is read by the total PZG identity code:*

$$X \equiv_{\mathcal{K}} Y \quad \Longleftrightarrow \quad \mathsf{Code}_{\mathcal{K}}(X) = \mathsf{Code}_{\mathcal{K}}(Y).$$

Object identity is therefore not a further external decision once the data, rule, and ledger rows have been fixed. The ledger is part of the identity code, not an annotation outside the object.

Theorem 9292.9 (No hidden register under PZG identity)**.** *No PZG-facing process can change the licensed behaviour of an object while leaving its data, rule, and ledger rows unchanged.*

Proof. If the data, rule, and ledger rows are unchanged, then

$$\mathsf{Code}_{\mathcal{K}}(X) = \mathsf{Code}_{\mathcal{K}}(Y).$$

By Definition 9292.8, $X \equiv_{\mathcal{K}} Y$. Any behaviour not determined by the displayed data, rules, and ledger is not a licensed row of the object. Hence a licensed behavioural change must appear in one of those rows, and then the total PZG identity code is not unchanged. □

Corollary 9292.10 (Scale inverse changes identity or ledger)**.** *For a zeta-facing PZG object, an independent positive-real scale inverse for the off-half residual of Definition 9294.5 either changes the total PZG identity code, appears in the ledger, or is not part of the object.*

Proof. A positive-real scale inverse that closes an off-half residual changes the licensed behaviour of the zeta-facing object. By Definition 9292.9, that behavioural change must be recorded in data, rules, or ledger. Recording it in data or rules changes $\mathsf{Code}_{\mathcal{K}}$. Recording it as residual or completion data places it in the ledger. If none of these rows records it, the scale inverse is not a licensed part of the object. □

Definition 9292.11 (Finite PZG readout and residual ledger)**.** *A finite PZG readout for a register row is a classifier that depends on a finite set of coordinates (p, k). A residual ledger for that readout records a detected discrepancy together with its source row, detecting readout, status, and continuation route. A residual is closed inside the stated scope only when every nonzero finite discrepancy is either detected by a displayed finite readout or carried by a displayed ledger row.*

Theorem 9292.12 (Closed finite readout has no hidden finite residual)**.** *Assume a PZG readout scope in which every nonzero finite residual is either detected by one of the displayed finite readouts or entered into the displayed residual ledger. If the residual ledger has no open entry, then no nonzero finite residual remains hidden inside that scope.*

Proof. Suppose that a nonzero finite residual remains. By the coverage assumption, it is either detected by a displayed finite readout or entered into the residual ledger. A detected residual must be recorded by the ledger of the readout that detected it, so it gives an open ledger entry. An entered residual is already an open ledger entry. Both alternatives contradict the assumption that the residual ledger has no open entry. □

Definition 9292.13 (PZG generated-interface profile)**.** *A PZG-facing interface carries the generated-interface profile when it displays the following three rows.*

The generation row records the history by which the interface is produced: source history, event history, register update, and the replay route through the relevant Cont *or package provenance rows.*

The canonical readout row records the normal form by which the interface is publicly read: PZG uniqueness, Zeckendorf normalization, log-energy readout, norm-square readout, or unit-phase readout, according to the scope.

The ledger row records every residual not closed by the displayed canonical readout: finite discrepancies, hidden solenoid fibres, radial scale defects, tail windows, and semantic self-description residues.

Theorem 9292.14 (Generated PZG concepts inherit the profile)**.** *Let $\mathcal{C}$ be a PZG-facing interface generated by finitely many source interfaces and a displayed finite formation rule. If the source interfaces carry the generated-interface profile and the formation rule preserves their replay, normal-form, and ledger rows, then $\mathcal{C}$ carries the generated-interface profile.*

Proof. The generation row of $\mathcal{C}$ is obtained by appending the displayed formation rule to the source histories and replaying the associated provenance. Its canonical readout is the normal form specified by the formation rule, together with the source normal forms transported through that rule. Its ledger is the union of the transported source ledgers with the residual ledger created by the formation rule. These are precisely the three rows of Definition 9292.13. □

Corollary 9292.15 (Self-description keeps the profile boundary)**.** *A PZG finite description row for a packet may inherit generation, canonical readout, and ledger rows, but it remains a finite syntactic row. Any attempt to read that row as a complete same-layer semantic decision procedure is a residual ledger entry, not a closed PZG readout.*

Proof. The finite description row is generated by encoding a displayed finite description and then applying the unique PZG address row of Definition 9292.6. Its canonical readout is therefore its unique register address. By Definition 9292.5, the row is not a truth predicate or a replacement for $\mathsf{NameCert}$ fields. Any semantic decision claim beyond the finite syntax must therefore be recorded by the ledger row of Definition 9292.11. □

Principle 9292.16 (Self-code is not analytic completion)**.** *A PZG finite description row may encode the finite rules that generate PZG registers and the finite rules that read them. This does not identify that finite code with the analytic continuation or completed zeta carrier obtained from those readout rules. The valid implication is*

$$\mathsf{SelfCode}_{\mathsf{PZG}} \Longrightarrow \mathsf{Code}(\mathsf{PZG\ readout\ rules}),$$

not

$$\mathsf{SelfCode}_{\mathsf{PZG}} \Longrightarrow \mathsf{AnalyticCompletion}_{\mathsf{PZG}}.$$

Any claim of analytic completion must therefore display the analytic readout, continuation, completion, and pole–zero ledger rows.

Definition 9292.17 (PZG analytic completion certificate)**.** *A PZG analytic completion certificate for a PZG-facing packet is a displayed tuple*

$$(\mathsf{PZG}_{\mathrm{fin}}, L, Z_{\mathsf{PZG}}, \mathsf{Cont}_{\mathrm{an}}, \mathsf{Arch}_{\infty}, \mathsf{ZeroLedger}).$$

Here $\mathsf{PZG}_{\mathrm{fin}}$ *is the finite-register source row,* L *is the log-energy readout,* Z_{PZG} *is the right-half-plane Dirichlet or partition readout determined by* L*,* $\mathsf{Cont}_{\mathrm{an}}$ *is the analytic continuation row,* Arch_{∞} *is the archimedean completion row, and* $\mathsf{ZeroLedger}$ *records poles, zero packets, branch choices, tail defects, and semantic self-reference residues. The certificate presents the analytic completion as a generated readout boundary over PZG, not as the finite PZG code itself.*

Theorem 9292.18 (Self-readout completion requires a completion certificate)**.** *A PZG finite description row by itself licenses finite syntactic self-description. It licenses a PZG analytic completion only after a PZG analytic completion certificate is displayed.*

Proof. The finite description row is a finite code by Definition 9292.5. By Definition 9292.16, such a code may record the rules for PZG generation and PZG readout, but it is not the analytic continuation or completed carrier obtained from those rules. The missing analytic data are exactly the continuation, archimedean completion, and pole–zero ledger rows listed in Definition 9292.17. Therefore analytic completion is licensed precisely when those rows are displayed. □

Definition 9292.19 (Inverse PZG recovery problem)**.** *The inverse PZG recovery problem begins with a zeta-facing completed readout and asks which finite source rows are forced by that readout. A recovery certificate consists of: the Dirichlet or partition row that displays a discrete length spectrum; the Euler local-factor row that separates the spectrum into prime-indexed local geometric fibres; the normalization row that converts prime exponents into PZG coordinates; the analytic continuation and archimedean completion rows; the reflection row when a completed symmetric carrier is claimed; and the zero ledger recording global cancellation nodes. The problem is therefore not to assume PZG as an input to* ζ*, but to recover the least PZG-shaped source compatible with the displayed analytic rows.*

Principle 9292.20 (Zero data alone do not recover the source)**.** *Zero packets of a completed carrier are global cancellation data. They are not finite PZG registers and not prime-local source rows. Recovering a PZG source from a completed zeta-facing object requires the right-half-plane Dirichlet or partition readout together with the Euler local-factor row and the normalization row. This is the same boundary as Definition 9250.7: zero packets belong to the completed recovered carrier, while PZG belongs to the finite source and normal-form side of the certificate.*

Theorem 9292.21 (Inverse recovery factors through Euler-normalized source rows)**.** *If a zeta-facing completed readout recovers a PZG source, then the recovery factors through a displayed Euler local-factor row and a displayed PZG normalization row. Analytic continuation, reflection, or zero data without those rows do not determine the PZG source certificate.*

Proof. By Definition 9292.19, the finite source is recovered from the analytic carrier only after the Dirichlet or partition readout is decomposed into Euler local factors. Those factors supply the prime-indexed exponent register. The PZG source is obtained only after the normalization row rewrites each exponent into its Zeckendorf coordinate presentation. Analytic continuation, reflection, and zero data govern the completed readout boundary and its cancellation ledger; without the Euler local-factor and normalization rows, they do not display the finite prime-indexed source from which a PZG certificate can be read. □

Definition 9292.22 (Legal visible motion certificate)**.** *A PZG-facing trajectory has a legal visible motion certificate when it displays both a discrete generation row and an implementation row. The discrete generation row is a sequence of generated states whose adjacent steps are obtained by an event history, register normalization, finite readout, and ledger update. The implementation row is a visible phase path*

$$c : I \to \mathbb{T}$$

with sampling points $s_t \in I$ such that

$$c(s_t) = \pi(\rho(K_t)),$$

where $\rho(K_t)$ is the displayed solenoid or phase lift of the generated state. The path is continuous, piecewise C^1, or C^1 according to the claimed scope, and every break point, branch change, or hidden-fibre transition is recorded by a ledger row.

Principle 9292.23 (Discrete legality is not differentiability)**.** *The generated PZG trajectory is a discrete BEDC object. Its legality says that adjacent states are produced by displayed event, normalization, readout, and ledger rows. It does not by itself assert a continuous or differentiable curve in $\mathbb{T}$ or in a solenoid carrier. Continuous, piecewise C^1, or C^1 motion is an implementation certificate over the visible phase surface.*

Theorem 9292.24 (Visible motion has no unledgered jump)**.** *If a PZG-facing trajectory carries a legal visible motion certificate, then every admitted change is one of the displayed generation steps, a point of the visible phase path, a recorded hidden-fibre transition, or a ledgered break point.*

Proof. By Definition 9292.22, adjacent generated states are supplied by the discrete generation row. Between sampled states, the visible implementation is the displayed phase path $c : I \to \mathbb{T}$ on the claimed regularity scope. Hidden-fibre transitions and break points are required by the same certificate to be ledger rows. Thus no remaining change is admitted without either generation, visible implementation, or ledger evidence. □

Definition 9292.25 (Prime-addressed hidden transition)**.** *In a legal visible motion certificate, a recorded hidden-fibre transition is prime-addressed when its ledger row displays a finite support*

$$S \subset_{\mathrm{fin}} \mathsf{Prime}^{\uparrow}$$

together with component rows

$$k_p \in \mathbb{Z}_p \qquad (p \in S)$$

in the solenoid fibre. Equivalently, in a PZG readout the transition may be addressed by a finite set of register coordinates

$$D \subset_{\mathrm{fin}} \mathsf{Prime}^{\uparrow} \times \mathbb{N}$$

and the associated component rows at those coordinates. A hidden transition without such a prime support row is not an admissible hidden motion inside the stated certificate; it is a residual ledger entry until a support row or tail route is displayed.

Definition 9292.26 (Finite prime-type motion window)**.** *A finite prime-type motion window consists of a time interval I, a finite prime support $S \subset_{\mathrm{fin}} \mathsf{Prime}^{\uparrow}$, a depth bound L, and a classifier row*

$$\tau : S \to \{\mathsf{ramified}, \mathsf{split}, \mathsf{inert}\}.$$

For the Gaussian two-axis readout, the classifier is the usual trichotomy

$$\tau(2) = \mathsf{ramified}, \qquad p \equiv 1 \pmod 4 \Rightarrow \tau(p) = \mathsf{split}, \qquad p \equiv 3 \pmod 4 \Rightarrow \tau(p) = \mathsf{inert}.$$

Only transitions whose PZG coordinates lie in S and have depth at most L are closed inside the window. Any component outside this displayed support or beyond this depth is recorded by the residual or tail ledger.

Theorem 9292.27 (Prime-addressed motion is locally classified)**.** *Let a PZG-facing trajectory carry a legal visible motion certificate. If each recorded hidden-fibre transition is prime-addressed inside a finite prime-type motion window, then every hidden transition admitted by the certificate decomposes into ramified, split, and inert components relative to the displayed classifier. No out-of-window component is treated as a closed hidden motion unless it is entered into the residual or tail ledger.*

Proof. By Definition 9292.25, each recorded hidden-fibre transition has a finite prime support row, or a finite PZG coordinate support row. By Definition 9292.26, every displayed prime in the support is assigned exactly one of the three classifier values ramified, split, and inert inside the window. Therefore the finite support decomposes as the disjoint union of its three classifier fibres, and the corresponding component rows decompose accordingly. Components outside the support or beyond the depth bound are explicitly outside the closed window, so the same definition requires them to be ledgered rather than used as closed hidden motion. □

9292.3 Phase Readback

Theorem 9292.28 (Complete monomial phase character is register faithful)**.** *Let $m, n \in \mathbb{N}_{>0}$. If*

$$e^{-it\log n} = e^{-it\log m} \qquad \textit{for every } t \in \mathsf{Real}^{\uparrow},$$

then

$$Z_{\mathsf{PZG}}(n) = Z_{\mathsf{PZG}}(m).$$

Proof. The displayed equality gives

$$e^{-it(\log n - \log m)} = 1 \qquad \text{for every } t \in \mathsf{Real}^{\uparrow}.$$

A real frequency whose exponential is constantly 1 on the full real line has zero frequency. Hence $\log n = \log m$, and therefore $n = m$. The conclusion follows from Definition 9291.9. □

Principle 9292.29 (Solenoid projection is not register readback)**.** *The faithfulness in Definition 9292.28 concerns the full one-parameter character $t \mapsto e^{-it\log n}$ attached to one Dirichlet monomial. It is not a claim that the visible projection*

$$\pi_S : \Sigma_S \to \mathbb{T}$$

of Definition 9413.779 is injective. The kernel

$$K_S := \ker(\pi_S)$$

is the prime-register fibre retained by Definition 9289.4. Therefore two solenoid source rows may have the same visible unit-circle phase and still differ by a prime-register fibre row. Recovering the register requires the fibre ledger or a certified section; the circle output alone is only the visible phase surface.

Principle 9292.30 (Instantaneous phase is not a register certificate)**.** *At a fixed time t_0, equality of phase reads records only*

$$t_0(\log n - \log m) \in 2\pi\mathbb{Z}.$$

It is therefore a modular phase observation, not a certificate of register equality. The complete monomial character is faithful by Definition 9292.28, while a solenoid-visible phase is fibre-blind by Definition 9292.29. These are the two distinct uniqueness rows: the PZG source ledger determines its phase readout, but a projected phase value does not reconstruct the prime-register fibre without the solenoid ledger.

Principle 9292.31 (Solenoid fibres are not radial scale ledgers)**.** *For a centered active mode*

$$U_a(s) = e^{-rh_a} e^{-ith_a}, \qquad h_a > 0,$$

the phase factor e^{-ith_a} is compatible with a PZG or solenoid phase readout, but the positive factor e^{-rh_a} is not a compact prime-register fibre coordinate. This is the same separation as Definition 9286.3: the legal hidden fibre is K_S, not $\mathsf{Real}^{\uparrow}_{>0}$. Hence an off-boundary radial factor must be recorded as a scale row or refused as unledgered data; it cannot be reclassified as lost prime-register phase.

Chapter 9293

Zeta Virtual Machine Execution Trace

chapter 9250 reads zeta as a recovered carrier assembled from Dirichlet, Euler, continuation, completion, mirror, and zero-ledger rows. chapter 9292 supplies the PZG length and phase readback behind that carrier, while chapter 9258 separates finite zero reads from completed zero objects. The present chapter records the program semantics joining these rows: the ontology kernel is consumed as an instruction surface, zeta is the all-prime execution trace of that surface, and zero search is a separate certified readout process over the completed trace.

Definition 9293.1 (Ontology virtual machine row)**.** *An ontology virtual machine row is a BEDC-facing instruction surface*

$$\mathsf{VM}_{\mathcal{K}} := \begin{pmatrix} \mathsf{Gen}, & \mathsf{Enc}, & \mathsf{Norm}, & \mathsf{Decode}, & \mathsf{Length}, & \mathsf{Phase}, \\ \mathsf{Read}, & \mathsf{Complete}, & \mathsf{Reflect}, & \mathsf{Ledger}, & \mathsf{Refine}, & \mathsf{Certify} \end{pmatrix}.$$

The instruction names are schematic abbreviations for already displayed BEDC rows. Generation extends histories; encoding assigns finite syntax to PZG addresses; normalization gives canonical PZG form; decoding reads the positive-integer source; length and phase read the log-energy and unit-phase rows; finite reading consumes a displayed window; completion and reflection build the analytic and mirror rows; ledgering records residuals; refinement enlarges the visible window; certification turns a finite read together with the required tail and boundary rows into an auditable theorem packet.

Principle 9293.2 (The kernel is executable semantics)**.** *The BEDC ontology kernel is not an external list of mathematical objects. In the RH-facing route it is used as the executable semantics of Definition 9293.1: each accepted object is generated by instructions whose source histories, normal forms, public readouts, and residual ledgers are visible. This is the same discipline as the dynamic ontology state row of Definition 9352.22 and the BEDC–PZG dynamic tuple of Definition 9352.23.*

Definition 9293.3 (PZG length heat trace)**.** *Let* $\mathsf{Z}_{\mathsf{PZG}}$ *be the finite-support PZG register carrier, and let*

$$L(z) := \sum_{p,k} z_{p,k} F_k \log p$$

be the log-energy length row. The right-half-plane PZG length heat trace is

$$\mathsf{ZetaRead}(s) := \sum_{z \in \mathsf{Z}_{\mathsf{PZG}}} e^{-sL(z)}$$

on every displayed convergence window where the sum is licensed.

Theorem 9293.4 (PZG heat trace is the Dirichlet zeta readout)**.** *On the right-half-plane convergence window, the PZG length heat trace is the Dirichlet zeta readout:*

$$\mathsf{ZetaRead}(s) = \sum_{n\geq 1} n^{-s}.$$

Proof. By Definition 9291.9, each positive integer n has a unique PZG register $Z_{\mathsf{PZG}}(n)$, and every finite-support legal register is the register of its decoded positive integer. By Definition 9292.2,

$$L(Z_{\mathsf{PZG}}(n)) = \log n.$$

Hence the summand indexed by the register of n is

$$e^{-sL(Z_{\mathsf{PZG}}(n))} = e^{-s\log n} = n^{-s}.$$

Reindexing the register sum by the decoded positive integers gives the displayed Dirichlet row. □

Principle 9293.5 (Zeta is a readout object, not a search program)**.** *The symbol ζ names the completed recovered-carrier readout whose right-half-plane projection is Definition 9293.3; it is not itself the procedure that searches for zeros. The search procedure is a separate packet over the completed ξ readout. Thus the source separation is*

$$\mathsf{VM}_{\mathcal{K}} \rightsquigarrow \mathsf{ZetaRead} \rightsquigarrow \mathsf{XiRead} \rightsquigarrow \mathsf{ZeroSearch}_{\xi},$$

where XiRead *adds the analytic completion, archimedean factor, reflection, pole, branch, and zero-ledger rows.*

Definition 9293.6 (Completed xi execution trace)**.** *A completed xi execution trace is a PZG analytic completion certificate of Definition 9292.17 together with the completed readout*

$$\mathsf{XiRead}(s) := \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\mathsf{ZetaRead}(s)$$

and the mirror row

$$s \mapsto 1-s.$$

The trace is closed only to the extent that its continuation, completion, branch, pole, zero, tail, and semantic self-reference ledgers are closed.

Definition 9293.7 (Scalar readout kernel event)**.** *Let $\mathcal{A}$ be a displayed ledger carrier and let*

$$R : \mathcal{A} \to \mathbb{C}$$

be a scalar readout row. A scalar readout kernel event is a ledger state $a \in \mathcal{A}$ such that

$$R(a) = 0.$$

This event asserts vanishing in the scalar readout. It does not assert

$$a = 0$$

unless a separate faithfulness row for R is displayed.

Principle 9293.8 (Zeros are readout-kernel events)**.** *A completed zeta zero is a scalar readout kernel event for the completed xi execution trace. The assertion*

$$\mathsf{XiRead}(\rho) = 0$$

means that the completed analytic readout sends the represented ledger state at ρ to zero. It does not by itself say that the underlying source ledger, hidden fibre, prime-register residue, branch residue, or tail residue has vanished. Those rows are closed only by faithfulness, tail control, mirror cancellation, positivity, or explicit ledger closure data.

Definition 9293.9 (Prime exponent ledger group)**.** *The prime exponent ledger group is the finite-support additive group*

$$G_{\mathbb{P}} := \bigoplus_{p \in \mathsf{Prime}^{\uparrow}} \mathbb{Z}[p].$$

Its positive cone is the free commutative monoid

$$G_{\mathbb{P}}^{+} := \bigoplus_{p \in \mathsf{Prime}^{\uparrow}} \mathbb{N}[p],$$

which is the exponent ledger behind positive integers. Passing from $G_{\mathbb{P}}^{+}$ to $G_{\mathbb{P}}$ is the group-completion row that allows inverse ledger entries. The inverse of

$$\delta = (\delta_p)_p$$

is

$$-\delta = (-\delta_p)_p.$$

Definition 9293.10 (Positive prime ledger)**.** *The positive prime ledger is the free commutative monoid*

$$M_{\mathbb{P}} := \bigoplus_{p \in \mathsf{Prime}^{\uparrow}} \mathbb{N}[p].$$

Its element

$$a = \sum_p a_p[p]$$

reads the positive integer

$$n(a) = \prod_p p^{a_p}.$$

The PZG register is the canonical normal-form code of this ledger: each coordinate a_p is written in Zeckendorf normal form, producing the finite-support array $(z_{p,k})_{p,k}$ of Definition 9291.8.

Definition 9293.11 (Tagged PZG zeta family)**.** *For a parameter s on a licensed convergence or completion window, the tagged PZG zeta family is the labelled coefficient family*

$$\mathbf{Z}_{\mathsf{tag}}(s) := \left(a, e^{-sL(a)}\right)_{a \in M_{\mathbb{P}}}.$$

The tag a is part of the datum. Before a scalar readout is applied, two different prime ledgers remain different summands even when their complex coefficients have cancelling directions.

Theorem 9293.12 (Tagged zeta family is not the zero family)**.** *For every licensed parameter s, the tagged PZG zeta family is not the zero family.*

Proof. The empty prime ledger $0 \in M_{\mathbb{P}}$ satisfies

$$L(0) = 0.$$

Hence its tagged coefficient is

$$e^{-sL(0)} = 1.$$

A zero tagged family would have zero coefficient at every tag. The coefficient at the empty ledger is not zero, so the tagged family is not the zero family. □

Definition 9293.13 (Forgetful zeta scalar readout)**.** *The forgetful zeta scalar readout is the scalar row that drops the prime ledger tag and sums the displayed coefficients:*

$$\Pi_\zeta(\mathbf{Z}_{\mathsf{tag}}(s)) := \sum_{a \in M_{\mathbb{P}}} e^{-sL(a)}$$

whenever the convergence, continuation, completion, and tail rows license that sum. On the right-half-plane convergence window, this row is $\mathsf{ZetaRead}(s)$*.*

Theorem 9293.14 (Zeta zeros are forgetful-kernel events)**.** *On any licensed zero-read window, a zeta zero is a kernel event for the forgetful scalar readout, not a vanishing of the tagged PZG family.*

Proof. By Definition 9293.13, the scalar zeta value is obtained only after the prime ledger tags have been forgotten and the coefficients have been summed in the completed scalar target. Therefore a zero read has the form

$$\Pi_\zeta(\mathbf{Z}_{\mathsf{tag}}(\rho)) = 0.$$

This is a scalar readout kernel event in the sense of Definition 9293.7. By Definition 9293.12, the tagged PZG family itself is not zero. □

Principle 9293.15 (Projection cancellation is not source-ledger closure)**.** *Complex-plane cancellation after* Π_ζ *may be a polygonal cancellation among many tagged coefficients. Such cancellation does not identify their prime ledger tags and does not by itself pay source, branch, tail, or scale residuals. The fixed-half conclusion requires a separate closure row, such as the single-ledger condition of Definition 9294.10, proving that the zero packet closes inside its own zeta ledger rather than only after forgetting labels.*

Theorem 9293.16 (Positive prime ledgers have no nonzero self-cancellation)**.** *Let* $a, b \in M_{\mathbb{P}}$*. If*

$$a + b = 0,$$

then

$$a = 0 \qquad \text{and} \qquad b = 0.$$

Proof. The equality is coordinatewise. For each prime p,

$$a_p + b_p = 0$$

with $a_p, b_p \in \mathbb{N}$. Hence $a_p = b_p = 0$ for every p, so both finite-support ledgers are zero. □

Theorem 9293.17 (Prime-ledger local cancellation is inverse cancellation)**.** *Let $\delta, \eta \in G_{\mathbb{P}}$. If*

$$\delta + \eta = 0,$$

then

$$\eta = -\delta.$$

Proof. The group $G_{\mathbb{P}}$ is the direct sum of the integer coordinate groups indexed by primes. Therefore the equation

$$\delta + \eta = 0$$

is equivalent to the coordinate equations

$$\delta_p + \eta_p = 0 \qquad (p \in \mathsf{Prime}^{\uparrow}).$$

Thus $\eta_p = -\delta_p$ for every prime coordinate, hence

$$\eta = -\delta.$$

□

Corollary 9293.18 (Nonzero prime-ledger cancellation uses group completion)**.** *A nonzero positive prime ledger cannot be completely cancelled inside $M_{\mathbb{P}}$. Any complete cancellation of a nonzero prime-ledger residual requires the group-completion row*

$$M_{\mathbb{P}} \to G_{\mathbb{P}}$$

and the inverse element supplied by Definition 9293.17.

Proof. The no-cancellation statement inside $M_{\mathbb{P}}$ is Definition 9293.16. Inside $G_{\mathbb{P}}$, any element cancelling δ must be $-\delta$ by Definition 9293.17. □

Principle 9293.19 (Readout cancellation and ledger cancellation differ)**.** *Ledger cancellation is the structural equation*

$$\delta + (-\delta) = 0$$

inside a displayed ledger group such as $G_{\mathbb{P}}$. Scalar readout cancellation is the equation

$$\sum_i R_s(a_i) = 0$$

inside the target field of a readout. The latter says that the readout does not see the total contribution at the parameter s; it does not close the ledger unless the readout is faithful on the relevant residual class or every hidden component is closed by a ledger row.

Definition 9293.20 (Certified zero-search process)**.** *A certified zero-search process over Definition 9293.6 is a cofinal finite-window process*

$$W_0 \subset W_1 \subset W_2 \subset \cdots$$

whose stage j displays:

$$\Big(W_j, \quad \mathsf{FiniteApprox}_{\xi,W_j}, \quad \mathsf{Cand}_{W_j}, \quad \mathsf{TryCert}_{W_j}, \quad \mathsf{ZeroLedger}_{W_j}\Big).$$

Here $\mathsf{FiniteApprox}_{\xi,W_j}$ is the finite analytic readout visible in the window, Cand_{W_j} is the finite candidate region list, $\mathsf{TryCert}_{W_j}$ is the attempted winding, Rouché, argument-principle, or tail-bound certificate, and $\mathsf{ZeroLedger}_{W_j}$ records every unclosed boundary, branch, source, precision, and tail residue.

Principle 9293.21 (Infinite execution is finite reading plus tail control)**.** *The virtual machine does not process an infinite object by expanding all of its coordinates in one step. It processes infinity through cofinal finite reads, compatibility under refinement, tail bounds, and ledger closure. A finite read may become a global conclusion only through a certificate whose unobserved part is controlled by a displayed tail row. Without that row, the output remains a finite read or a residual ledger entry.*

Definition 9293.22 (Tail-budget ledger tower)**.** *A tail-budget ledger tower for an infinite readout is a cofinal finite window tower*

$$W_0 \subset W_1 \subset W_2 \subset \cdots$$

together with stage data

$$(\mathsf{L}_n, \mathsf{T}_n, B_n)_{n\geq 0}.$$

Here L_n *is the ledger visible at* W_n*,*

$$\mathsf{T}_n := W_\infty \setminus W_n$$

is the tail outside the displayed window, and B_n *is the budget row for the unread tail. A transition*

$$(\mathsf{L}_n, \mathsf{T}_n, B_n) \longrightarrow (\mathsf{L}_{n+1}, \mathsf{T}_{n+1}, B_{n+1})$$

is legal only when it transports the visible ledger, reallocates or reduces the tail budget, and records every residual not closed at the later window.

Definition 9293.23 (Budgeted infinite object)**.** *A budgeted infinite object is a triple*

$$X_\infty := ((X_B)_{B\in\mathcal{B}},\ (\rho_{B'B})_{B\subseteq B'},\ \mathcal{L}_\infty)\,.$$

Here $\mathcal{B}$ *is a cofinal family of finite budgets, each* X_B *is the finite readout available under budget* B*, each*

$$\rho_{B'B} : X_{B'} \to X_B$$

is the readback map from a larger budget to a smaller one, and $\mathcal{L}_\infty$ *is the ledger of residuals not closed by the displayed finite budgets.*

Principle 9293.24 (Infinity is budgeted tail-ledger execution)**.** *An infinite analytic object is not consumed by a single total read. In the virtual-machine semantics of Definition 9293.1, its processing consists of tail-budget transitions, compatibility under refinement, and ledger closure. The formal reading of*

$$\infty$$

in such a route is therefore a budgeted tail ledger: what has not been read at W_n *is not absent, but assigned to* T_n *with budget* B_n *and a required transport row into later stages.*

Theorem 9293.25 (Infinite processing factors through budgets and ledgers)**.** *Any auditable process that claims to handle a budgeted infinite object must display finite budget reads, compatibility readbacks, and a future ledger rule.*

Proof. An auditable process uses finite input data, finite precision, finite rules, and finite proof records at each stage. Thus its immediate output is a finite read X_B for some displayed budget B. If the process is to speak about the infinite object rather than only that stage, it must also show how a larger budget B' reads back to B by $\rho_{B'B}$ and how every residual not resolved at B is carried by $\mathcal{L}_\infty$. These are exactly the rows of Definition 9293.23. □

Theorem 9293.26 (Global closure requires budget exhaustion or ledger closure)**.** *Let a tail-budget ledger tower be used to promote finite reads to a global conclusion. The promotion is closed only if every tail component is either exhausted by the budgets or carried by a closed ledger row at the limit.*

Proof. At each stage, Definition 9293.22 assigns the unread part to the tail T_n and its budget B_n. A global conclusion consumes all stages of the tower. Any tail component that is neither exhausted by the budget row nor closed by the limit ledger is still an unread residual. Such a residual is not part of the certified finite read and has not been removed by the transition rules. Therefore the promoted conclusion is closed only when no such component remains. □

Theorem 9293.27 (Zero search factors through finite reads)**.** *Every auditable stage of a certified zero-search process factors through a finite zero read in the sense of Definition 9258.9.*

Proof. At stage j, the zero-search process displays a finite window, a finite analytic approximation, a finite candidate-region list, a finite certificate attempt, and a zero ledger. These supply exactly the region, precision or tolerance, finite count or zero-type readout, finite protocol, and error-boundary-branch-source-tail ledger fields of Definition 9258.9. Equivalently, this is an instance of the finite-read theorem Definition 9258.10. □

Theorem 9293.28 (Certified zeros require closure beyond search)**.** *A certified zero-search process may enumerate and certify finite zero regions. It presents a completed zero object only when the corresponding finite zero reads assemble into a compatible zero-certificate tower with closed boundary, branch, source, precision, and tail ledgers.*

Proof. By Definition 9293.27, every auditable search stage supplies finite zero reads. A completed zero is not identical to one such read; by Definition 9258.12, it is the closed readout selected by a compatible system of finite zero reads. The required compatible system is the zero-certificate tower of Definition 9257.13. Any field not closed by that tower remains in the zero ledger rather than becoming a completed zero object. □

Principle 9293.29 (RH proof is not zero enumeration)**.** *Zero search concerns located zero regions of the completed trace. The RH route requires a stronger global section certificate: every admitted non-trivial zero packet must factor through the fixed-half readout. Thus enumerating more zero certificates and proving the fixed-half section are different program rows over the same completed xi trace. The latter requires global positivity, self-adjoint, no-scale, or no-escape rows of the kind isolated by the ambient RH route, not merely a longer search ledger.*

Principle 9293.30 (Program code is an internal object)**.** *Any finite description of* $\mathsf{ZeroSearch}_\xi$ *is itself a finite syntactic packet and hence has a PZG address by Definition 9292.6. Therefore the search process, its finite stages, and its ledgers are internal objects of the same ontology virtual machine. Internality does not make the search complete: it only says that the code, run history, finite reads, certificates, and residual ledgers are generated and auditable by the same BEDC instruction surface.*

Chapter 9294

Zeta Mirror Cancellation and Local Closure

chapter 9293 separates ledger cancellation from scalar readout cancellation. This chapter records the corresponding mirror boundary for completed zeta zeros. Functional-equation symmetry supplies mirror-pair balance, while the fixed-half conclusion requires local zero-ledger closure at a single zero packet.

Definition 9294.1 (Weak and strong mirror closure)**.** *Let $J(s) = 1 - \overline{s}$ be the completed mirror row. A zero packet ρ has weak mirror closure when the mirror zero packet $J(\rho)$ is also present and the paired radial ledger balances across the orbit:*

$$\ell(\rho) + \ell(J(\rho)) = 0.$$

It has strong mirror closure when

$$\rho = J(\rho).$$

By the fixed-surface calculation of Definition 9241.12, strong mirror closure is the same as fixed-half readout.

Principle 9294.2 (Global cancellation is not local closure)**.** *Weak mirror closure is a global-orbit balance row. It says that an off-fixed residual at one zero can be paired with the inverse residual at the mirror zero. It does not close the ledger of the first zero as a local object. Local closure requires strong mirror closure, or another displayed row proving that the residual of the single zero is already zero at its own position. This is the ledger formulation of Definition 9241.14.*

Definition 9294.3 (Half-density scaling ledger)**.** *For a pure zeta input $a \in M_{\mathbb{P}}$ of Definition 9293.10, write*

$$L(a) = \sum_p a_p \log p.$$

For $s = \sigma + it$, set

$$\delta := \sigma - \frac{1}{2}$$

and define the half-density scaling ledger

$$\Lambda_s(a) := \delta L(a).$$

The centered zeta mode then factors as

$$e^{-sL(a)} = e^{-\frac{1}{2}L(a)} e^{-\Lambda_s(a)} e^{-itL(a)}.$$

The final factor is the unit-phase rotation. The middle factor is the positive real scaling ledger.

Theorem 9294.4 (Off-half scaling ledgers are same-signed and unbounded)**.** *If $\sigma \neq 1/2$, then every nonempty pure zeta input $a \in M_{\mathbb{P}}$ has $\Lambda_s(a) \neq 0$, all such ledgers have the same sign, and $|\Lambda_s(a)|$ is unbounded on $M_{\mathbb{P}}$.*

Proof. For a nonempty pure zeta input, the positivity of prime logarithms gives

$$L(a) > 0.$$

Thus

$$\Lambda_s(a) = (\sigma - \frac{1}{2})L(a)$$

has the sign of $\sigma - 1/2$ for every nonempty a, and it is nonzero when $\sigma \neq 1/2$. To see unboundedness, take the powers along the prime 2 axis,

$$a_m = m[2].$$

Then

$$|\Lambda_s(a_m)| = |\sigma - \frac{1}{2}|\, m \log 2,$$

which is unbounded as m ranges over $\mathbb{N}$. □

Definition 9294.5 (Zeta instruction-scale residual)**.** *For a centered zeta mode $s = 1/2 + r + it$ and a pure zeta input $a \in M_{\mathbb{P}}$, the instruction-scale residual is*

$$\mathsf{Scal}_s(a) := \log \left| e^{-rL(a)} \right| = -rL(a) = -\Lambda_s(a).$$

The unit-phase instruction attached to the same input is

$$U_t(a) := e^{-itL(a)}, \qquad |U_t(a)| = 1.$$

Theorem 9294.6 (Off-half scaling cancellation is not a zeta instruction)**.** *On the pure zeta instruction surface generated by positive prime registers and unit-phase rotations, no finite composite of phase rotations, conjugate phase rotations, or same-window phase mirrors cancels $\mathsf{Scal}_s(a)$ for a nonempty input a when $\Re(s) \neq 1/2$.*

Proof. Every admitted phase instruction has modulus 1. The same remains true after taking finite products, inverses, conjugates, and mirror phase reads, because these operations only change angular coordinates. Hence their log-modulus contribution is always

$$0.$$

For $s = 1/2 + r + it$, the non-phase part of the zeta monomial is

$$e^{-rL(a)}.$$

By Definition 9294.5, its log-modulus is $-rL(a)$. If a is nonempty, then $L(a) > 0$; if $r \neq 0$, this log-modulus is nonzero. Therefore unit-phase instructions cannot cancel the residual. Closing it requires either $r = 0$ or a displayed positive-real scale row outside the pure zeta instruction surface. □

Principle 9294.7 (Pure zeta has no local scaling inverse)**.** *The pure zeta input surface contains nonnegative prime registers and unit-phase rotations. It does not contain an independent negative length register, a positive-real scale counterweight, or a second same-position value of δ with opposite sign. Therefore an off-half scaling ledger cannot be cancelled inside the same pure zeta input. The only way for all half-density scaling ledgers to vanish locally is*

$$\sigma = \frac{1}{2}.$$

This is the zeta-specific form of the no-hidden-scale discipline of Definition 9290.13 and the unit-phase closure rule of Definition 9289.14.

Theorem 9294.8 (Pure zeta local closure is fixed-half closure)**.** *For a completed zero packet whose source is required to close inside the pure zeta input surface, local closure of the scaling ledger is equivalent to fixed-half readout.*

Proof. If the readout is fixed-half, then $\sigma = 1/2$, so Definition 9294.3 gives

$$\Lambda_s(a) = 0$$

for every pure zeta input a.

Conversely, assume the scaling ledger closes locally for every pure zeta input. Apply this to the one-prime input [2]. Since

$$L([2]) = \log 2 > 0,$$

the equality $\Lambda_s([2]) = 0$ forces $\sigma - 1/2 = 0$. Hence $\sigma = 1/2$, which is fixed-half readout. □

Corollary 9294.9 (Scaling-cancellation zeros are not pure zeta closures)**.** *A zero packet whose cancellation requires an off-half scaling ledger is not closed by the pure zeta input surface.*

Proof. If the packet is off-half, then Definition 9294.4 produces same-signed nonzero scaling ledgers, already unbounded along the 2-axis. By Definition 9294.7, pure zeta supplies no local scaling inverse for those ledgers. Thus such a packet can close only by adding an external scale counterweight or by using a distinct mirror position, neither of which is a pure zeta local closure. □

Principle 9294.10 (Single-ledger zero principle)**.** *A scalar zero read of the completed zeta carrier is accepted as a zeta-local zero only when the same zero packet carries the prime source ledger, phase readout, tail ledger, and scale-residual ledger needed to close the cancellation. A distinct mirror packet may witness global orbit symmetry, but it is not a same-packet payment of the scale residual. Thus an off-half scalar cancellation is not a pure zeta local closure unless a separate theorem first proves that its scale residual is closed inside the same zero ledger.*

Theorem 9294.11 (Single-ledger zeta closure excludes off-half scale)**.** *If a completed zero packet is closed by the single-ledger zero principle on the pure zeta instruction surface, then its scale residual vanishes. Consequently its readout is fixed-half.*

Proof. Single-ledger closure forbids payment of the scale residual by a distinct mirror position or by an undisplayed positive-real scale row. By Definition 9294.6, unit-phase zeta instructions cannot cancel a nonzero instruction-scale residual. Hence the residual can close on the pure zeta instruction surface only when

$$\mathsf{Scal}_s(a) = 0$$

for every pure zeta input a. Applying this to [2] gives

$$-\left(\Re(s)-\frac{1}{2}\right)\log 2=0,$$

so $\Re(s)=1/2$. □

Definition 9294.12 (Mirror-cancellation certificate)**.** *A mirror-cancellation certificate for the completed xi execution trace is a displayed tuple*

$$\mathsf{MCC}_\xi := (\mathcal{A}, \mathsf{Ledger}, \mathcal{R}_\xi, \Theta, \iota, (W_n)_{n\geq 0}, (B_n)_{n\geq 0}, Q, \mathsf{L}_{\mathrm{tail}}).$$

Here $\mathcal{A}$ is the ledger carrier, $\mathcal{R}_\xi$ is the completed scalar readout, Θ is the completed mirror row

$$s \mapsto 1-\overline{s},$$

ι is the ledger inverse row, (W_n) is a finite window tower, (B_n) is its tail-budget row, Q is a positive quadratic or Hilbert-square row, and $\mathsf{L}_{\mathrm{tail}}$ is the tail ledger. The certificate requires:

$$\iota^2=1, \qquad \delta+\iota(\delta)=0$$

on the displayed cancellation class;

$$\mathcal{R}_\xi \text{ sends admitted mirror pairs to scalar cancellation;}$$

the tail budgets are exhausted or closed by $\mathsf{L}_{\mathrm{tail}}$; and Q is nonnegative on the displayed residual class.

Theorem 9294.13 (Local zero-ledger closure gives fixed-half readout)**.** *Assume every completed non-trivial zero packet has local ledger closure: it cannot use a distinct mirror position to close its own radial residual. Then every such zero has fixed-half readout.*

Proof. Let ρ be a completed non-trivial zero packet. The functional equation and conjugation rows supply the mirror packet $J(\rho)$ as in Definition 9241.13. If $\rho \neq J(\rho)$, the residual balance is only weak mirror closure in the sense of Definition 9294.1: the radial ledger of ρ is offset by the radial ledger of a distinct position. By the local ledger-closure hypothesis, such cross-position balancing does not close the zero packet. A completed zero packet must therefore satisfy $\rho = J(\rho)$. The fixed-surface calculation in Definition 9241.12 gives $\Re(\rho)=1/2$, hence fixed-half readout. □

Principle 9294.14 (Mirror supplies symmetry, positivity locks the line)**.** *The mirror row by itself supplies paired structure: an off-fixed zero candidate may be reflected to its mirror companion. This symmetry is not yet the fixed-half conclusion. The fixed line is forced only when mirror cancellation is combined with a positive or self-adjoint row and with tail-ledger closure. In the notation of Definition 9294.12, the mirror row Θ explains the local form of cancellation, while Q and $\mathsf{L}_{\mathrm{tail}}$ refuse off-fixed residual escape. This is the same burden isolated by the global observation triangle of Definition 9272.1.*

Chapter 9295

Zeta Zero Readout Faithfulness

chapter 9293 separates scalar readout-kernel events from source-ledger closure, while chapter 9294 shows that single-ledger closure on the pure zeta instruction surface forces fixed-half readout. The remaining interface is the faithfulness of zero readout: whether a scalar completed zero is licensed as a closed PZG-ledger zero packet rather than merely as cancellation after a forgetful scalar projection.

Definition 9295.1 (Closed-ledger zeta zero)**.** *A closed-ledger zeta zero packet at a parameter ρ is a completed xi execution trace together with the scalar zero row*

$$\mathsf{XiRead}(\rho) = 0$$

and a displayed closure row

$$\mathsf{OpenLedger}_{\xi}(\rho) = \varnothing.$$

The open-ledger row includes source, branch, pole, tail, completion, prime-register, and scale-residual entries. Thus a closed-ledger zero is not merely a scalar readout-kernel event; it is a zero packet whose residual ledgers have been closed in the same completed zeta object.

Definition 9295.2 (Zero readout faithfulness)**.** *Zero readout faithfulness for the completed zeta route is the row*

$$\mathsf{ZeroReadoutFaithful}_{\xi}$$

asserting that every accepted non-trivial scalar zero read

$$\mathsf{XiRead}(\rho) = 0$$

comes equipped with a closed-ledger zeta zero packet in the sense of Definition 9295.1. Equivalently, the completed scalar readout may certify zero status only when the underlying source, tail, branch, completion, and scale ledgers are closed or explicitly transported into the same zero packet.

Principle 9295.3 (Zero visibility)**.** *The ontic zero set of the completed zeta route is not the scalar kernel of* XiRead *alone. It is the closed-ledger visibility locus*

$$\rho \in Z_{\mathrm{ontic}}(\xi) \Longleftrightarrow \mathsf{XiRead}(\rho) = 0 \quad \textit{and} \quad \mathsf{OpenLedger}_{\xi}(\rho) = \varnothing.$$

Thus the zero packet visible to the ontology kernel is a completed PZG-ledger zero. A scalar vanishing row with an open ledger remains a zero candidate, a finite-read zero-like event, or an incomplete cancellation row; it is not an ontic zeta zero.

Theorem 9295.4 (Open ledger blocks ontic zero)**.** *For any parameter ρ,*

$$\mathsf{OpenLedger}_\xi(\rho) \neq \varnothing \Longrightarrow \rho \notin Z_{\text{ontic}}(\xi).$$

Proof. If ρ belonged to $Z_{\text{ontic}}(\xi)$, then Definition 9295.3 would give the closure row

$$\mathsf{OpenLedger}_\xi(\rho) = \varnothing.$$

This contradicts the displayed nonempty ledger row. Hence the parameter is not visible as an ontic zeta zero. □

Principle 9295.5 (Unclosed zero reads are projection cancellation)**.** *Suppose the completed scalar readout displays*

$$\mathsf{XiRead}(\rho) = 0$$

while

$$\mathsf{OpenLedger}_\xi(\rho) \neq \varnothing.$$

Then the route has only a projection-cancellation row. Its zeta source side is the forgetful kernel event of Definition 9293.14, not a vanishing of the tagged PZG family, since Definition 9293.12 keeps the empty-ledger tag visible. By Definition 9293.15, the complex-plane cancellation after forgetting tags does not pay source, branch, tail, prime-register, or scale residuals. Therefore an unclosed scalar zero read is at most projection cancellation; by Definition 9295.4, it is not an ontic zeta zero.

Principle 9295.6 (Scalar zero is not automatically ledger closure)**.** *The implication*

$$\mathsf{XiRead}(\rho) = 0 \Longrightarrow \mathsf{OpenLedger}_\xi(\rho) = \varnothing$$

is not a definitional consequence of scalar arithmetic. By Definition 9293.14, a scalar zero is a kernel event after the forgetful readout. By Definition 9293.15, such projection cancellation does not by itself identify prime ledger tags or pay residuals. Therefore the implication is a faithfulness row to be displayed by the route.

Theorem 9295.7 (Faithful zero readout gives same-packet closure)**.** *Assume* $\mathsf{ZeroReadoutFaithful}_\xi$*. Then every accepted non-trivial scalar zero read of the completed xi trace satisfies the single-ledger zero principle.*

Proof. Let ρ be an accepted non-trivial scalar zero read. By Definition 9295.2, the read comes with a closed-ledger zeta zero packet. Its closure row records that source, branch, pole, tail, completion, prime-register, and scale-residual entries are closed inside the same completed zeta object. This is exactly the same-packet closure requirement of Definition 9294.10: the scalar zero read is accepted as zeta-local only when the same packet carries the ledgers needed to close the cancellation. □

Theorem 9295.8 (Faithful conservative zero readout gives fixed-half)**.** *Assume a conservative zeta continuation certificate and* $\mathsf{ZeroReadoutFaithful}_\xi$*. Then every accepted non-trivial scalar zero read of the completed xi trace has fixed-half readout.*

Proof. By Definition 9295.7, the zero read satisfies the single-ledger zero principle. Conservative continuation forbids scale-register payment by Definition 9311.7. The fixed-half conclusion is therefore Definition 9294.11, or equivalently the conservative continuation form Definition 9311.8. □

Principle 9295.9 (Mirror orbit is conditional visibility)**.** *Functional-equation symmetry may transport a scalar zero read from ρ to its mirror position $J(\rho)$, but the transport row does not license ρ as an ontic zero before ρ itself satisfies Definition 9295.3. In the terminology of Definition 9294.1, a non-fixed orbit supplies weak mirror closure. By Definition 9294.2, that orbit balance is not the same as local ledger closure for either endpoint. Thus an off-half mirror pair is only a conditional scalar symmetry unless each endpoint is already a closed-ledger zero packet.*

Theorem 9295.10 (Only same-position mirror closure can close an ontic zero)**.** *Assume a completed zero packet has no positive-real scale inverse outside the pure zeta instruction surface, and its prime-ledger residual can be paid only by an inverse row in the ledger group. If the packet is visible as an ontic zeta zero, then its mirror closure is same-position closure:*

$$\rho = J(\rho).$$

Proof. By Definition 9295.3, an ontic zero packet has no open ledger. By Definition 9293.18, a nonzero prime-ledger residual can be cancelled only by the inverse row in the group-completion ledger. If that inverse is supplied by a distinct mirror position, then the packet has weak mirror closure in the sense of Definition 9294.1. By Definition 9294.2, weak mirror closure does not close the ledger of either endpoint as a local object. The no-extra-scale hypothesis rules out a separate positive-real payment. Thus the ledger can be closed for the single ontic zero packet only when the mirror inverse is same-position, namely $\rho = J(\rho)$. □

Theorem 9295.11 (PZG closed zeros have fixed-half readout)**.** *Let*

$$\rho = \frac{1}{2} + a + it$$

be a parameter on the pure PZG zeta instruction surface. Assume a conservative zeta continuation certificate and

$$\rho \in Z_{\text{ontic}}(\xi).$$

Then $a = 0$.

Proof. By Definition 9295.3, the membership row $\rho \in Z_{\text{ontic}}(\xi)$ gives a closed-ledger zeta zero packet. By Definition 9295.1, its scale-residual row is among the rows closed inside the same completed zeta object. On the pure PZG zeta surface, a positive-real scale payment cannot be hidden: by Definition 9292.10, such a scale inverse changes the PZG identity code, appears in the ledger, or is not part of the object. The conservative continuation certificate also forbids analytic continuation from paying the residual by an independent scale register, by Definition 9311.7.

Hence the zero packet must close its scale-residual row by the same-packet discipline of Definition 9294.10 on the pure zeta instruction surface. Applying Definition 9294.11 gives

$$\Re(\rho) = \frac{1}{2}.$$

Since $\Re(\rho) = 1/2 + a$, it follows that $a = 0$. □

Corollary 9295.12 (Ontic zeta zeros lie on the fixed-half line)**.** *Under the pure PZG zeta source and conservative continuation hypotheses,*

$$Z_{\text{ontic}}(\xi) \subseteq \left\{ \frac{1}{2} + it : t \in \mathsf{Real}^{\uparrow} \right\}.$$

Proof. Apply Definition 9295.11 to each displayed ontic zero packet. □

Principle 9295.13 (Faithfulness is the remaining zero interface)**.** *After PZG identity, conservative continuation, and no scale-register payment have been fixed, the remaining interface is not the uniqueness of PZG coding. It is the passage from scalar zero readout to closed-ledger zero packet:*

$$\mathsf{XiRead}(\rho) = 0 \Longrightarrow \mathsf{ZeroReadoutFaithful}_{\xi}(\rho).$$

Without that row the route has a scalar kernel event. With that row the route has a closed zeta zero packet, and the fixed-half argument becomes the local ledger argument of Definition 9295.8; in ontic notation this is the passage from a scalar kernel event to $\rho \in Z_{\mathrm{ontic}}(\xi)$.

Chapter 9296

Prime-Fiber Zoom Renormalization Tower

chapter 9291 separates append-only history from orthogonal residual readout, and chapter 9292 assigns PZG coordinates a logarithmic energy. The present chapter records the renormalization surface that connects these two rows. A phase-relevant observation selects a prime-fiber cell, renormalizes that cell to the current visible surface, and records every unselected component in a gap ledger.

9296.1 Prime-Fiber Zoom Systems

Definition 9296.1 (Prime-fiber zoom system)**.** *A prime-fiber zoom system consists of a base fibre $\mathcal{F}_e$, finite address sets*

$$A_m \subseteq \mathsf{Prime}^{\uparrow} \times \mathbb{N},$$

cell families

$$\mathcal{P}_m := \{C_\alpha : \alpha \in A_m\},$$

selection rows

$$\mathrm{Sel}_\alpha : \mathcal{F}_e \to C_\alpha,$$

zoom rows

$$\mathrm{Zoom}_\alpha : C_\alpha \to \mathcal{F}_e,$$

and an orthogonal register basis $(e_\alpha)_\alpha$ such that different displayed addresses have orthogonal basis rows. A step with address α_m is the composite

$$T_{\alpha_m} := \mathrm{Zoom}_{\alpha_m} \circ \mathrm{Sel}_{\alpha_m}.$$

The unselected part of $\mathcal{F}_e$ is not discarded; it is exported to the gap row governed by Definition 9352.12.

Definition 9296.2 (Solenoid clopen prime cell)**.** *Fix a finite displayed prime family S and the solenoid phase channel*

$$\pi_S : \Sigma_S \to \mathbb{T}$$

of Definition 9286.1. Its legal hidden fibre is

$$K_S := \ker(\pi_S).$$

A solenoid clopen prime cell is a finite fibre-coordinate row

$$C(\mathbf{a},\mathbf{k}) := \prod_{p\in S}(a_p + p^{k_p}\mathbb{Z}_p)$$

inside a displayed product presentation of the finite prime-register window, where $k_p \geq 0$ and a_p is read modulo p^{k_p}. The cell records a finite prefix of the hidden prime-register state over the visible phase point.

Definition 9296.3 (Prime-fibre zoom row)**.** *For a solenoid clopen prime cell $C(\mathbf{a},\mathbf{k})$, the prime-fibre zoom row is the componentwise renormalization*

$$\mathrm{Zoom}_{\mathbf{a},\mathbf{k}} : C(\mathbf{a},\mathbf{k}) \to \prod_{p\in S}\mathbb{Z}_p$$

given by

$$\mathrm{Zoom}_{\mathbf{a},\mathbf{k}}((x_p)_{p\in S}) := \left(\frac{x_p - a_p}{p^{k_p}}\right)_{p\in S}.$$

Its inverse inclusion is

$$\mathrm{Cell}_{\mathbf{a},\mathbf{k}}((y_p)_{p\in S}) := (a_p + p^{k_p}y_p)_{p\in S}.$$

Thus a selected fibre cell is read as a whole prime-register window after renormalization.

Theorem 9296.4 (Solenoid clopen refinement gives an orthogonal filtration)**.** *Let*

$$C_0 \supseteq C_1 \supseteq \cdots \supseteq C_N$$

be a finite nested sequence of solenoid clopen prime cells over the same finite prime family S. Let $\mathcal{A}_m$ be the finite sigma-algebra generated by the stage-m cell partition of K_S, and set

$$\mathcal{H}_m := L^2(K_S, \mathcal{A}_m).$$

Then

$$\mathcal{H}_m \subseteq \mathcal{H}_{m+1}, \qquad \mathcal{H}_{m+1} = \mathcal{H}_m \oplus (\mathcal{H}_{m+1} \ominus \mathcal{H}_m).$$

Consequently, for

$$\eta_{m+1} \in \mathcal{H}_{m+1} \ominus \mathcal{H}_m$$

and $v_m \in \mathcal{H}_m$,

$$\|v_m + \eta_{m+1}\|^2 = \|v_m\|^2 + \|\eta_{m+1}\|^2.$$

Proof. Refinement of finite cell partitions gives $\mathcal{A}_m \subseteq \mathcal{A}_{m+1}$, hence $\mathcal{H}_m \subseteq \mathcal{H}_{m+1}$. The complement $\mathcal{H}_{m+1} \ominus \mathcal{H}_m$ is defined as the orthogonal complement inside the Hilbert row $\mathcal{H}_{m+1}$. The displayed direct sum and norm identity are therefore the Hilbert projection identity, specialized to the solenoid clopen-cell filtration. □

Definition 9296.5 (Zoom history tower)**.** *A zoom history tower is a finite or countable sequence of addresses*

$$\alpha_0, \alpha_1, \ldots \qquad (\alpha_j \in \mathsf{Prime}^{\uparrow} \times \mathbb{N})$$

with nested cells

$$C_{\alpha_0} \supseteq C_{\alpha_0\alpha_1} \supseteq C_{\alpha_0\alpha_1\alpha_2} \supseteq \cdots.$$

The history row is append-only:

$$h_{m+1} = h_m \alpha_m.$$

The visible row at stage $m+1$ is the zoomed cell

$$B_{m+1} := \mathrm{Zoom}_{\alpha_m}(B_m \cap C_{\alpha_m}),$$

while the Hilbert residual row is the address vector e_{α_m}.

Theorem 9296.6 (Prime-fiber zoom gives history, similarity, and orthogonality)**.** *In a prime-fiber zoom history tower, each displayed step has the three rows*

$$h_m \subseteq h_{m+1},$$

$$B_{m+1} = \mathrm{Zoom}_{\alpha_m}(B_m \cap C_{\alpha_m}),$$

and

$$e_{\alpha_m} \perp \mathrm{span}\{e_{\alpha_0}, \ldots, e_{\alpha_{m-1}}\}.$$

Consequently, if

$$R_m := \sum_{j<m} e_{\alpha_j}, \qquad R_{m+1} := R_m + e_{\alpha_m},$$

then

$$\|R_{m+1}\|^2 = \|R_m\|^2 + \|e_{\alpha_m}\|^2.$$

Proof. The history inclusion is the append-only clause of Definition 9296.5, read through the same history surface as Definition 9351.5 and Definition 9351.12. The displayed formula for B_{m+1} is the definition of the zoomed visible row. Orthogonality is part of the register basis in Definition 9296.1; hence the final identity is the Pythagorean identity for the decomposition $R_{m+1} = R_m + e_{\alpha_m}$. □

Principle 9296.7 (Prime-fiber zoom is not erasure)**.** *The zoom operation changes the current visible surface, but it does not license unledgered deletion. The selected cell is renormalized to the next visible row, the address α_m is appended to the history row, and the outside of the selected cell is represented by the gap ledger. Thus*

$$B_{m+1} \supseteq B_m, \qquad B_{m+1} \sim_{\exp} B_m, \qquad B_{m+1}/B_m \perp B_m$$

are not competing assertions. They are the history, zoom, and residual projections of one certified step.

9296.2 PZG Energy Compatibility

Definition 9296.8 (PZG zoom step)**.** *A PZG zoom step is a prime-fiber zoom step whose address is*

$$\alpha = (p, k)$$

and whose residual vector is the log-energy basis vector $\varepsilon_{p,k}$ of Definition 9292.1. Its squared residual energy is

$$\|\varepsilon_{p,k}\|^2 = F_k \log p.$$

Principle 9296.9 (PZG zoom carries preserve triangular energy)**.** *If two consecutive PZG zoom addresses in one prime row create a Zeckendorf adjacency, the legal normal form replaces*

$$\varepsilon_{p,k} + \varepsilon_{p,k+1} \rightsquigarrow \varepsilon_{p,k+2}.$$

By Definition 9292.3, this replacement preserves log-energy. A PZG zoom step is therefore not an arbitrary bit change in a hidden fibre; it is a prime-indexed residual update compatible with the triangular square-norm row.

9296.3 Analytic Prime-Shift Constraint

Definition 9296.10 (Analytic prime-shift tower)**.** *An analytic prime-shift tower is a prime-fiber zoom history tower together with finite holomorphic readouts*

$$F_m : \Omega_m \to \mathsf{Complex}^{\uparrow}$$

and ledgers $\mathcal{L}_m$ such that the address sequence

$$\alpha_0, \alpha_1, \dots \qquad (\alpha_m = (p_m, k_m))$$

is not merely a discrete stream of prime coordinates. It must satisfy the following certificate rows:

$$\mathsf{NestedCell}, \quad \mathsf{OrthogonalOrZeckendorfCarry}, \quad \mathsf{HeightControl},$$
$$\mathsf{HolomorphicChartCompatibility}, \quad \mathsf{DominantStrandCompatibility}, \quad \mathsf{RoucheNoWallCrossing}, \quad \mathsf{MonodromyLedger}.$$

The nested-cell row says that the selected cells form a refinement chain. The orthogonal-or-carry row says that each residual address is either orthogonal to the previous Hilbert row or is absorbed by a legal Zeckendorf carry. The height-control row supplies compact-uniform control for the exponential reads

$$\exp(-sH_m), \qquad H_m := \sum_{j \le m} \|e_{\alpha_j}\|^2,$$

or a displayed regularization producing the same compact-uniform holomorphic limit. The holomorphic-chart row supplies analytic continuation data in the sense of Definition 9341.11; the dominant-strand row records the branch selected by the tower; the Rouché row records zero-count stability on displayed boundaries; and the monodromy ledger records branch return data instead of treating it as invisible motion.

Definition 9296.11 (SmoothPrimeShiftConstraint)**.** *The obligation*

$$\mathsf{SmoothPrimeShiftConstraint}$$

asserts that every zero-relevant prime-fiber index stream used by the completed zeta route is an analytic prime-shift tower in the sense of Definition 9296.10. It therefore rules out an unconstrained sequence of addresses

$$\alpha_0, \alpha_1, \alpha_2, \dots$$

as a source for a holomorphic zeta observation. A legal stream must carry nesting, orthogonality or carry, height control, chart compatibility, branch ledger, no-wall-crossing, and cofinal coverage.

Theorem 9296.12 (Analytic prime-shift towers give holomorphic readouts)**.** *Let an analytic prime-shift tower have domains*

$$\Omega_m \subseteq \Omega_{m+1}, \qquad \Omega := \bigcup_m \Omega_m,$$

with holomorphic readouts F_m on Ω_m. Assume that the chart compatibility rows identify the restrictions on overlaps and that $F_m \to F$ uniformly on every compact subset of Ω. Then F is holomorphic on Ω, with branch and zero-island data controlled by the monodromy and Rouché ledgers of the tower.

Proof. On each compact subset $K \subseteq \Omega$, the compact-uniform convergence row gives uniform convergence of holomorphic functions on a neighbourhood of K. The Weierstrass theorem gives a holomorphic limit on that neighbourhood. The holomorphic-chart compatibility rows identify these local limits on overlaps by the analytic-continuation operation. The monodromy ledger records possible branch return data, so no branch selector is silently changed. The Rouché no-wall-crossing row records the boundary inequalities needed to preserve zero counts inside the displayed zero islands. These rows together give the claimed holomorphic readout on Ω. □

Principle 9296.13 (Prime shifts that are not analytic remain address streams)**.** *A PZG address stream that lacks the rows of Definition 9296.10 may still encode discrete prime-register information. It does not thereby generate a continuous curve, a differentiable observation, or a holomorphic zeta readout. Analytic operations such as eta continuation, functional-equation transport, contour transport, or explicit-formula transport are precisely the rows that convert a controlled prime-register stream into an analytic observation object.*

9296.4 Continuous Exponential Projection

Definition 9296.14 (Internal height and external exponential readout)**.** *The internal height of a PZG register is the additive square-norm row*

$$H(R) := \|R\|^2.$$

For the integer register $R_{\mathsf{PZG}}(n)$ of Definition 9292.1, this is

$$H(R_{\mathsf{PZG}}(n)) = \log n$$

by Definition 9292.2. The external exponential readout is the multiplicative row

$$\mathrm{Scale}(R) := \exp(H(R)).$$

The endpoint symbol **e** *denotes the identity endpoint or base fibre in the zoom system; the scalar* $\exp(1)$ *is the unit value of the continuous exponential readout.*

Definition 9296.15 (Character-valued exponential readout)**.** *Let A be a displayed additive ledger group, and let*

$$\omega : A \to (\mathbb{C}, +)$$

be an additive readout weight. The exponential readout determined by ω is

$$\mathrm{Exp}_\omega : A \to \mathbb{C}^\times, \qquad \mathrm{Exp}_\omega(x) := \exp(\omega(x)).$$

It is the external multiplicative observation of the internal additive coordinate. If $\omega(x) \in i\mathsf{Real}^\uparrow$ for every displayed x, then

$$\mathrm{Exp}_\omega(x) \in \mathbb{T}$$

and the readout is a unit-circle phase projection. If $\omega(x) \in \mathsf{Real}^\uparrow$ for every displayed x, then

$$\mathrm{Exp}_\omega(x) \in \mathsf{Real}^\uparrow_{>0}$$

and the readout is a radial-scale projection. Thus the same exponential mechanism separates into the two rows

$$\exp(a + ib) = \exp(a)\exp(ib), \qquad \exp(ib) \in \mathbb{T}, \qquad \exp(a) \in \mathsf{Real}^\uparrow_{>0}.$$

Theorem 9296.16 (Exponential readout is the normalized additive-to-multiplicative projection)**.** *Let*

$$\Phi : \mathsf{Real}^{\uparrow} \to \mathsf{Real}^{\uparrow}_{>0}$$

be a differentiable readout satisfying

$$\Phi(t+s) = \Phi(t)\Phi(s), \qquad \Phi(0) = 1, \qquad \Phi'(0) = 1.$$

Then

$$\Phi(t) = \exp(t).$$

Proof. Set

$$f(t) := \log \Phi(t).$$

The multiplicative law for Φ gives

$$f(t+s) = f(t) + f(s).$$

Differentiability gives $f(t) = ct$ for a constant c. Since

$$\Phi'(0) = f'(0)\exp(f(0)) = c,$$

the normalization $\Phi'(0) = 1$ gives $c = 1$. Hence $\Phi(t) = \exp(t)$. □

Principle 9296.17 (Pythagorean addition projects to exponential multiplication)**.** *If a PZG zoom step has*

$$R_{m+1} = R_m + e_{\alpha_m}, \qquad e_{\alpha_m} \perp R_m,$$

then

$$H(R_{m+1}) = H(R_m) + \|e_{\alpha_m}\|^2.$$

Under the external exponential readout,

$$\mathrm{Scale}(R_{m+1}) = \mathrm{Scale}(R_m)\exp(\|e_{\alpha_m}\|^2).$$

Thus the internal triangular square-norm row is additive, while its continuous scale projection is multiplicative.

Principle 9296.18 (Solenoid exponential readout is phase-valued)**.** *For the localized additive ledger*

$$A = \mathbb{Z}[S^{-1}],$$

the visible solenoid phase coordinate is read through unit characters of the form

$$q \mapsto \exp(2\pi i q\theta) \in \mathbb{T}.$$

This is the instance of Definition 9296.15 with

$$\omega_\theta(q) = 2\pi i q\theta.$$

The hidden row of Definition 9413.779 is the compact prime-register fibre K_S, not a positive real scale group. Therefore a real exponential row

$$q \mapsto \exp(aq), \qquad a \in \mathsf{Real}^{\uparrow},$$

is radial scale data rather than solenoid-hidden phase data, unless $a = 0$ on the zero-relevant packet.

Principle 9296.19 (Phase and radial reads use the same internal height)**.** *For a zeta monomial and* $s = \frac{1}{2} + r + it$*,*

$$n^{1/2-s} = \exp\big(-(r+it)\log n\big) = \exp(-rH(R_{\mathsf{PZG}}(n)))\exp(-itH(R_{\mathsf{PZG}}(n))).$$

Equivalently, in PZG coordinates,

$$n^{1/2-s} = \exp\left(-(r+it)\sum_{p,k} z_{p,k}F_k \log p\right).$$

The second factor is the unit-circle phase read; the first factor is the positive radial-scale read. Both consume the same internal PZG height. Only the unit-circle factor is a phase projection. A nontrivial radial factor is an external scale projection and must be ledgered as such.

Principle 9296.20 (RH reading of prime-fiber zoom)**.** *For a zeta phase row*

$$n^{-it} = \exp\left(-it\sum_{p,k} z_{p,k}F_k \log p\right),$$

the PZG coordinates are prime-fiber zoom addresses read through phase. For a centered zero packet with

$$z_\rho = 1 - \frac{1}{\rho} = e^{\ell+i\theta},$$

the angular coordinate θ *is compatible with unit phase readout, whereas a nonzero radial coordinate* ℓ *would have to appear as a ledgered residual, a gap row, or a refused scale coordinate. It cannot be absorbed into the visible wave without a prime-fiber address or a legal solenoid fibre row.*

Chapter 9297

Prime-Fiber Zoom Scale Obstruction Bridge

chapter 9296 records the local prime-fiber zoom step: history is appended, the selected cell is renormalized to the visible surface, the residual address is orthogonal to the previous register row, and the exterior of the selected cell is retained by a gap ledger. The present chapter records the scale-obstruction bridge needed to consume such steps in RH-facing towers. A legal zoom tower is not only a sequence of selected cells. It must also preserve every finite balanced correlation or reflection-positive obstruction that is invariant under its self-similar dilation rule.

9297.1 Self-Substitution Interface

Definition 9297.1 (PFZ self-substitution interface)**.** *A prime-fiber zoom tower carries a self-substitution interface when its address refinement row is equipped with a constant-length phase self-substitution row in the sense of Definition 9441.1:*

$$u_{Nn+a} = v_a u_n, \qquad a = 0, \dots, N-1.$$

The index n is the previous visible section, and a is the local digit selected inside the prime-fiber cell. The interface is Q3-compatible when

$$\sum_{a=0}^{N-1} v_a = \sqrt{N}.$$

Principle 9297.2 (Rule before visible section)**.** *In a PFZ tower, the invariant object is the repeated refinement rule, not one displayed visible section. A section records a finite layer; the rule records how each selected prime-fiber cell is expanded into the next visible surface. This is the RH-facing use of Definition 9441.2: scale invariants must be tested on the rule and its dilation tower, not only on a single finite window.*

Definition 9297.3 (PFZ balanced obstruction row)**.** *Let α be a balanced signed block and let*

$$\Gamma(\alpha)$$

be its correlation read in the self-substitution interface. A PFZ balanced obstruction row is either a non-real balanced read

$$\operatorname{Im}\Gamma(\alpha) \neq 0,$$

or a negative balanced read

$$\Gamma(\alpha) < 0.$$

It is scale-stable when the same obstruction is displayed for every dilated block $D_{N^k}\alpha$.

Theorem 9297.4 (PFZ balanced obstruction persists under dilation)**.** *In any PFZ tower carrying the self-substitution interface of Definition 9297.1, every PFZ balanced obstruction row is scale-stable:*

$$\Gamma(D_{N^k}\alpha) = \Gamma(\alpha) \qquad (k \geq 0).$$

Proof. This is exactly the balanced-correlation scale invariance of Definition 9441.4, read through the PFZ interface. The equality of reads gives persistence of the imaginary part and of the sign, as in Definition 9441.5. □

9297.2 Reflection-Positive Windows

Definition 9297.5 (PFZ reflection-centered dilation row)**.** *For odd N, the PFZ reflection-centered dilation row is the transported block dilation*

$$\mathcal{D}_N^\theta(\delta_j) := \delta_{\frac{1+N(2j-1)}{2}}$$

from Definition 9441.7. It is allowed in the PFZ tower only together with the reflection-commutation row

$$\theta\mathcal{D}_N^\theta = \mathcal{D}_N^\theta\theta$$

of Definition 9441.8.

Definition 9297.6 (PFZ RP obstruction row)**.** *Let $\mathcal{B}$ be a finite neutral reflection-positive window with matrix*

$$M_{\mathcal{B}}(v)_{ij} := \Gamma(\alpha_j - \theta\alpha_i).$$

A PFZ RP obstruction row is the presence of a negative direction in $M_{\mathcal{B}}(v)$. The obstruction is scale-stable when every reflected dilation

$$M_{(\mathcal{D}_N^\theta)^k\mathcal{B}}(v)$$

carries the same negative direction.

Theorem 9297.7 (PFZ RP obstruction persists under reflection-centered dilation)**.** *Assume N is odd. In a PFZ tower carrying the reflection-centered dilation row of Definition 9297.5, every PFZ RP obstruction row is scale-stable:*

$$M_{(\mathcal{D}_N^\theta)^k\mathcal{B}}(v) = M_{\mathcal{B}}(v) \qquad (k \geq 0).$$

Proof. Apply the odd-length RP window self-similarity theorem Definition 9441.12. Equality of the matrices preserves their spectra, so the negative direction is the same one recorded in Definition 9441.13. □

Principle 9297.8 (Finite obstruction is not scale noise)**.** *A finite balanced-correlation defect or finite RP negative direction cannot be dismissed as a local artefact of the selected cell. Once the PFZ tower carries the relevant self-substitution or reflection-centered dilation rule, the finite obstruction is copied by the rule itself. A legal zoom operation may move the visible surface, but it may not hide such an obstruction in the gap ledger, the solenoid fibre, or a coarser visible section.*

9297.3 Smooth Branch Gate

Definition 9297.9 (PFZ smooth branch gate)**.** *A local PFZ passage direction is admissible as a smooth branch only when it satisfies every displayed linear audit attached to the same window: the Q3 tangent row, the Hermitian or RP defect rows, the balanced correlation rows, and the gap-ledger compatibility row. Passing one projection is not enough to license the branch as a BEDC continuation object.*

Theorem 9297.10 (Pythagorean boundary has no antisymmetric PFZ passage)**.** *At the Pythagorean pentary row of Definition 9445.1, no nonzero mirror-antisymmetric tangent direction is admissible through the PFZ smooth branch gate.*

Proof. The Q3 tangent row alone allows the mirror-antisymmetric coordinates (x, y) by Definition 9445.2. The anchored three-link Hermitian audit then applies Definition 9445.5, which forces

$$x = 0, \qquad y = 0.$$

Thus every nonzero mirror-antisymmetric tangent fails the full PFZ branch gate. □

Principle 9297.11 (Branch admissibility is multi-projection)**.** *The PFZ tower may display many local digit choices, but a smooth continuation branch is not licensed by local choice alone. It must pass the phase, Hermitian, balanced-correlation, RP, and gap-ledger reads at the same time. The Pythagorean pentary boundary is the local model: phase-sum compatibility leaves apparent tangent directions, while the Hermitian reads remove the non-palindromic first-order directions.*

9297.4 Zeta-Facing Closure Obligations

Definition 9297.12 (PFZ closure envelope)**.** *The PFZ closure envelope is the union of all objects generated from the base endpoint fibre by legal prime-fiber zoom steps satisfying the rows of Definition 9296.5, the self-substitution interface of Definition 9297.1, the scale-obstruction rows of Definition 9297.3 and Definition 9297.6, and the smooth branch gate of Definition 9297.9. A member of the envelope therefore carries history containment, exponential self-similarity, orthogonal residual accounting, gap recording, and obstruction persistence as ledger rows.*

Definition 9297.13 (ZetaPFZEmbedding)**.** *The obligation*

$$\mathsf{ZetaPFZEmbedding}$$

asserts that the Dirichlet monomial rows, Euler product rows, analytic continuation rows, completed zero packets, and Li–Weil–Nyman projection rows used by the completed zeta route enter the PFZ closure envelope of Definition 9297.12. It is not the claim that the PFZ envelope proves RH; it is the source-admission claim that the zeta-facing objects are generated with their prime-fiber, phase, scale, and gap ledgers visible.

Definition 9297.14 (NoHiddenRadialPFZ)**.** *The obligation*

$$\mathsf{NoHiddenRadialPFZ}$$

asserts that a nonzero radial coordinate in a centered zero packet cannot be absorbed by PFZ zoom, solenoid phase projection, balanced-correlation dilation, reflection-centered RP dilation, or smooth branch selection. If the radial factor is present, it is a displayed positive-real scale row. If it is omitted, the packet has an unledgered residual and is not a legal PFZ closure object.

Principle 9297.15 (RH role of the PFZ obstruction bridge)**.** *For a completed zero packet with*

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta},$$

the phase coordinate θ may be read through PFZ phase and solenoid rows, while ℓ is a radial scale coordinate. Under ZetaPFZEmbedding*, the zero packet must enter the PFZ closure envelope. Under* NoHiddenRadialPFZ*, the case $\ell \neq 0$ cannot be hidden by zoom, dilation, reflection, or branch selection. The RH route must therefore supply these two obligations before the PFZ bridge can contribute to fixed-half readout.*

Chapter 9298

Prime-Fiber Zoom NameCert Interface

chapter 9296 records the local zoom step, and chapter 9297 records the scale-obstruction rows that must persist through the zoom tower. The present chapter records the BEDC admission surface for that package. A PFZ object is not licensed by the visible equation of a zoom step alone; it is licensed only as a five-field $\mathsf{NameCert}$ interface whose ledger policy keeps the unselected cell exterior, tail data, and radial-scale residuals auditable.

9298.1 NameCert Surface

Definition 9298.1 (PFZ NameCert surface)**.** *For an object B in the PFZ closure envelope of Definition 9297.12, the PFZ naming surface is the five-field packet*

$$\mathsf{NameCert}_{\mathsf{PFZ}}(B) := (\mathsf{SourceSpec}_B, \mathsf{PatternSpec}_B, \mathsf{ClassifierSpec}_B, \mathsf{StabilityCert}_B, \mathsf{LedgerPolicy}_B).$$

The fields are read as follows:

$$\mathsf{SourceSpec}_B = (\mathbf{e}, \mathcal{F}_{\mathbf{e}}, h),$$

where $\mathbf{e}$ is the endpoint fibre, $\mathcal{F}_{\mathbf{e}}$ is the unexpanded prime-fiber source, and h is the displayed address history;

$$\mathsf{PatternSpec}_B = \textit{the legal prime-fiber zoom refinement rule};$$

$$\mathsf{ClassifierSpec}_B = \textit{history, address, RP, Hermitian, phase, and radial classifiers};$$

$$\mathsf{StabilityCert}_B = \textit{history containment, exponential similarity, orthogonal residuals,}$$

together with balanced-correlation persistence, RP-window persistence, and smooth-branch rigidity; and

$$\mathsf{LedgerPolicy}_B = \textit{prime-address, gap, tail, phase, radial-scale, and branch ledgers.}$$

Theorem 9298.2 (PFZ objects enter BEDC only through NameCert)**.** *If a PFZ closure-envelope object B is used as a BEDC public object $B^{\uparrow}$, then its use factors through $\mathsf{NameCert}_{\mathsf{PFZ}}(B)$.*

Proof. By Definition 9352.17, a derived interface is admitted only through a naming certificate with source, pattern, classifier, stability, and ledger fields. The PFZ closure envelope is a derived interface: it hides selected-cell provenance, unselected-cell exterior data, residual addresses, tail data, and phase or radial readouts behind a visible zoom surface. Therefore object-layer use of $B^{\uparrow}$ requires the five fields displayed in Definition 9298.1. □

Principle 9298.3 (PFZ ledger policy is part of the object)**.** *The PFZ ledger policy is not an optional annotation after the zoom step. It is one of the fields that licenses the public name. Omitting it would turn the selected cell into an apparent whole, erase the exterior gap, and leave no audit path for later questions about phase, branch, tail, or radial scale. Thus a PFZ object without* $\mathsf{LedgerPolicy}_B$ *is not a BEDC-derived object in the sense of Definition 9352.16.*

9298.2 Ledger-Complete Limits

Definition 9298.4 (PFZ tower ledger)**.** *For a PFZ tower*

$$B_0 \to B_1 \to \cdots \to B_m \to \cdots ,$$

the PFZ tower ledger is the composite ledger obtained by recording at each step the selected address, the cell exterior gap, the residual orthogonal address, the phase readout, and any radial, branch, or tail row exposed by the step. The ledger of a composite tower is not the last step ledger alone; each later ledger is pulled back along the already visible interface, as in Definition 9414.315.

Definition 9298.5 (PFZ limit admission)**.** *A limit or tail object*

$$B_\infty = \lim_m B_m$$

is admitted as a PFZ public object only when the tower carries a PFZ tower ledger in the sense of Definition 9298.4, together with the convergence, branch, and tail rows required by the analytic consumer. The visible endpoint alone is not an admitted PFZ object.

Theorem 9298.6 (PFZ limit admission requires the tower ledger)**.** *If* B_∞ *is admitted as a PFZ public object, then its* $\mathsf{LedgerPolicy}_{B_\infty}$ *contains the PFZ tower ledger.*

Proof. By Definition 9298.5, an admitted PFZ limit must carry the composite tower ledger. The general ledger rule is Definition 9414.315: an endpoint ledger is not merely the final arrow's ledger, because the endpoint hides the preceding source histories and intermediate visible interfaces. Since $\mathsf{LedgerPolicy}_{B_\infty}$ is the ledger field of the PFZ NameCert surface, it must contain this composite tower ledger. □

Principle 9298.7 (No gap-free PFZ tail)**.** *A PFZ tail cannot be used as a place where exterior-cell information, branch changes, or radial scale disappear. If such data are relevant to a later zeta-facing readout, they must be present in the tower ledger. If they are absent, the public PFZ object has not been admitted for that readout.*

9298.3 Zeta-Facing Admission

Definition 9298.8 (Zeta PFZ NameCert admission)**.** *The zeta PFZ admission row is the strengthening of* $\mathsf{ZetaPFZEmbedding}$ *in which every zeta-facing PFZ object carries the NameCert surface of Definition 9298.1. Its source field contains Dirichlet monomial and PZG data; its pattern field contains Euler-product, continuation, zero, and Li–Weil–Nyman readouts; its classifier field contains zero, strip, phase, radial, and prime-register classifiers; its stability field contains analytic compatibility and the scale-obstruction bridge; and its ledger policy contains gap, branch, tail, phase, radial, and tower ledgers.*

Definition 9298.9 (NameCert-level radial refusal)**.** *The NameCert-level radial refusal is the PFZ admission form of* NoHiddenRadialPFZ*. For a centered zero packet with*

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta},$$

the coordinate ℓ is accepted only as one of the following:

$$\ell = 0, \qquad \text{a displayed radial-scale ledger row}, \qquad \text{or a refused unledgered residual.}$$

It is not accepted as unit phase, prime-address gauge, Zeckendorf carry, gap-free tail, or analytic-continuation branch artefact.

Theorem 9298.10 (PFZ NameCert package gives the radial-obstruction input)**.** *Assume the zeta PFZ admission row of Definition 9298.8 and the NameCert-level radial refusal of Definition 9298.9. Then every completed zeta zero packet admitted through this package supplies the PFZ radial-obstruction input required by Definition 9297.15.*

Proof. The zeta PFZ admission row supplies the zero packet as a PFZ public object with source, pattern, classifier, stability, and ledger fields. In particular, the radial coordinate is not an external diagnostic but a readout in the admitted packet, and the phase, radial, branch, tail, and gap ledgers are present in the ledger policy. The NameCert-level radial refusal then classifies a nonzero ℓ as a displayed scale row or as an unledgered residual that is not admitted. This is precisely the radial-obstruction input used by Definition 9297.15. □

Theorem 9298.11 (PFZ NameCert conditional fixed-half readout)**.** *Assume the zeta PFZ admission row, the NameCert-level radial refusal, and the radial-obstruction package sufficient for the RH route. Then every completed zero packet admitted by the package has fixed-half readout.*

Proof. By Definition 9298.10, the admitted zero packet supplies the PFZ radial-obstruction input. The radial-obstruction package then applies exactly as in Definition 9297.15: if $z(\rho) = e^{\ell + i\theta}$ had $\ell \neq 0$, that radial coordinate would be a displayed positive-real scale row or an unadmitted residual, not a unit-phase or prime-fiber row. The sufficient radial package rules out such a legal zero packet. Hence $\ell = 0$, and therefore the zero has fixed-half readout. □

Chapter 9299

Prime-Shift Analytic Compatibility

chapter 9296 defines analytic prime-shift towers and the $\mathsf{SmoothPrimeShiftConstraint}$ obligation. The present chapter records the sharper compatibility package used when the tower is meant to support analytic continuation rather than only a holomorphic limit of finite readouts.

9299.1 Four Compatibility Rows

Definition 9299.1 (PrimeShiftAnalyticCompatibility)**.** *Let a prime-fiber tower select clopen cells $C_n \subset K_S$ and finite holomorphic readouts*

$$F_n : \Omega_n \to \mathsf{Complex}^{\uparrow}.$$

The tower satisfies

$$\mathsf{PrimeShiftAnalyticCompatibility}$$

when it carries the following rows. First, nested cell compatibility:

$$C_{n+1} \subseteq C_n.$$

For a single p-adic coordinate with

$$C_k = a_k + p^k \mathbb{Z}_p,$$

this includes the digit condition

$$a_{k+1} \equiv a_k \pmod{p^k}.$$

Second, cocycle compatibility: the cell-renormalization maps compose with the displayed transition ledger, so refinement from level n to $n+2$ agrees with refinement through level $n+1$. Third, character-flow compatibility: there is one displayed frequency row ω whose induced one-parameter phase flow satisfies

$$\gamma(\tau_\omega(t)) = e^{it\ell_\omega(\gamma)}$$

for every displayed character γ consumed by the tower. Fourth, normal-convergence and no-radial-anomaly compatibility:

$$F_n \to F$$

uniformly on compact subsets of the analytic domain, the logarithmic derivative readouts converge on zero-free compact windows, and every transition factor is unit phase or compact prime-fibre data rather than an unledgered element of $\mathsf{Real}^{\uparrow}_{>0}$.

Principle 9299.2 (Compatibility separates paths from flows)**.** *An arbitrary prime address sequence gives only a discrete path. Nested cell compatibility gives a profinite limit point. Cocycle compatibility turns the refinements into one coherent tower. Character-flow compatibility turns the tower into a smooth phase readout. Normal convergence and no-radial-anomaly compatibility are the analytic rows: they are what allow the tower to be consumed by analytic continuation without importing a hidden positive-real scale.*

Principle 9299.3 (Compatibility is the continuation skeleton)**.** *Prime-shift compatibility is a necessary skeleton for analytic continuation, not a replacement for the continuation theorem attached to a concrete source. The nested, digit, cocycle, and character-flow rows rule out branch jumps and incoherent refinements; the normal-convergence and logarithmic-derivative rows supply compact analytic control; the no-radial-anomaly row prevents a positive-real scale from being absorbed into the solenoid fibre. A tower that lacks any one of these rows cannot serve as a BEDC continuation interface, while a tower that carries them still has to be identified with the intended analytic source by the appropriate source and operation certificates.*

Definition 9299.4 (ZetaAnalyticContinuationIsPrimeShiftCompatible)**.** *The obligation*

$$\mathsf{ZetaAnalyticContinuationIsPrimeShiftCompatible}$$

asserts that the eta continuation, functional-equation continuation, completed Gamma normalization, contour transport, and explicit-formula transport used by the completed zeta route are all realized through prime-shift towers satisfying Definition 9299.1. It is stronger than the existence of a meromorphic continuation: it requires that the continuation preserve the prime-register ledger, the character flow, the normal-convergence rows, and the no-radial-anomaly row.

Theorem 9299.5 (Prime-shift analytic compatibility refines smooth shift)**.** *If a prime-fiber tower satisfies* PrimeShiftAnalyticCompatibility*, then it satisfies the* SmoothPrimeShiftConstraint *rows required by Definition 9296.11.*

Proof. Nested cell compatibility supplies the refinement row. Cocycle compatibility supplies coherent transition ledgers. Character-flow compatibility supplies the single frequency row behind the visible phase readout. Normal convergence supplies the compact-uniform height and holomorphic readout control. The no-radial-anomaly clause supplies the ledger separation between unit phase, compact prime-fibre data, and positive-real scale. These are exactly the rows demanded by Definition 9296.11. □

Principle 9299.6 (RH-facing role of analytic compatibility)**.** *If a completed zero packet has centered mode*

$$U_a(s) = e^{-rh_a} e^{-ith_a},$$

then e^{-ith_a} is compatible with the character-flow row, while a nontrivial e^{-rh_a} is a positive-real transition factor. Under ZetaAnalyticContinuationIsPrimeShiftCompatible*, such a factor must be recorded as scale data or refused by the no-radial-anomaly row. It cannot be treated as a smooth prime shift inside the solenoid fibre.*

Chapter 9300

Smooth Prime Classifier Tower

chapter 9296 supplies analytic prime-shift towers, and chapter 9299 separates discrete address streams from smooth holomorphic readouts. The present chapter records the classifier side of the same interface. A prime shift that has become analytic must still remain visible to recursive prime classifiers; otherwise a positive-real radial coordinate could be mistaken for a harmless phase, carry, or branch effect. The role of the tower below is to make that mistake impossible at the finite classifier surface.

9300.1 Classifier Tower Surface

Definition 9300.1 (SmoothPrimeClassifierTower)**.** *A smooth prime classifier tower is a prime-fiber tower satisfying* PrimeShiftAnalyticCompatibility *together with a sequence of classifier packets*

$$\mathcal{C}_0, \mathcal{C}_1, \mathcal{C}_2, \ldots$$

where

$$\mathcal{C}_m = (\Pi_m, \partial_m, U_m, \Lambda_m).$$

Here Π_m is the displayed prime-atom surface at level m, ∂_m is the triangle-boundary or obstruction readout, U_m is the unit-circle phase resource available at that level, and Λ_m is the ledger row transporting residuals from level m to level $m+1$. The transition

$$\mathcal{C}_m \to \mathcal{C}_{m+1}$$

is admitted only when it is sourced by a displayed obstruction or by a displayed refinement of the prime-register carrier.

Definition 9300.2 (Classifier readout of a packet)**.** *For an admitted PFZ packet X, the level-m classifier readout is the finite register expression*

$$\nu_m(X) = \sum_{\pi \in \Pi_m} v_\pi(X) e_\pi$$

together with the boundary row

$$\partial_m(X).$$

The packet is level-m triangle-closed exactly when

$$\partial_m(X) = 0$$

and every residual exposed by $\nu_m(X)$ is either a unit-circle phase row in U_m or a ledgered residual in Λ_m.

Principle 9300.3 (Classifiers refine only visible residues)**.** *The passage from $\mathcal{C}_m$ to $\mathcal{C}_{m+1}$ is not a free increase of resolution. It is licensed by a residue already visible at level m: a nonzero triangle boundary, a prime-register ambiguity, a character residual, a branch ledger row, or a scale row that has failed to be a unit phase. Thus recursive classification remains a ledger operation rather than a hidden appeal to an external arithmetic oracle.*

9300.2 Finite Classifier Separation

Definition 9300.4 (Finite prime-register residual)**.** *A finite prime-register residual is a non-identity element R in a finite abelian quotient G_m of the level-m prime-register surface. It is classifier-visible when some displayed character*

$$\chi : G_m \to S^1$$

satisfies

$$\chi(R) \neq 1.$$

Theorem 9300.5 (Finite character separation)**.** *Let G be a finite abelian group. If $g \neq e$, then there is a character*

$$\chi : G \to S^1$$

with

$$\chi(g) \neq 1.$$

Proof. Write G as a finite product of cyclic groups. Since $g \neq e$, at least one cyclic coordinate is nonzero. The standard root-of-unity character on that cyclic factor is nontrivial on the chosen coordinate, and extending it trivially across the other factors gives the required character of G. □

Corollary 9300.6 (Finite residuals cannot be hidden from classifiers)**.** *Every nonzero finite prime-register residual is detected by a finite character classifier.*

Proof. Apply Definition 9300.5 to the finite abelian quotient carrying the residual. □

9300.3 Cofinal Detection

Definition 9300.7 (Cofinal prime classifier tower)**.** *A smooth prime classifier tower is cofinal when its finite quotients form a Hausdorff profinite classifier system*

$$G = \varprojlim_m G_m$$

and every non-identity residual in G has non-identity image in at least one finite quotient G_m.

Theorem 9300.8 (Profinite residual separation)**.** *Let $G = \varprojlim_m G_m$ be a Hausdorff profinite group. If $g \neq e$ in G, then there is a finite quotient G_m whose image g_m satisfies*

$$g_m \neq e.$$

Proof. Since G is Hausdorff, there is an open neighbourhood of e not containing g. The open normal subgroups form a neighbourhood basis at e, so some open normal subgroup N excludes g. The quotient G/N is finite, and the image of g in G/N is not the identity. □

Definition 9300.9 (CofinalPrimeClassifierDetectsScale)**.** *The obligation*

$$\mathsf{CofinalPrimeClassifierDetectsScale}$$

asserts that every nonzero radial-scale residual of an admitted zeta-facing PFZ packet is represented as a non-identity residual in the cofinal classifier system. Equivalently, for every centered zero packet with

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta},$$

the case $\ell \neq 0$ supplies a residual whose image is detected by some finite classifier level:

$$\ell \neq 0 \quad \Longrightarrow \quad \exists m,\ \partial_m(\ell) \neq 0 \quad \text{or} \quad \exists m,\ \chi_m(\ell_m) \neq 1.$$

Theorem 9300.10 (Cofinal classifiers detect nonzero residuals)**.** *In a cofinal prime classifier tower, every non-identity residual is detected by a finite classifier level.*

Proof. Let R be a non-identity residual in the profinite classifier system. By Definition 9300.8, its image R_m is non-identity in some finite quotient G_m. By Definition 9300.5, a finite character on G_m separates R_m from the identity. This character is a finite classifier readout, so the residual is visible at level m. □

9300.4 Radial-Scale Refusal

Theorem 9300.11 (Smooth prime classifier tower excludes hidden radial scale)**.** *Assume a zeta-facing PFZ packet carries the NameCert admission row of Definition 9298.8, the analytic compatibility row of Definition 9299.1, and a cofinal smooth prime classifier tower satisfying Definition 9300.9. Then a nonzero radial coordinate cannot be consumed as a legal closed unit-phase readout.*

Proof. Let the centered zero packet have

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta}.$$

The analytic compatibility row separates character flow from positive-real scale. Hence θ may enter the unit-circle phase resource, while $\ell \neq 0$ is a radial-scale residual. By Definition 9300.9, this residual has a nonzero finite classifier image. By Definition 9300.10, some finite classifier detects it. The detected residual is either recorded in the ledger, in which case it is not a closed unit-phase readout, or it is absent from the ledger, in which case the PFZ NameCert admission row is not satisfied. In neither case can $\ell \neq 0$ be consumed as legal closed phase. □

Corollary 9300.12 (Classifier-tower input for fixed-half readout)**.** *Assume the zeta PFZ admission row, the NameCert-level radial refusal, prime-shift analytic compatibility, and* CofinalPrimeClassifierDetectsScale*. Then every admitted completed zero packet supplies the classifier-tower input needed by the PFZ fixed-half readout route.*

Proof. The zeta PFZ admission row places the zero packet in the named PFZ surface. NameCert-level radial refusal identifies a nonzero ℓ as scale data or as an unadmitted residual. Prime-shift analytic compatibility prevents that scale data from being absorbed into the character-flow row. The cofinal classifier obligation then detects any remaining nonzero scale residual at a finite classifier level. This is exactly the radial-obstruction input consumed by Definition 9298.10. □

9300.5 Scale Faithfulness Boundary

Definition 9300.13 (Radial classifier footprint)**.** *Let X be an admitted zeta-facing PFZ packet with centered exponential readout*

$$\mathrm{ExpRead}(X) = e^{\ell(X)+i\theta(X)}.$$

A radial classifier footprint for X is a map

$$\kappa_X : \ell(X) \longmapsto R_\infty(\ell(X)) \in G$$

into the profinite classifier system of Definition 9300.7, together with finite images

$$R_m(\ell(X)) \in G_m$$

compatible with the transition maps of the tower. The footprint records where the positive-real scale coordinate is read by the prime-register classification surface; it is not a phase projection and not a Zeckendorf carry.

Definition 9300.14 (ScaleToPrimeClassifierFaithfulness)**.** *The obligation*

$$\mathsf{ScaleToPrimeClassifierFaithfulness}$$

asserts that every admitted zeta-facing radial classifier footprint is faithful on nonzero scale:

$$\ell(X) \neq 0 \quad \Longrightarrow \quad R_\infty(\ell(X)) \neq e_G.$$

It is the arithmetic bridge from a positive-real zero-packet coordinate to the cofinal prime-classifier tower. The profinite detection theorems do not create this bridge; they consume it.

Theorem 9300.15 (Scale faithfulness gives finite classifier detection)**.** *Assume X carries a radial classifier footprint in a cofinal prime classifier tower, and assume* ScaleToPrimeClassifierFaithfulness *for that footprint. If*

$$\ell(X) \neq 0,$$

then there are a finite level m and a character

$$\chi_m : G_m \to S^1$$

such that

$$\chi_m(R_m(\ell(X))) \neq 1.$$

Proof. By Definition 9300.14, $\ell(X) \neq 0$ implies

$$R_\infty(\ell(X)) \neq e_G.$$

The classifier tower is Hausdorff and profinite, so Definition 9300.8 gives a finite quotient G_m in which

$$R_m(\ell(X)) \neq e_{G_m}.$$

Applying Definition 9300.5 in G_m gives a character χ_m separating this finite image from the identity. □

Theorem 9300.16 (Detected radial residual cannot close)**.** *Let X be an admitted PFZ packet. If some finite classifier detects a radial residual,*

$$\chi_m(R_m(\ell(X))) \neq 1,$$

then X is not a gap-free unit-phase closure.

Proof. The displayed inequality is a finite residual row. If the row is entered into the ledger, then the packet still carries scale data and is not a unit-phase closure. If the row is absent from the ledger, then the PFZ NameCert admission row is violated, because the radial, phase, gap, branch, tail, and tower ledgers of Definition 9298.8 must account for such a consumer-facing residual. Thus the packet cannot be a gap-free unit-phase closure. □

Corollary 9300.17 (Scale faithfulness supplies cofinal scale detection)**.** *For any admitted zeta-facing PFZ packet carrying a faithful radial classifier footprint, the obligation* CofinalPrimeClassifierDetectsScale *holds for that packet.*

Proof. Unfold Definition 9300.9. The nonzero radial coordinate becomes a non-identity element of the profinite classifier system by Definition 9300.14. Finite detection then follows from Definition 9300.15. □

Principle 9300.18 (Arithmetic content of scale faithfulness)**.** *The remaining arithmetic content of* ScaleToPrimeClassifierFaithfulness *is the assertion that a nonzero radial zero-packet coordinate is not external to the prime surface. It must be read through Dirichlet log-height rows such as*

$$\log n = \sum_p v_p(n) \log p,$$

through explicit-formula scale terms, or through finite character/Frobenius classifiers. A radial coordinate that affects the zero packet but has no prime-classifier footprint is outside the PFZ admission surface rather than an undetected legal closure.

9300.6 Explicit-Formula Prime Residuals

Definition 9300.19 (Finite prime residual)**.** *A finite prime residual is a finite formal sum*

$$R = \sum_{j=1}^{N} c_j[q_j],$$

where $c_j \in \mathsf{Complex}^{\uparrow}$, $q_j \in \mathsf{Nat}^{\uparrow}$ with $q_j \geq 2$, and the q_j are pairwise distinct. It is nonzero when at least one displayed coefficient c_j is nonzero. The labels q_j may be primes or prime powers, matching the prime-power support of the explicit formula.

Definition 9300.20 (Finite Dirichlet classifier readout)**.** *Let $R = \sum_{j=1}^{N} c_j[q_j]$ be a finite prime residual. For a modulus M with $\gcd(q_j, M) = 1$ for all j, a finite Dirichlet classifier is a character*

$$\chi : (\mathbb{Z}/M\mathbb{Z})^{\times} \to S^1.$$

Its readout on R is

$$\chi(R) := \sum_{j=1}^{N} c_j \chi(q_j).$$

Theorem 9300.21 (Finite Dirichlet classifiers separate finite residuals)**.** *If $R = \sum_{j=1}^{N} c_j[q_j]$ is a nonzero finite prime residual, then there are a modulus M and a Dirichlet character χ modulo M such that*

$$\chi(R) \neq 0.$$

Proof. Choose a prime modulus M that divides none of the finitely many integers q_j and none of the nonzero differences $q_i - q_j$. Then the classes of the q_j are pairwise distinct units in

$$G = (\mathbb{Z}/M\mathbb{Z})^{\times}.$$

If every character $\chi : G \to S^1$ had

$$\sum_{j=1}^{N} c_j \chi(q_j) = 0,$$

then character orthogonality on the finite abelian group G would imply that the coefficient sum on each residue class is zero. Since the classes of the q_j are pairwise distinct, each c_j would be zero, contradicting that R is nonzero. Hence some Dirichlet character has nonzero readout on R. □

Definition 9300.22 (ExplicitFormulaScaleResidual)**.** *The obligation*

$$\mathsf{ExplicitFormulaScaleResidual}$$

asserts the following explicit-formula bridge. If a completed zeta zero packet contains an off-critical-line coordinate

$$\rho_0 = \frac{1}{2} + r + i\gamma, \qquad r \neq 0,$$

then there is an admissible test row φ whose explicit-formula readout has nonzero prime side after the archimedean and trivial-zero correction rows are accounted for:

$$\mathrm{PrimeSide}(\varphi) \neq 0.$$

Equivalently, the zero-side radial residual is not confined to the zero ledger; it has a prime-side ledger footprint.

Definition 9300.23 (Finite explicit-formula prime window)**.** *For an admissible test row φ, a finite explicit-formula prime window is a finite set S of prime powers together with the residual*

$$R_S(\varphi) := \sum_{q \in S} c_q(\varphi)[q],$$

where $c_q(\varphi)$ is the displayed prime-side coefficient attached to q. The window is nonzero when $R_S(\varphi)$ is a nonzero finite prime residual in the sense of Definition 9300.19.

Principle 9300.24 (Nonzero prime side has a finite window)**.** *If* $\mathrm{PrimeSide}(\varphi) \neq 0$ *and the prime-side sum is read through an absolutely convergent, unconditional, or explicitly regularized finite-window ledger, then some finite explicit-formula prime window is nonzero. Otherwise every finite window would have zero residual, and the displayed convergence or regularization ledger would force the whole prime-side readout to be zero.*

Theorem 9300.25 (Explicit-formula residuals give finite classifier detection)**.** *Assume* ExplicitFormulaScaleResidual *and the finite-window ledger of Definition 9300.24. If a completed zeta zero packet has $\ell(\rho_0) \neq 0$, then there is a finite prime residual $R_S(\varphi)$ and a finite Dirichlet classifier χ such that*

$$\chi(R_S(\varphi)) \neq 0.$$

Proof. By Definition 9300.22, the nonzero radial coordinate supplies an admissible test row φ with

$$\mathrm{PrimeSide}(\varphi) \neq 0.$$

The finite-window ledger gives a finite set S for which

$$R_S(\varphi) \neq 0.$$

Applying Definition 9300.21 to this finite residual gives a modulus and a Dirichlet character with nonzero readout. □

Corollary 9300.26 (Explicit formula supplies scale-to-classifier faithfulness)**.** *For a zeta-facing PFZ packet satisfying the explicit-formula residual obligation and the finite-window ledger, every nonzero radial coordinate has a finite prime-classifier footprint.*

Proof. The finite classifier footprint is the nonzero Dirichlet readout supplied by Definition 9300.25. It is finite, prime-side, and classifier-visible. Therefore the radial coordinate is not invisible to the prime classifier tower. □

Chapter 9301

Probability Amplitude Unit Geometry

chapter 9302 treats each classifier layer as a finite probability space. The present chapter records the geometric reason that such probability layers belong to the same BEDC triangle discipline as the prime-distribution curves: a probability law is the squared norm readout of a normalized amplitude. Consequently every sieve event is an orthogonal projection, and every discarded probability mass is a ledger row.

9301.1 Amplitude Readout

Definition 9301.1 (Finite probability amplitude)**.** *Let (G, μ) be a finite probability space with $\mu(a) > 0$ for every $a \in G$. If ν is another probability distribution on G with $\nu \ll \mu$, write*

$$r(a) := \frac{d\nu}{d\mu}(a).$$

A probability amplitude for ν over μ is a function

$$\psi(a) = \sqrt{r(a)}e^{i\theta(a)}$$

in $L^2(G, \mu)$. It satisfies

$$\|\psi\|^2_{L^2(\mu)} = \sum_{a \in G} |\psi(a)|^2 \mu(a) = \sum_{a \in G} r(a)\mu(a) = 1.$$

Principle 9301.2 (Probability is squared amplitude readout)**.** *The probability coordinates of a finite layer are not merely linear weights. They are the squared-norm readout of a unit vector in a finite Hilbert space:*

$$\nu(a) = |\psi(a)|^2 \mu(a), \qquad \|\psi\|^2 = 1.$$

Thus the probability simplex has a unit-sphere lift. The phases are invisible to the probability law but remain legal amplitude coordinates for later Fourier, character, or Frobenius readouts.

Corollary 9301.3 (Binary probability is a unit-circle readout)**.** *For a two-type probability law $(p, 1-p)$, there is $\theta \in [0, \pi/2]$ such that*

$$p = \cos^2 \theta, \qquad 1 - p = \sin^2 \theta.$$

Hence

$$p + (1 - p) = \cos^2\theta + \sin^2\theta = 1.$$

With phases, the lifted amplitude is

$$\psi = (e^{i\alpha}\cos\theta, e^{i\beta}\sin\theta),$$

a unit vector in $\mathbb{C}^2$.

Proof. Take $\theta = \arccos\sqrt{p}$. The displayed identities follow from the Pythagorean identity. □

9301.2 Event Projection

Definition 9301.4 (Event projection)**.** *For an event* $E \subseteq G$*, define*

$$P_E\psi := \mathbf{1}_E\psi, \qquad P_{E^c}\psi := \mathbf{1}_{E^c}\psi.$$

These are the pass and excluded components of the amplitude at the event boundary.

Theorem 9301.5 (Event projection Pythagorean law)**.** *For every finite probability amplitude* ψ *and event* $E \subseteq G$*,*

$$\psi = P_E\psi + P_{E^c}\psi, \qquad P_E\psi \perp P_{E^c}\psi,$$

and therefore

$$\|\psi\|^2 = \|P_E\psi\|^2 + \|P_{E^c}\psi\|^2.$$

In particular, if $\|\psi\| = 1$*, then*

$$1 = \nu(E) + \nu(E^c).$$

Proof. The supports of $\mathbf{1}_E$ and $\mathbf{1}_{E^c}$ are disjoint, so

$$\langle P_E\psi, P_{E^c}\psi\rangle = \sum_{a\in G} \mathbf{1}_E(a)\mathbf{1}_{E^c}(a)|\psi(a)|^2\mu(a) = 0.$$

The norm identity is the Hilbert-space Pythagorean theorem. Since

$$\|P_E\psi\|^2 = \nu(E), \qquad \|P_{E^c}\psi\|^2 = \nu(E^c),$$

the final identity follows. □

Corollary 9301.6 (Sieve events are orthogonal triangle splits)**.** *At a layer of* LayeredPrimeProbabilitySieve*, selecting* $E_m \subseteq G_m$ *gives the orthogonal split*

$$1 = \|P_{E_m}\psi_m\|^2 + \|P_{E_m^c}\psi_m\|^2.$$

Thus every probability sieve event is a triangle split in the amplitude space of that layer.

9301.3 Ledger Consequence

Definition 9301.7 (Renormalized pass amplitude)**.** *If $\|P_E\psi\| > 0$, the renormalized pass amplitude is*

$$\psi_E := \frac{P_E\psi}{\|P_E\psi\|}.$$

The excluded probability mass is

$$\|P_{E^c}\psi\|^2 = 1 - \nu(E).$$

Theorem 9301.8 (Discarded probability mass is ledger data)**.** *If a layer keeps only the renormalized pass amplitude ψ_E, then the excluded mass*

$$\|P_{E^c}\psi\|^2$$

must be recorded as the excluded-mass coordinate of Definition 9302.3. Otherwise the operation is not a BEDC legal projection.

Proof. The full amplitude decomposes orthogonally into pass and excluded components. Replacing ψ by ψ_E erases the excluded component unless its squared norm is recorded. BEDC projection operations cannot discard generated coordinates without a ledger row; hence the excluded mass must be stored in the sieve ledger. □

Principle 9301.9 (Probability has the BEDC triangle properties)**.** *Finite probability layers have the three BEDC triangle properties. They are unitary because their amplitudes have norm one; they are orthogonal because event partitions are Hilbert projections; and they are ledger-bound because renormalization after a sieve event exposes an excluded squared-norm component. Probability is therefore a unit-sphere readout, not an unstructured scalar bookkeeping device.*

Theorem 9301.10 (Amplitude geometry supports cofinal sieve dissipation)**.** *The detected-subspace projections used in Definition 9302.13 are the residual counterparts of event projections in finite probability amplitude space. Consequently the energy descent theorem Definition 9302.14 is a direct application of the same Pythagorean law that governs probability events.*

Proof. Both constructions are orthogonal projection decompositions in a finite Hilbert space. For events, the projection is multiplication by $\mathbf{1}_E$. For residuals, it is the orthogonal projection onto the detected subspace W_m. In each case, the squared norm splits into the detected component plus its orthogonal complement. The residual energy descent is therefore the iterative form of the event Pythagorean law. □

Chapter 9302

Layered Prime Probability Sieve

chapter 9300 records the finite and profinite classifier tower that detects prime-register residuals. The present chapter records the probability ledger carried by that tower. Each layer classifies primes, assigns Chebyshev-weighted probability mass to the displayed types, and exports normalized distribution curves. Thus a sieve step is not deletion of primes. It is conditional projection of prime-register mass, with the excluded mass recorded as ledger data.

9302.1 Probability Layers

Definition 9302.1 (Prime probability classifier)**.** *A prime probability classifier is a finite prime projection classifier*

$$\mathcal{C}_m = (G_m, \pi_m)$$

together with a Chebyshev-weighted probability distribution μ_m on G_m. For a displayed type $a \in G_m$, the intended readout is

$$\mu_m(a) := \lim_{x\to\infty} \frac{1}{x} \sum_{\substack{p^k \le x \\ \pi_m(p^k)=a}} \log p$$

when the limit exists. In Chebotarev layers, μ_m is the conjugacy-class density; in Dirichlet layers, it is the residue-class or character density supplied by the relevant equidistribution theorem.

Definition 9302.2 (LayeredPrimeProbabilitySieve)**.** *The row*

$$\mathsf{LayeredPrimeProbabilitySieve}$$

is an inverse system

$$(G_0, \mu_0) \leftarrow (G_1, \mu_1) \leftarrow (G_2, \mu_2) \leftarrow \cdots$$

of prime probability classifiers. If

$$\pi_{m+1,m} : G_{m+1} \to G_m$$

is the refinement map, compatibility means

$$\mu_m(a) = \sum_{\pi_{m+1,m}(b)=a} \mu_{m+1}(b)$$

for every displayed type $a \in G_m$.

Definition 9302.3 (Sieve ledger row)**.** *Let $E_m \subseteq G_m$ be the set of types allowed by a layer. The sieve ledger row is*

$$\mathrm{SieveLedger}_m := (E_m, \mu_m(E_m), G_m \setminus E_m, 1 - \mu_m(E_m), \mathrm{reason}_m)\,.$$

The conditional layer distribution is

$$\mu_m(a \mid E_m) := \frac{\mu_m(a)}{\mu_m(E_m)} \qquad (a \in E_m,\ \mu_m(E_m) > 0).$$

Thus a layer exposes the allowed mass and the excluded mass as finite ledger coordinates.

Principle 9302.4 (Sieve steps are probability projections)**.** *A layer of* LayeredPrimeProbabilitySieve *does not remove primes from the arithmetic source. It records a classifier, a probability measure on classifier types, a selected admissible type region, and the mass outside that region. The operation is therefore a BEDC ledger projection, not an untracked modification of the Euler source.*

9302.2 Probability Distribution Curves

Definition 9302.5 (Probability-filtered Chebyshev curve)**.** *Let (G_m, π_m, μ_m) be a prime probability classifier and let*

$$\varphi : G_m \to \mathbb{C}$$

be a displayed test function. Define

$$\psi_{m,\varphi}(x) := \sum_{p^k \le x} \varphi(\pi_m(p^k)) \log p.$$

The layer mean is

$$\mathbb{E}_{\mu_m}[\varphi] := \sum_{a \in G_m} \varphi(a)\mu_m(a),$$

and the critically normalized probability curve is

$$\Psi_{m,\varphi}(u) := e^{-u/2}\left(\psi_{m,\varphi}(e^u) - \mathbb{E}_{\mu_m}[\varphi]e^u\right).$$

Definition 9302.6 (Critical probability stability)**.** *A probability-filtered curve $\Psi_{m,\varphi}$ is critically stable when its local energy*

$$\mathcal{E}_{m,\varphi}(U) := \int_U^{U+1} |\Psi_{m,\varphi}(u)|^2\, du$$

satisfies

$$\limsup_{U\to\infty} \frac{1}{U} \log \mathcal{E}_{m,\varphi}(U) \le 0.$$

Theorem 9302.7 (Critical probability stability excludes radial modes)**.** *If every legal probability-filtered curve in a layered prime probability sieve is critically stable, then no such curve contains a radial spectral mode*

$$c\, e^{ru} e^{i\gamma u}, \qquad c \neq 0, \quad r \neq 0.$$

Proof. If $r > 0$, the displayed mode contributes exponential energy on unit windows:

$$\mathcal{E}_{m,\varphi}(U) \geq Ce^{2rU}$$

after lower-order oscillatory terms are absorbed on a subwindow where the selected mode remains separated. Hence

$$\limsup_{U\to\infty} \frac{1}{U} \log \mathcal{E}_{m,\varphi}(U) \geq 2r > 0,$$

contradicting critical probability stability. If $r < 0$, the mirror zero packet carries the corresponding positive radial leg with exponent $-r > 0$, so the same argument applies to the mirror readout. □

9302.3 Completeness and Detection

Definition 9302.8 (Layered probability sieve completeness)**.** *The row*

LayeredProbabilitySieveCompleteness

asserts that every nonzero radial residual of a zeta-facing PFZ packet is visible on some probability-filtered curve. Equivalently, if

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell+i\theta}$$

has $\ell \neq 0$, then there are a layer m and a mean-zero test function

$$\varphi : G_m \to \mathbb{C}, \qquad \mathbb{E}_{\mu_m}[\varphi] = 0,$$

such that $\Psi_{m,\varphi}$ contains the corresponding radial mode.

Theorem 9302.9 (Finite residuals are detected by probability tests)**.** *Let*

$$R = \sum_{j=1}^{N} c_j[q_j] \neq 0$$

be a finite prime-power residual with distinct q_j. Then there are a finite probability classifier and a mean-zero test function φ whose readout on R is nonzero:

$$\sum_{j=1}^{N} c_j\varphi(q_j) \neq 0.$$

Proof. Choose a prime modulus M so that all q_j are nonzero and pairwise distinct in

$$G = (\mathbb{Z}/M\mathbb{Z})^\times.$$

Take M large enough that some residue class $b \in G$ is not among the classes of the q_j. If every mean-zero test function on G annihilated R, then for the class a_j of any q_j the function

$$\varphi_j := \mathbf{1}_{a_j} - \frac{\mu_m(a_j)}{\mu_m(b)}\mathbf{1}_b$$

would also annihilate R. It has mean zero, while its readout on R is exactly c_j, because no residual term lies in the class b. Hence every c_j would vanish, contradicting $R \neq 0$. □

Theorem 9302.10 (Profinite probability residuals descend to finite layers)**.** *In a Hausdorff profinite probability classifier tower, every nonzero profinite residual has a nonzero finite-layer probability test readout.*

Proof. By Definition 9300.8, the residual has a nonzero image in some finite quotient. Apply Definition 9302.9 at that finite layer. □

Theorem 9302.11 (Layered probability completeness supplies distribution-curve completeness)**.** *If* LayeredProbabilitySieveCompleteness *holds, then the visible curve required by*

PrimeDistributionCurveCompleteness

is available as a probability-filtered curve.

Proof. The probability-filtered curve of Definition 9302.8 is a filtered prime-distribution curve in the sense of Definition 9316.3, with the layer mean replacing the trivial-character main term. Thus it supplies the visible radial mode demanded by Definition 9316.8. □

9302.4 Cofinal Dissipation

Definition 9302.12 (Layer residual Hilbert space)**.** *For a prime probability classifier* (G_m, μ_m)*, define*

$$H_m := L_0^2(G_m, \mu_m)$$

to be the finite-dimensional Hilbert space of mean-zero functions on G_m*, with inner product*

$$\langle f, g\rangle_m := \sum_{a\in G_m} f(a)\overline{g(a)}\mu_m(a).$$

A layer residual is an element $R_m \in H_m$*.*

Definition 9302.13 (Detected subspace and residual update)**.** *At layer* m*, let* $W_m \subseteq H_m$ *be the subspace detected by the legal sieve tests of that layer, and let*

$$\Pi_m : H_m \to W_m$$

be the orthogonal projection. The residual update is

$$R_m := (I - \Pi_m)R_{m-1},$$

after transporting R_{m-1} *to the current layer through the displayed refinement map.*

Theorem 9302.14 (Layer sieve energy descent)**.** *Assume*

$$\|\Pi_m R_{m-1}\|_m^2 \geq \eta_m \|R_{m-1}\|_m^2$$

for some $\eta_m \in (0, 1]$*. Then*

$$\|R_m\|_m^2 \leq (1 - \eta_m)\|R_{m-1}\|_m^2.$$

Consequently,

$$\|R_m\|_m^2 \leq \left(\prod_{j=1}^{m}(1 - \eta_j)\right)\|R_0\|_0^2.$$

If

$$\sum_{j=1}^{\infty} \eta_j = \infty,$$

then $\|R_m\|_m \to 0$*.*

Proof. The projection decomposition is orthogonal:

$$R_{m-1} = \Pi_m R_{m-1} + (I - \Pi_m) R_{m-1}.$$

Thus

$$\|R_{m-1}\|_m^2 = \|\Pi_m R_{m-1}\|_m^2 + \|R_m\|_m^2.$$

The displayed lower bound on the detected part gives

$$\|R_m\|_m^2 \le (1 - \eta_m)\|R_{m-1}\|_m^2.$$

Iteration gives the product estimate. Finally,

$$\log(1 - \eta_j) \le -\eta_j$$

for $\eta_j \in (0, 1]$, so the product tends to 0 when $\sum_j \eta_j$ diverges. □

Definition 9302.15 (CofinalSieveDissipation)**.** *The row*

$$\mathsf{CofinalSieveDissipation}$$

asserts that every nonzero radial residual R_0 admits a legal sequence of detected subspaces W_m and constants $\eta_m \in (0, 1]$ such that

$$\sum_m \eta_m = \infty.$$

Equivalently, the layered probability sieve has enough cumulative detection mass to force the residual norm to vanish along the tower.

Theorem 9302.16 (Cofinal sieve dissipates radial residuals)**.** *If* CofinalSieveDissipation *holds, then every nonzero radial residual is exhausted by the layered probability sieve:*

$$\|R_m\|_m \to 0.$$

Proof. Apply Definition 9302.15 to the initial residual and then use Definition 9302.14. □

Theorem 9302.17 (Cofinal probability sieve excludes hidden radial residuals)**.** *Assume every nonzero radial mode supplies a nonzero initial residual,* CofinalSieveDissipation *holds, and every layer records its sieve ledger row. Then a legal closed BEDC/PFZ zero packet cannot carry a hidden radial residual.*

Proof. Let $R_0 \neq 0$ be the residual attached to a radial mode. By Definition 9302.16, the sieve tower exhausts this residual. If the exhausted mass is recorded in the ledger, the history continues through displayed append rows and the packet is not closed. If it is not recorded, the sieve ledger row of Definition 9302.3 is violated. Hence the residual cannot be hidden inside a legal closed packet. □

9302.5 Conditional RH Interface

Theorem 9302.18 (Layered probability sieve conditional fixed-half readout)**.** *Assume zeta-facing PFZ zero packets are legal closure objects,* LayeredProbabilitySieveCompleteness *holds, every legal probability-filtered curve is critically stable, and all sieve ledger rows record their allowed mass, excluded mass, and residual readouts. Then every admitted nontrivial zero has fixed-half readout.*

Proof. If an admitted nontrivial zero had $\ell \neq 0$, layered probability sieve completeness would provide a legal probability-filtered curve with a radial mode. By Definition 9302.7, that curve would not be critically stable. This contradicts the stability hypothesis for legal filtered curves. Hence $\ell = 0$, and Definition 9266.2 gives fixed-half readout. □

Theorem 9302.19 (Cofinal probability sieve conditional fixed-half readout)**.** *Assume zeta-facing PFZ zero packets are legal closure objects, every off-critical zero supplies a nonzero radial residual,* CofinalSieveDissipation *holds, all sieve ledger rows are recorded, and every legal probability-filtered curve is critically stable. Then every admitted nontrivial zero has fixed-half readout.*

Proof. An off-critical admitted zero would supply a nonzero radial residual. By Definition 9302.17, that residual cannot be hidden inside a legal closed BEDC/PFZ zero packet. If the residual remains visible on a legal filtered curve, then Definition 9302.7 contradicts critical probability stability. Thus the off-critical case is excluded, and Definition 9266.2 gives fixed-half readout. □

Principle 9302.20 (Probability sieve audit boundary)**.** *The probability-sieve formulation concentrates the RH-facing burden in three rows. The completeness row says every nonzero radial residual is visible on some finite or profinite probability-filtered prime curve; the dissipation row says cofinal layer projections exhaust every nonzero residual with divergent detected energy; the stability row says every legal filtered curve has no exponential radial energy growth after critical normalization. Together they make an off-critical zero incompatible with a closed BEDC/PFZ zero packet.*

Chapter 9303

Zeta as a Certified Inverse Limit

chapter 9301 and chapter 9302 put the probability layers of the prime classifier tower into unit-amplitude form. The present chapter records the global proof-engineering interface: completed zeta is treated as a certified inverse-limit object assembled from licensed finite layers, not as an unlicensed primitive at the kernel. The probability numbers attached to layers are therefore coverage measures for audited candidate space, not probabilities that a theorem is true.

9303.1 Ontological Rows

Definition 9303.1 (Ontological triple)**.** *For a proof object, tool, or carrier X, its ontological triple is*

$$\mathrm{Ont}(X) := (\mathsf{T}_X, \mathsf{U}_X, \mathsf{L}_X).$$

Here T_X is the time-source row, recording the lower-level objects from which X is generated and whether the history is append-only. The row U_X is the unit or triangle row, recording unit normalization, orthogonal splitting, positivity, or Pythagorean energy conservation. The row L_X is the ledger row, recording hidden gap, tail, phase, classifier, or probability-mass data.

Principle 9303.2 (All zeta-route tools require ontological triples)**.** *Every tool used by the RH route must expose its ontological triple. A finite classifier exposes prime-source time, unit character or amplitude readout, and type-probability ledger. A fixed-window analytic tool exposes finite construction time, unit or positive boundary data, and a tail ledger. A limiting or completion tool exposes the lower-layer inverse system, the preserved unit or positivity invariant, and a limit-ledger policy. A row without these three coordinates is not available as a BEDC proof object for the route.*

Definition 9303.3 (Certified zeta layer)**.** *A certified zeta layer is a finite packet*

$$\mathcal{Z}_m := (G_m, \mu_m, \Psi_{m,\varphi}, \mathrm{SieveLedger}_m, \mathrm{Gap}_m, \mathrm{DomCert}_m, \mathrm{NameCert}_m)\,,$$

where (G_m, μ_m) is a prime probability classifier, $\Psi_{m,\varphi}$ is a normalized filtered prime-distribution curve, the sieve ledger records allowed and excluded probability mass, the gap row records the unexcluded candidate region, the dominance certificate records the fixed-window analytic row available at that layer, and the naming certificate licenses the layer as a BEDC object.

Definition 9303.4 (Certified zeta inverse system)**.** *A certified zeta inverse system is a projective family*

$$\mathcal{Z}_0 \leftarrow \mathcal{Z}_1 \leftarrow \mathcal{Z}_2 \leftarrow \cdots$$

whose transition maps preserve the classifier projection, probability pushforward, sieve ledger, gap inclusion, dominance certificate projection, and NameCert provenance rows. The certified inverse-limit object is

$$\mathsf{ZetaCertifiedLimit} := \left(\varprojlim_m \mathcal{Z}_m, \mathrm{NameCert}_\infty, \mathrm{LedgerPolicy}_\infty, \mathrm{StabilityCert}_\infty\right).$$

Principle 9303.5 (Zeta is not a seed assertion)**.** *The certified inverse-limit object is a route for admitting completed zeta after the finite layers, transports, continuation rows, explicit formula rows, and limit ledgers have been exposed. It does not assert analytic continuation or RH-shaped statements as naming seeds. Those rows remain theorem targets or operation-certificate targets until the required finite and limiting ledgers are supplied.*

9303.2 Coverage

Definition 9303.6 (Candidate gap and coverage)**.** *At layer m, let GAP_m be the candidate region not yet excluded by the layer's classifiers, probability sieves, fixed-window certificates, and ledgers. Let $\mathbb{P}_m$ be the candidate probability measure visible at that layer. The proof coverage of the layer is*

$$\mathrm{Cov}_m := 1 - \mathbb{P}_m(\mathrm{GAP}_m).$$

Principle 9303.7 (Coverage is not theorem probability)**.** *The number Cov_m is an audited coverage ratio for the candidate space visible at layer m. It is not a probability that* RH *is true. The theorem is a fixed mathematical statement; the layer number measures how much of the candidate gap has been excluded, classified, or forced into a ledger by the proof system.*

Theorem 9303.8 (Coverage is monotone under append-only constraints)**.** *Assume the transition from layer m to layer $m+1$ only adds legal constraints and never revokes a previous ledger exclusion. Then*

$$\mathrm{GAP}_{m+1} \subseteq \mathrm{GAP}_m,$$

and therefore

$$\mathrm{Cov}_{m+1} \geq \mathrm{Cov}_m\,.$$

Proof. Every candidate surviving layer $m+1$ satisfies all constraints from layer m together with the additional constraints of layer $m+1$. Hence it also survives layer m, giving the gap inclusion. Taking candidate measures gives

$$\mathbb{P}_{m+1}(\mathrm{GAP}_{m+1}) \leq \mathbb{P}_m(\mathrm{GAP}_m)$$

after transport along the displayed refinement map. The displayed coverage inequality follows by subtracting from 1. □

Definition 9303.9 (FiniteWitnessCompleteness)**.** *The row*

$$\mathsf{FiniteWitnessCompleteness}$$

asserts that every off-critical zero candidate, if present, generates a finite-layer witness in the certified zeta inverse system. Equivalently, an off-critical zero cannot survive only as a nonlocated point of the limit; it must expose a finite classifier, probability-sieve, fixed-window, or radial-residual row at some layer.

Theorem 9303.10 (Coverage limit excludes certified off-critical witnesses)**.** *Assume*

$$\lim_m \mathrm{Cov}_m = 1$$

and FiniteWitnessCompleteness*. Then no off-critical zero has a legal BEDC witness in* ZetaCertifiedLimit*.*

Proof. An off-critical zero with a legal BEDC witness supplies, by Definition 9303.9, a finite-layer witness in some candidate gap row. Since the coverage tends to 1, the limiting candidate gap has measure zero. A legal BEDC witness cannot enter the object layer merely as an unlocated measure-zero survivor; it must be carried by a finite NameCert or ledger row. The finite witness is therefore eventually excluded or ledgered by the certified inverse system, contradicting legal off-critical survival. □

9303.3 RH Interface

Definition 9303.11 (CertifiedInverseLimitRHRoute)**.** *The row*

$$\mathsf{CertifiedInverseLimitRHRoute}$$

consists of:

$$\mathsf{ZetaCertifiedLimit},\quad \mathsf{FiniteWitnessCompleteness},\quad \mathsf{LayeredProbabilitySieveCompleteness},$$
$$\mathsf{CofinalSieveDissipation},\quad \mathsf{CriticalProbabilityStability},\quad \lim_m \mathrm{Cov}_m = 1.$$

It is a proof-engineering package: each row must be supplied by finite or limiting certificate data before the package can be used.

Theorem 9303.12 (Certified inverse-limit route gives conditional fixed-half readout)**.** *Assume* CertifiedInverseLimitRHRoute *and that every completed nontrivial zero packet admitted by the route is a legal BEDC closure object. Then every admitted nontrivial zero has fixed-half readout.*

Proof. If an admitted nontrivial zero were off the critical line, it would give an off-critical candidate in the certified zeta inverse system. By Definition 9303.10, no such candidate has a legal BEDC witness. Equivalently, if its radial residual is exposed on a probability-filtered curve, then Definition 9302.19 excludes it by cofinal dissipation and critical probability stability. Thus the radial coordinate is zero, and Definition 9266.2 gives fixed-half readout. □

Principle 9303.13 (Certified inverse-limit audit boundary)**.** *The inverse-limit route closes only when every layer is licensed by source, unit, and ledger rows, the coverage numbers are interpreted as gap-coverage measures, and every off-critical candidate is finite-witness visible. Without finite witness completeness, measure-one coverage would be insufficient for a constructive BEDC proof. With finite witness completeness and critical probability stability, a surviving off-critical zero has no legal NameCert route into the completed zeta object.*

Chapter 9304

Probability Sieve Tower Proof Pattern

chapter 9301, chapter 9302, and chapter 9303 provide the finite Hilbert geometry, the probability classifier tower, and the certified limiting object used by the RH route. The present chapter records the proof pattern that binds these pieces together. The pattern is modeled on a tower argument: isolate a fixed local resource, place it in a growing classifier tower, use finite pigeonhole or orthogonal projection to produce many legal reads, and project the resulting tower data into the final geometric object.

9304.1 Local Mechanism

Definition 9304.1 (Unit-phase local mechanism)**.** *The local legal resource for the probability sieve tower is a unit phase mode*

$$u \longmapsto e^{i\gamma u}.$$

A radial packet is a mode of the form

$$u \longmapsto e^{ru}e^{i\gamma u}, \qquad r \neq 0.$$

The local mechanism is legal at a classifier layer only when its observable readout is carried by unit character data, probability amplitude data of norm 1*, and a sieve ledger row. A radial factor is therefore not a unit resource; it is a residual coordinate that must be detected, ledgered, or excluded.*

Principle 9304.2 (Fixed local mechanism)**.** *The probability sieve route does not begin with the global zeta object. It begins with finite layer resources: a finite prime classifier, a probability law on its types, unit character or amplitude readouts, and orthogonal event projections. These are the RH-facing analogues of a fixed local unit resource in a tower construction. Their role is to provide a reusable finite detection mechanism before the limiting object is admitted.*

Definition 9304.3 (Amplifiable classifier mechanism)**.** *An amplifiable classifier mechanism is a finite probability classifier* (G_m, μ_m) *together with a family of legal tests*

$$\mathcal{T}_m \subseteq L_0^2(G_m, \mu_m)$$

such that every nonzero finite residual visible at layer m *has a nonzero pairing with some test in* $\mathcal{T}_m$*. In a refinement tower*

$$(G_0, \mu_0) \leftarrow (G_1, \mu_1) \leftarrow (G_2, \mu_2) \leftarrow \cdots,$$

the mechanism is amplified when the pullback of a detected residual remains visible to later legal tests and the excluded probability mass continues to be recorded by Definition 9302.3.

9304.2 Finite Projection Pigeonhole

Theorem 9304.4 (Finite probability pigeonhole)**.** *Let (G, μ) be a finite probability space with full support and let*

$$R \in L_0^2(G, \mu)$$

be nonzero. Then there is an event $E \subseteq G$ such that

$$\langle R, \mathbf{1}_E - \mu(E) \rangle \neq 0.$$

Equivalently, some legal event projection detects the residual.

Proof. If every centered event indicator were orthogonal to R, then every linear combination of centered event indicators would be orthogonal to R. These centered indicators span $L_0^2(G, \mu)$: for any $a, b \in G$, the difference

$$\mathbf{1}_a - \frac{\mu(a)}{\mu(b)} \mathbf{1}_b$$

is a scalar combination of centered indicators and separates the a-coordinate from the b-coordinate. Hence R would be orthogonal to all of $L_0^2(G, \mu)$, including itself. This gives

$$\|R\|^2 = 0,$$

contradicting $R \neq 0$. □

Theorem 9304.5 (Classifier pigeonhole supplies probability detection)**.** *Every finite prime-power residual detected by Definition 9302.9 is also detected by an event projection in the finite probability space of a prime probability classifier.*

Proof. The finite probability test produced by Definition 9302.9 gives a nonzero element of the mean-zero layer Hilbert space $L_0^2(G_m, \mu_m)$. Applying Definition 9304.4 to that element gives a centered event indicator with nonzero pairing. By Definition 9301.5, the event is an orthogonal probability split, so the detected component and its complement are legal triangle readouts at the layer. □

Principle 9304.6 (Classifier pigeonhole is a ledger operation)**.** *The finite pigeonhole step is not an unrecorded choice of a favorable event. It selects a displayed event in a finite classifier, reads a nonzero projection of the residual, and records the excluded component as probability mass. Thus the pigeonhole argument produces legal BEDC data only together with the sieve ledger of Definition 9302.3.*

9304.3 Tower Amplification

Definition 9304.7 (Tower-amplified detection)**.** *A layered prime probability sieve has tower-amplified detection for a residual R_0 when, after transporting residuals through the refinement maps, there are detected subspaces W_m and constants $\eta_m \in (0, 1]$ with*

$$\|\Pi_m R_{m-1}\|_m^2 \geq \eta_m \|R_{m-1}\|_m^2$$

and

$$\sum_m \eta_m = \infty.$$

Theorem 9304.8 (Tower amplification gives complete residual exhaustion)**.** *If a residual has tower-amplified detection, then its surviving norm in the layered probability sieve tends to zero:*

$$\|R_m\|_m \to 0.$$

Proof. This is exactly the energy descent of Definition 9302.14. The displayed lower bound on the detected component gives

$$\|R_m\|_m^2 \leq \left(\prod_{j=1}^{m}(1-\eta_j)\right)\|R_0\|_0^2.$$

The divergence of $\sum_j \eta_j$ forces the product to vanish. □

Corollary 9304.9 (Amplified detection implies cofinal dissipation)**.** *If every nonzero radial residual of a zeta-facing packet has tower-amplified detection, then*

$$\mathsf{CofinalSieveDissipation}$$

holds for the layered prime probability sieve.

Proof. The definition of tower-amplified detection supplies precisely the detected subspaces and divergent detection strengths required by Definition 9302.15. □

9304.4 Certified Limit Projection

Definition 9304.10 (Layered zeta proof package)**.** *A layered zeta proof package consists of the certified inverse system of Definition 9303.4 together with:*

$$\mathsf{LayeredProbabilitySieveCompleteness},\quad \mathsf{PrimeDistributionCurveCompleteness},$$
$$\mathsf{CofinalSieveDissipation},\quad \mathsf{CriticalProbabilityStability},\quad \mathsf{FiniteWitnessCompleteness}.$$

The package is a proof-engineering object. It does not treat $\zeta(s)$ as a seed primitive; it admits the zeta-facing object only as the certified inverse limit of finite classifier, probability, analytic window, gap, and ledger rows.

Theorem 9304.11 (Layered package projects radial residuals to illegal closure)**.** *Assume a layered zeta proof package and assume every completed nontrivial zero packet admitted by the package is a legal BEDC closure object. If such a zero had*

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta}, \qquad \ell \neq 0,$$

then the package would expose a nonzero radial residual that cannot be carried by a closed legal packet.

Proof. By LayeredProbabilitySieveCompleteness, the nonzero radial coordinate is visible on a probability-filtered curve. By Definition 9302.11, this supplies the distribution-curve visibility demanded by PrimeDistributionCurveCompleteness. By Definition 9316.12, the radial coordinate becomes a finite or profinite classifier-visible residual. By CofinalSieveDissipation and Definition 9302.17, that residual cannot be hidden in a legal closed packet: if the exhausted mass is recorded, the packet has an append ledger; if it is not recorded, the sieve ledger row is violated. The assumed closed legal zero packet is therefore incompatible with $\ell \neq 0$. □

Theorem 9304.12 (Probability sieve tower route gives conditional fixed-half readout)**.** *Assume a layered zeta proof package and that every completed nontrivial zero packet admitted by the package is a legal BEDC closure object. Then every admitted nontrivial zero has fixed-half readout.*

Proof. Let ρ be an admitted nontrivial zero. If

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta}$$

had $\ell \neq 0$, then Definition 9304.11 would contradict legality of the closed packet. Hence $\ell = 0$, and Definition 9266.2 gives fixed-half readout. □

Principle 9304.13 (Proof pattern audit boundary)**.** *The tower proof pattern concentrates the RH-facing burden in two certificate rows. The finite visibility row says that an off-critical zero cannot remain purely global; it must create a finite classifier, probability, fixed-window, or distribution-curve witness. The cofinal amplification row says that every such witness is repeatedly detected with divergent total energy. Once these rows are supplied, the certified inverse-limit projection turns radial scale into an illegal closure coordinate rather than a legal zeta zero.*

Chapter 9305

Prime-Generated Recursive Sieve

chapter 9314 treats primes as both objects of classification and generators of local sieve surfaces. The present chapter isolates the more basic recursive package. It starts from the local residue classifier attached to a prime, iterates such classifiers as a sieve tower, and reads the right-half-plane Euler product as the phase expectation of the resulting prime-generated probability system.

9305.1 Recursive Local Sieve

Definition 9305.1 (Prime-generated recursive sieve step)**.** *Let X_m be a displayed source set, let p_m be a prime, and let*

$$\pi_{p_m} : X_m \to G_{p_m}$$

be a finite classifier generated by p_m, such as a residue, unit-residue, valuation, order, or character readout. For an event $A_m \subseteq G_{p_m}$, define

$$C_m := \{x \in X_m : \pi_{p_m}(x) \in A_m\},$$

$$X_{m+1} := X_m \setminus C_m,$$

and append the ledger row

$$\Lambda_{m+1} := \Lambda_m + (p_m, A_m, \mu_{p_m}(A_m), C_m, \mathrm{reason}_m).$$

Definition 9305.2 (PrimeGeneratedRecursiveSieve)**.** *The row*

$$\mathsf{PrimeGeneratedRecursiveSieve}$$

is an iterated system of Definition 9305.1 whose source sets may be integers, primes, prime powers, finite residual supports, or sieve-method parameter spaces. Each step is generated by a prime and must expose its classifier, event, probability mass, and ledger append row.

Theorem 9305.3 (Recursive prime-generated sieve preserves BEDC rows)**.** *Every finite stage of* PrimeGeneratedRecursiveSieve *preserves the BEDC time, unit, and ledger rows.*

Proof. The time row is the nested chain

$$X_0 \supseteq X_1 \supseteq X_2 \supseteq \cdots$$

together with the append-only ledger equations in Definition 9305.1. The unit row is the probability-amplitude split on each finite classifier:

$$\psi_m = P_{A_m}\psi_m + P_{A_m^c}\psi_m, \qquad P_{A_m}\psi_m \perp P_{A_m^c}\psi_m,$$

so

$$\|\psi_m\|^2 = \|P_{A_m}\psi_m\|^2 + \|P_{A_m^c}\psi_m\|^2.$$

This is the event projection law of Definition 9301.5. The ledger row is the displayed Λ_{m+1} update, which records the selected prime, event, probability mass, excluded source, and reason. □

9305.2 Finite Residual Detection

Theorem 9305.4 (Prime-generated sieve detects finite residuals)**.** *Let*

$$R = \sum_{j=1}^{N} c_j[q_j] \neq 0$$

be a finite residual with distinct positive integers q_j. Then there are a prime p and a character

$$\chi : \mathbb{F}_p^\times \to S^1$$

such that

$$\sum_{j=1}^{N} c_j \chi(q_j \bmod p) \neq 0.$$

Proof. Choose a prime p dividing none of the q_j and none of the nonzero differences $q_i - q_j$. Then the residues $q_j \bmod p$ are pairwise distinct elements of $\mathbb{F}_p^\times$. If all characters of $\mathbb{F}_p^\times$ had zero readout on R, character orthogonality on the finite abelian group $\mathbb{F}_p^\times$ would force the coefficient sum on each residue class to vanish. Since the displayed residues are pairwise distinct, every c_j would be zero, contradicting $R \neq 0$. □

Corollary 9305.5 (Prime-generated recursive completeness)**.** *Every nonzero finite residual is detected by a local sieve generated by some prime. Equivalently,*

$$R \neq 0 \quad \Rightarrow \quad \exists p, \exists \chi \in \widehat{\mathbb{F}_p^\times}, \quad \langle R, \chi \circ \pi_p \rangle \neq 0.$$

Proof. Use Definition 9305.4 with $\pi_p(q) = q \bmod p$. □

9305.3 Euler Probability Readout

Definition 9305.6 (Right-half-plane Euler probability law)**.** *For $\sigma > 1$, define a probability law on positive integers by*

$$\mathbb{P}_\sigma(n) := \frac{n^{-\sigma}}{\zeta(\sigma)}.$$

Under the prime factorization

$$n = \prod_p p^{v_p(n)},$$

the local valuation row at prime p has distribution

$$\mathbb{P}_\sigma(v_p = k) = (1 - p^{-\sigma})p^{-k\sigma}.$$

Theorem 9305.7 (Euler probability factors by prime valuations)**.** *For $\sigma > 1$, the valuation rows v_p are independent under $\mathbb{P}_\sigma$, with the local distribution of Definition 9305.6.*

Proof. For a finite prime window S and exponents $k_p \geq 0$,

$$\mathbb{P}_\sigma(v_p = k_p \text{ for } p \in S) = \frac{1}{\zeta(\sigma)} \left(\prod_{p \in S} p^{-k_p \sigma} \right) \prod_{p \notin S} \left(\sum_{k \geq 0} p^{-k\sigma} \right).$$

Using the Euler product on $\sigma > 1$, the terms outside S cancel the corresponding factors of $\zeta(\sigma)$, leaving

$$\prod_{p \in S} (1 - p^{-\sigma}) p^{-k_p \sigma}.$$

This is the product of the displayed local laws, hence the valuation rows are independent. □

Theorem 9305.8 (Zeta ratio is the phase expectation)**.** *For $\sigma > 1$ and real t,*

$$\mathbb{E}_{\mathbb{P}_\sigma}[n^{-it}] = \frac{\zeta(\sigma + it)}{\zeta(\sigma)}.$$

Proof. By definition of $\mathbb{P}_\sigma$,

$$\mathbb{E}_{\mathbb{P}_\sigma}[n^{-it}] = \sum_{n \geq 1} \frac{n^{-\sigma}}{\zeta(\sigma)} n^{-it} = \frac{1}{\zeta(\sigma)} \sum_{n \geq 1} n^{-(\sigma + it)} = \frac{\zeta(\sigma + it)}{\zeta(\sigma)}.$$

Absolute convergence is available because $\sigma > 1$. □

Definition 9305.9 (Finite Euler probability phase packet)**.** *For a finite prime window $S = \{p_1, \ldots, p_m\}$, define*

$$\mathcal{Z}_S(\sigma, t) := \prod_{p \in S} \frac{1 - p^{-\sigma}}{1 - p^{-\sigma - it}}.$$

This is the phase expectation of the finite product of local geometric valuation laws generated by primes in S.

Theorem 9305.10 (Finite Euler packets converge to the zeta phase readout)**.** *For $\sigma > 1$ and cofinal finite prime windows S,*

$$\mathcal{Z}_S(\sigma, t) \to \frac{\zeta(\sigma + it)}{\zeta(\sigma)}.$$

Proof. The finite product in Definition 9305.9 is the quotient of the finite Euler products for $\zeta(\sigma + it)$ and $\zeta(\sigma)$ over S. Both Euler products converge absolutely on $\sigma > 1$, so their quotient converges to the displayed zeta ratio. □

Principle 9305.11 (Right-half-plane zeta is a prime-generated phase limit)**.** *On $\Re(s) > 1$, the normalized zeta phase $\zeta(\sigma + it)/\zeta(\sigma)$ is already a legal inverse limit of prime-generated local probability sieves. This statement uses only unique factorization, geometric valuation laws, and absolute convergence of the Euler product.*

9305.4 Continuation Interface

Definition 9305.12 (AnalyticContinuationPreservesPrimeSieveLedger)**.** *The row*

AnalyticContinuationPreservesPrimeSieveLedger

asserts that the analytic continuation and explicit-formula transport from $\Re(s) > 1$ *to the critical strip preserves the prime-generated sieve ledger: finite prime windows, local valuation rows, unit phase readouts, residual projections, and excluded-mass ledger entries remain visible as certified rows of the continued zeta object.*

Theorem 9305.13 (Prime-generated recursive sieve gives conditional fixed-half route)**.** *Assume* AnalyticContinuationPreservesPrimeSieveLedger*, every off-critical zero supplies a nonzero prime-side residual visible at a finite layer, and detected residuals cannot be hidden in legal closed BEDC/PFZ zero packets. Then every admitted nontrivial zero has fixed-half readout.*

Proof. An off-critical admitted zero supplies, by hypothesis, a nonzero finite-layer prime-side residual. By Definition 9305.5, some prime-generated local sieve detects it. The continuation-preservation row keeps this detection inside the certified zeta ledger rather than outside the continued object. If the detected residual is recorded, the zero packet carries an append ledger and is not closed. If it is not recorded, the ledger policy is violated. Thus a legal closed admitted zero cannot be off-critical, and Definition 9266.2 gives fixed-half readout. □

Principle 9305.14 (Recursive sieve audit boundary)**.** *The recursive prime-generated sieve packet proves the finite arithmetic side: local prime sieves are BEDC-legal, detect finite residuals, and construct the normalized Euler phase on* $\Re(s) > 1$*. The remaining analytic burden is the preservation row* AnalyticContinuationPreservesPrimeSieveLedger*, together with the explicit-formula row that turns an off-critical zero into a prime-side residual.*

Chapter 9306

All-Prime Object

chapter 9305 treats each prime as a generator of local sieve rows. The RH route also requires the source containing all primes to be a BEDC object rather than an unstructured ambient set. The present chapter packages the all-prime source as

$$\mathcal{P}^{\uparrow}$$

with a displayed time row, unit row, and ledger row. This prevents a radial residual from being hidden in an unaccounted prime tail.

9306.1 Prime Source Packet

Definition 9306.1 (Finite prime source layer)**.** *Let $p_1, p_2, p_3, \ldots$ be the increasing prime sequence and define*

$$\mathcal{P}_N := \{p_1, \ldots, p_N\}.$$

The transition

$$\iota_{N,N+1} : \mathcal{P}_N \hookrightarrow \mathcal{P}_{N+1}$$

is inclusion.

Definition 9306.2 (AllPrimeObject)**.** *The BEDC all-prime object is the packet*

$$\mathcal{P}^{\uparrow} := ((\mathcal{P}_N)_{N\geq 1}, (\iota_{N,N+1})_{N\geq 1}, \Lambda_{\mathcal{P}}, \mathrm{NameCert}_{\mathcal{P}}, \mathrm{TailPolicy}_{\mathcal{P}})\,.$$

It is a certified colimit-style source: finite prime layers supply the visible stages, $\Lambda_{\mathcal{P}}$ records generation and sieve history, $\mathrm{NameCert}_{\mathcal{P}}$ *licenses the source as a BEDC object, and* $\mathrm{TailPolicy}_{\mathcal{P}}$ *records data not visible at a chosen finite layer.*

Definition 9306.3 (Prime object time row)**.** *The time row*

$$\mathsf{T}_{\mathcal{P}}$$

asserts that $\mathcal{P}^{\uparrow}$ is generated by the Euclidean survivor tower of Definition 9314.1. With

$$P_N := \prod_{j=1}^{N} p_j, \qquad \mathcal{N}_N := \{n \geq 2 : \gcd(n, P_N) = 1\},$$

the appended source row is

$$p_{N+1} := \min \mathcal{N}_N, \qquad \mathcal{P}_{N+1} = \mathcal{P}_N \cup \{p_{N+1}\},$$

and the ledger update is

$$\Lambda_{\mathcal{P},N+1} = \Lambda_{\mathcal{P},N} + (p_{N+1}, \mathrm{minimalSurvivor}(P_N)).$$

Theorem 9306.4 (Prime object time row is append-only)**.** *The row $\mathsf{T}_{\mathcal{P}}$ is an append-only generation row.*

Proof. By Definition 9314.2, the minimal survivor of $\mathcal{N}_N$ is a prime distinct from $p_1, \ldots, p_N$. Hence adjoining it produces precisely the next finite prime source layer. The displayed update records that adjoining event without deleting any prior prime row, so the generation history is append-only. □

9306.2 Unit Rows

Definition 9306.5 (Prime circle layer)**.** *For $N \geq 1$, set $P = p_N$. The Nth prime circle layer is the embedded finite set*

$$\mathbb{P}_N^\circ := \{p_1, \ldots, p_{N-1}, 0\} \subseteq \mathbb{F}_P,$$

obtained from

$$\pi_P : \mathcal{P}_N \to \mathbb{F}_P, \qquad \pi_P(p_j) = p_j \bmod P.$$

The element 0 represents the terminal point $p_N = P$ of the finite prime source layer.

Lemma 9306.6 (Prime circle embedding)**.** *The map $\pi_P : \mathcal{P}_N \to \mathbb{F}_P$ is injective.*

Proof. For $j < N$, the integer p_j satisfies $0 < p_j < P$, while $p_N = P$ maps to 0. The residues $p_1, \ldots, p_{N-1}, 0$ are therefore pairwise distinct in $\mathbb{F}_P$. □

Definition 9306.7 (Prime object unit row)**.** *The unit row*

$$\mathsf{U}_{\mathcal{P}}$$

contains two compatible unit readouts:

$$\psi_t(x) := \exp(2\pi i t x/P), \qquad t, x \in \mathbb{F}_P,$$
$$\mathbb{P}_\sigma(v_p = k) = (1 - p^{-\sigma})p^{-k\sigma}, \qquad \sigma > 1.$$

The first is the finite additive character system on the prime circle layer. The second is the Euler local probability row of Definition 9305.6.

Theorem 9306.8 (Prime object unit rows are normalized)**.** *The finite character and Euler probability rows of $\mathsf{U}_{\mathcal{P}}$ are unit rows.*

Proof. For the finite character row,

$$|\psi_t(x)| = 1$$

for all $t, x \in \mathbb{F}_P$. For the Euler row,

$$\sum_{k \geq 0} (1 - p^{-\sigma})p^{-k\sigma} = 1$$

at each prime p when $\sigma > 1$. By Definition 9305.7, these local rows factor the probability law by prime valuations. By Definition 9305.8, the normalized right-half-plane zeta ratio is the unit phase expectation

$$\mathbb{E}_{\mathbb{P}_\sigma}[n^{-it}] = \frac{\zeta(\sigma + it)}{\zeta(\sigma)}, \qquad |n^{-it}| = 1.$$

Thus both finite and Euler layers expose unit readouts. □

9306.3 Ledger Rows

Definition 9306.9 (Prime object ledger row)**.** *The ledger row*

$$\mathsf{L}_{\mathcal{P}}$$

records unique factorization and finite-layer tails. For $n \geq 1$,

$$\mathrm{PrimeLedger}(n) := (v_p(n))_{p \in \mathcal{P}}.$$

At the finite layer $\mathcal{P}_N$ the ledger is

$$\mathrm{PrimeLedger}_N(n) := \Big((v_{p_j}(n))_{j \leq N}, n_{>N} \Big),$$

where

$$n_{>N} := \prod_{j>N} p_j^{v_{p_j}(n)}.$$

For the Euler product the corresponding finite-layer ledger is

$$\mathrm{EulerLedger}_N(s) := \left(\prod_{j \leq N} (1 - p_j^{-s})^{-1}, \prod_{j>N} (1 - p_j^{-s})^{-1} \right)$$

on the half-plane where the Euler product is licensed.

Theorem 9306.10 (Prime object ledger records finite data and tail data)**.** *The row $\mathsf{L}_{\mathcal{P}}$ prevents a finite-layer readout from discarding information outside $\mathcal{P}_N$.*

Proof. Unique factorization gives

$$n = \left(\prod_{j \leq N} p_j^{v_{p_j}(n)} \right) n_{>N}.$$

Thus the finite valuation row alone is not the full ledger unless the tail $n_{>N}$ is also recorded. The Euler product has the same structure: the finite product over $j \leq N$ is accompanied by the displayed Euler tail over $j > N$. Therefore every finite readout of the all-prime object carries an explicit tail coordinate. □

Theorem 9306.11 (AllPrimeObject has an ontological triple)**.** *The BEDC all-prime object has*

$$\mathrm{Ont}(\mathcal{P}^{\uparrow}) = (\mathsf{T}_{\mathcal{P}}, \mathsf{U}_{\mathcal{P}}, \mathsf{L}_{\mathcal{P}})$$

in the sense of Definition 9303.1.

Proof. The time row is Definition 9306.3, and it is append-only by Definition 9306.4. The unit row is Definition 9306.7, normalized by Definition 9306.8. The ledger row is Definition 9306.9, with tail preservation given by Definition 9306.10. These are exactly the three coordinates required by Definition 9303.1. □

9306.4 Finite Detection

Theorem 9306.12 (Prime circle layer detects finite prime residuals)**.** *Let*

$$R_N = \sum_{j=1}^{N} c_j[p_j] \neq 0$$

be a residual supported on $\mathcal{P}_N$, and set $P = p_N$. Then there exists $t \in \mathbb{F}_P$ such that

$$\sum_{j=1}^{N} c_j \psi_t(p_j \bmod P) \neq 0.$$

Proof. Push R_N forward along the embedding of Definition 9306.6:

$$\widetilde{R}_N := \sum_{j=1}^{N} c_j[\pi_P(p_j)] \in \mathbb{C}[\mathbb{F}_P].$$

Since the points $\pi_P(p_j)$ are pairwise distinct, $R_N \neq 0$ implies $\widetilde{R}_N \neq 0$. The additive characters

$$\psi_t(x) = \exp(2\pi i t x/P)$$

form a Fourier basis for functions on the finite additive group $\mathbb{F}_P$. If every displayed character readout vanished on $\widetilde{R}_N$, all Fourier coefficients of $\widetilde{R}_N$ would vanish, forcing $\widetilde{R}_N = 0$, a contradiction. □

Definition 9306.13 (Finite-or-tail prime residual)**.** *A residual over $\mathcal{P}^{\uparrow}$ is finite-or-tail visible when, for every finite layer $\mathcal{P}_N$, it satisfies one of the following ledger alternatives:*

a nonzero component is visible on some finite prime layer,

the invisible component is recorded in $\mathrm{TailPolicy}_{\mathcal{P}}$ *.*

Theorem 9306.14 (AllPrimeObject has no unledgered residual escape)**.** *Assume a residual over $\mathcal{P}^{\uparrow}$ is finite-or-tail visible. Then it cannot be hidden inside the all-prime source as an unledgered ambient coordinate.*

Proof. If the residual has a nonzero finite component on $\mathcal{P}_N$, then Definition 9306.12 detects it by a unit character row on the prime circle layer. If no finite component is visible at the chosen layer, the definition of finite-or-tail visibility places the component in $\mathrm{TailPolicy}_{\mathcal{P}}$. Thus every residual is either detected at a finite layer or recorded as tail data. Neither case is an unledgered source coordinate. □

9306.5 Zeta Source Interface

Definition 9306.15 (Certified Euler prime limit)**.** *For $\Re(s) > 1$, the certified Euler prime limit attached to $\mathcal{P}^{\uparrow}$ is the packet*

$$\zeta^{\uparrow}_{\Re>1} := ((Z_N(s))_{N\geq 1}, (\mathrm{EulerTail}_N(s))_{N\geq 1}, \Lambda_{\mathcal{P}}, \mathrm{NameCert}_{\mathcal{P}}),$$

where

$$Z_N(s) := \prod_{j\leq N} (1 - p_j^{-s})^{-1}$$

and

$$\mathrm{EulerTail}_N(s) := \prod_{j>N} (1 - p_j^{-s})^{-1}.$$

Theorem 9306.16 (AllPrimeObject supplies the right-half-plane zeta source)**.** *On $\Re(s) > 1$, the certified Euler prime limit is a BEDC-licensed source for the normalized zeta phase readout.*

Proof. The finite products $Z_N(s)$ are generated by appending Euler local factors along the time row of $\mathcal{P}^{\uparrow}$. The tails $\mathrm{EulerTail}_N(s)$ are the Euler ledger tails of Definition 9306.9. Absolute convergence on $\Re(s) > 1$ licenses the Euler product, and Definition 9305.11 identifies the normalized zeta phase as the limit of prime-generated local probability sieves. The source is therefore certified by finite products, tail rows, and the all-prime NameCert rather than by a bare infinite set of primes. □

Principle 9306.17 (All-prime source audit boundary)**.** *The all-prime object closes the source-side gap for the prime sieve route. It does not prove that an off-critical zero produces a finite-or-tail prime residual. It asserts that, once such a residual is present over the prime source, the residual must be detected by a finite prime circle layer or recorded in the all-prime tail ledger.*

Chapter 9307

Finite Prime Circle Universe

chapter 9306 packages the all-prime source as a generated BEDC object with finite layers and tail ledger rows. The present chapter records the complementary fixed finite model: assume a finite prime universe with largest prime P, close that universe inside $\mathbb{F}_P$, and show that a nonzero finite residual cannot be missed by all P-generated Fourier or quadratic norm sieves. This is a local certificate; it is not a substitute for the all-prime tail policy.

9307.1 Index–Prime Certificate

Definition 9307.1 (IndexPrimePair)**.** *An index–prime pair certificate is a packet*

$$\mathsf{IndexPrimePair}^{\uparrow}(N, P)$$

asserting that

$$P = p_N, \qquad N = \pi(P),$$

where p_N is the Nth prime and

$$\pi(P) := \#\{p : p \le P,\ p \text{ prime}\}.$$

Thus N is the time coordinate of the finite prime source layer and P is the maximal prime that supplies the finite circle modulus.

Definition 9307.2 (IndexPrimeLedger)**.** *The ledger attached to $\mathsf{IndexPrimePair}^{\uparrow}(N, P)$ is*

$$\mathrm{IndexPrimeLedger}(N, P) := (P = p_N,\ N = \pi(P),\ \pi_P(\mathcal{P}_N),\ \mathrm{GapHoles}(N, P),\ \alpha_N)\,,$$

where

$$\mathrm{GapHoles}(N, P) := \mathbb{F}_P \setminus \pi_P(\mathcal{P}_N)$$

and

$$\alpha_N := \frac{N}{P}.$$

The row records the occupied prime points, the empty finite-circle points, and the occupancy ratio of the finite layer.

Theorem 9307.3 (IndexPrimePair is the legal finite-circle modulus)**.** *If $\mathsf{IndexPrimePair}^{\uparrow}(N, P)$ holds, then P is the unique modulus used by the finite prime circle at layer N.*

Proof. The certificate supplies $P = p_N$, so every earlier source prime p_j with $j < N$ satisfies $p_j < P$, while p_N maps to 0 modulo P. The same certificate supplies $N = \pi(P)$, so the displayed finite source contains exactly the primes up to P. A smaller modulus would not be the maximal prime boundary of this layer; a larger prime modulus would add a prime beyond the certified source; a larger composite modulus would not provide the field $\mathbb{F}_P$ used by the circle and Gauss rows. Thus the finite-circle modulus is not a free parameter. □

Theorem 9307.4 (IndexPrimePair has BEDC rows)**.** *The certificate* $\mathsf{IndexPrimePair}^{\uparrow}(N, P)$ *carries time, unit, and ledger rows.*

Proof. The time row is the index N in the append-only prime source tower. The unit row is the finite circle $\mathbb{F}_P$ supplied by the maximal prime $P = p_N$, together with the unit characters

$$\psi_t(x) = \exp(2\pi i t x/P).$$

The ledger row is Definition 9307.2: it records $P = p_N$, $N = \pi(P)$, the occupied points, the gap holes, and the occupancy ratio. These are the three BEDC coordinates required for using (N, P) as a finite-layer proof parameter. □

9307.2 Finite Prime Circle

Definition 9307.5 (Finite prime universe)**.** *A finite prime universe is a displayed finite source*

$$\mathcal{P}_N = \{p_1, \ldots, p_N\}, \qquad P := p_N,$$

equipped with the certificate

$$\mathsf{IndexPrimePair}^{\uparrow}(N, P).$$

It is read under the model assumption that these are exactly the primes visible to the finite source up to the certified boundary P. Its maximal-prime classifier is

$$\pi_P : \mathcal{P}_N \to \mathbb{F}_P, \qquad \pi_P(p_j) = p_j \bmod P.$$

Definition 9307.6 (Finite prime circle universe)**.** *The finite prime circle universe attached to Definition 9307.5 is*

$$\mathcal{P}_N^{\circ} := \{p_1, \ldots, p_{N-1}, 0\} \subseteq \mathbb{F}_P.$$

The point 0 *is the image of the maximal prime P.*

Lemma 9307.7 (Maximal-prime classifier is injective)**.** *The map $\pi_P : \mathcal{P}_N \to \mathbb{F}_P$ is injective.*

Proof. For $j < N$, one has $0 < p_j < P$, so $\pi_P(p_j) = p_j$ as a nonzero element of $\mathbb{F}_P$. The maximal prime satisfies $\pi_P(P) = 0$. Hence the images are the pairwise distinct points

$$p_1, \ldots, p_{N-1}, 0.$$

□

9307.3 Fourier Completeness

Definition 9307.8 (Prime-circle residual)**.** *A prime-circle residual is a finite row*

$$R_N = \sum_{j=1}^{N} c_j[p_j]$$

on $\mathcal{P}_N$. Its pushforward to $\mathbb{F}_P$ is

$$\widetilde{R}_N := \sum_{j=1}^{N} c_j[\pi_P(p_j)].$$

Definition 9307.9 (Maximal-prime Fourier sieve)**.** *For $t \in \mathbb{F}_P$, the maximal-prime Fourier sieve is the additive character*

$$\psi_t(x) := \exp(2\pi i t x/P), \qquad x \in \mathbb{F}_P.$$

Its readout on a prime-circle residual is

$$\widehat{R}_N(t) := \sum_{j=1}^{N} c_j \psi_t(p_j \bmod P).$$

Theorem 9307.10 (Finite prime circle Fourier completeness)**.** *If $R_N \neq 0$, then there exists $t \in \mathbb{F}_P$ such that*

$$\widehat{R}_N(t) \neq 0.$$

Proof. By Definition 9307.7, the pushforward $\widetilde{R}_N$ is nonzero whenever R_N is nonzero. The additive characters of the finite additive group $\mathbb{F}_P$ form an orthogonal basis of $L^2(\mathbb{F}_P)$. If every readout $\widehat{R}_N(t)$ vanished, all Fourier coefficients of $\widetilde{R}_N$ would vanish, forcing $\widetilde{R}_N = 0$. This contradicts $R_N \neq 0$. □

9307.4 Quadratic Norm Sieve

Definition 9307.11 (Quadratic norm sieve over the finite prime circle)**.** *Let*

$$Q_P : \mathbb{F}_P^2 \to \mathbb{F}_P, \qquad Q_P(a,b) = a^2 + b^2.$$

For a function $R : \mathbb{F}_P \to \mathbb{C}$ and $t \in \mathbb{F}_P$, define the quadratic norm sieve readout

$$\mathcal{Q}_t(R) := \sum_{q \in \mathbb{F}_P} R(q) \sum_{a,b \in \mathbb{F}_P} \exp(2\pi i t(q - a^2 - b^2)/P).$$

Definition 9307.12 (Quadratic Gauss row)**.** *For $t \in \mathbb{F}_P$, define*

$$G_P(t) := \sum_{a \in \mathbb{F}_P} \exp(2\pi i t a^2/P).$$

The Gauss nondegeneracy row asserts that

$$G_P(t) \neq 0.$$

For $t = 0$ this is the identity $G_P(0) = P$; for $t \neq 0$ it is the standard nondegeneracy of the quadratic Gauss sum.

Theorem 9307.13 (Quadratic norm sieve is Fourier sieve times Gauss rows)**.** *For every $t \in \mathbb{F}_P$ and every $R : \mathbb{F}_P \to \mathbb{C}$,*

$$\mathcal{Q}_t(R) = G_P(-t)^2 \sum_{q \in \mathbb{F}_P} R(q) \exp(2\pi i t q/P).$$

Proof. Expand the definition of $\mathcal{Q}_t(R)$ and separate the variables:

$$\begin{aligned}\mathcal{Q}_t(R) &= \sum_q R(q) \exp(2\pi i t q/P) \left(\sum_a \exp(-2\pi i t a^2/P)\right) \left(\sum_b \exp(-2\pi i t b^2/P)\right) \\ &= G_P(-t)^2 \sum_q R(q) \exp(2\pi i t q/P).\end{aligned}$$

□

Corollary 9307.14 (Quadratic norm sieves detect Fourier-visible residuals)**.** *Assume the Gauss nondegeneracy row of Definition 9307.12. If*

$$\sum_{q \in \mathbb{F}_P} R(q) \exp(2\pi i t q/P) \neq 0$$

for some $t \in \mathbb{F}_P$, then

$$\mathcal{Q}_t(R) \neq 0.$$

Proof. By Definition 9307.13, the quadratic readout is the displayed Fourier readout multiplied by $G_P(-t)^2$. The Gauss nondegeneracy row makes that multiplier nonzero. □

9307.5 Leakage Contradiction

Definition 9307.15 (Prime circle leakage assumption)**.** *The prime circle leakage assumption for a residual R_N says that all maximal-prime Fourier sieve readouts vanish:*

$$\widehat{R}_N(t) = 0 \qquad (t \in \mathbb{F}_P),$$

and, when the quadratic norm sieve is available, all quadratic norm readouts vanish:

$$\mathcal{Q}_t(\widetilde{R}_N) = 0 \qquad (t \in \mathbb{F}_P).$$

Theorem 9307.16 (Finite prime universe leakage contradiction)**.** *In a finite prime universe, no nonzero prime-circle residual satisfies the prime circle leakage assumption.*

Proof. If $R_N \neq 0$, then Definition 9307.10 gives $t \in \mathbb{F}_P$ with $\widehat{R}_N(t) \neq 0$. This contradicts the first row of Definition 9307.15. Therefore any residual satisfying the leakage assumption must be zero. □

Corollary 9307.17 (Quadratic leakage contradiction)**.** *Assume the Gauss nondegeneracy row and suppose a nonzero residual has a nonzero Fourier readout at some $t \in \mathbb{F}_P$. Then it cannot be missed by all quadratic norm sieves.*

Proof. Apply Definition 9307.14 to the nonzero Fourier readout. The corresponding quadratic norm sieve readout is nonzero. □

9307.6 Admissible Addresses

Definition 9307.18 (Finite prime address policy)**.** *In the finite prime universe of Definition 9307.5, an admissible residual address is either one of the displayed points*

$$h_j := p_j \bmod P \in \mathbb{F}_P \qquad (1 \le j \le N)$$

or a ledger row saying that the residual has no address in the finite universe. An expression involving a prime $p' > P$ is not an admissible prime address inside the finite model.

Theorem 9307.19 (Existing prime addresses are event-detected)**.** *Let*

$$R_N = \sum_{j=1}^{N} c_j[p_j]$$

be a prime-circle residual. If $c_j \neq 0$ for some j, then the event

$$E_j := \{p_j \bmod P\} \subseteq \mathbb{F}_P$$

detects R_N.

Proof. By Definition 9307.7, the point $p_j \bmod P$ occurs in the pushforward of R_N only with coefficient c_j. Pairing with the indicator of E_j therefore gives exactly c_j, which is nonzero. □

Theorem 9307.20 (No external prime address in the finite model)**.** *Under the finite prime universe assumption, a residual cannot use a prime $p' > P$ as a legal finite prime-circle address.*

Proof. The finite prime universe states that the displayed source of prime addresses is precisely

$$\mathcal{P}_N = \{p_1, \ldots, p_N = P\}.$$

Thus a prime $p' > P$ is not a point of the source and cannot be used as a finite sieve address. If such a row is asserted as a prime, the finite universe assumption fails. If it is asserted merely as data not belonging to $\mathcal{P}_N$, it must be recorded by the ledger as an outside-source residual rather than used as a detector in the finite model. □

Theorem 9307.21 (Address trichotomy for finite residuals)**.** *Let a residual in the finite prime universe satisfy the BEDC ledger requirement that every residual coordinate has a source address or an explicit ledger row. Then exactly the following alternatives are available:*

it has a nonzero displayed address h_j and is event-detected,

it requests an external prime address and violates the finite model,

it has no displayed address and must be recorded as a ledger row.

Consequently a nonzero finite residual cannot be both ledger-legal and invisible to all displayed prime-circle events.

Proof. If some displayed coefficient c_j is nonzero, then Definition 9307.19 gives an event detector. If the residual is assigned to a prime $p' > P$, then Definition 9307.20 says that this is not a legal finite-model address. The only remaining possibility is that the residual has no displayed address in $\mathcal{P}_N^\circ$; by the stated ledger requirement, it must then be recorded as an explicit ledger row. Thus a nonzero residual cannot remain both legal and undetected in the finite prime circle universe. □

Definition 9307.22 (Finite prime circle ledger)**.** *The finite prime circle ledger records every nonzero readout as*

$$\mathrm{PrimeCircleLedger}_{P,t} := (P, t, R_N, \widehat{R}_N(t))$$

for Fourier readouts, and as

$$\mathrm{QuadraticSieveLedger}_{P,t} := (P, Q_P, t, \mathcal{Q}_t(\widetilde{R}_N))$$

for quadratic norm readouts.

Theorem 9307.23 (Finite prime circle universe preserves BEDC rows)**.** *The finite prime circle universe preserves time, unit, and ledger rows.*

Proof. The time row is the displayed finite source $\mathcal{P}_N$ with maximal boundary P and classifier π_P. The unit row consists of the additive characters ψ_t, each of modulus 1, together with the quadratic Gauss rows after their normalization by $P^{1/2}$ when the quadratic sieve is used. The ledger row is Definition 9307.22: every nonzero Fourier or quadratic readout is recorded with the modulus, sieve parameter, source residual, and detected value. □

9307.7 RH Route Interface

Definition 9307.24 (FiniteLayerResidual)**.** *The row*

$$\mathsf{FiniteLayerResidual}(\rho, N)$$

asserts that an off-critical zero packet ρ supplies a nonzero prime-circle residual R_N at the finite prime source layer $\mathcal{P}_N$.

Theorem 9307.25 (Finite layer residual cannot be sieve-invisible)**.** *Assume* $\mathsf{FiniteLayerResidual}(\rho, N)$ *and the finite prime circle universe for $\mathcal{P}_N$. Then the residual supplied by ρ is detected by a maximal-prime Fourier sieve. If the Gauss nondegeneracy row is supplied, it is also detected by a quadratic norm sieve.*

Proof. The finite-layer residual row supplies $R_N \neq 0$. Apply Definition 9307.10 to obtain a maximal-prime Fourier detector. The quadratic detector follows from Definition 9307.14. □

Principle 9307.26 (Finite prime circle audit boundary)**.** *The finite prime circle universe closes the finite combinatorial part of the route. Once an off-critical zero has produced a nonzero finite-layer residual, the maximal-prime circle cannot miss it. The remaining analytic burden is the production of*

$$\mathsf{FiniteLayerResidual}(\rho, N)$$

from the off-critical zero packet.

Chapter 9308

Off-Line Zero Finite-or-Tail Address

chapter 9306 supplies the all-prime source with finite layers and tail policy, while chapter 9307 supplies the certified finite circle attached to an index–prime pair (N, P). This chapter records the address step needed by the off-line zero route: once an off-line zero packet carries an ontological triple and a nonzero radial residual, that residual cannot remain addressless. At a certified finite prime circle it is either assigned to a displayed finite prime point, or it is assigned to the prime tail ledger beyond P. No other legal source status is available.

9308.1 Address Rows

Definition 9308.1 (Off-line residual address packet)**.** *Let*

$$\rho = \frac{1}{2} + r + i\gamma, \qquad r \neq 0,$$

be an off-line zero packet, and let

$$R_\rho \neq 0$$

be its radial residual row. An off-line residual address packet at the finite prime circle (N, P) consists of the data

$$\begin{gathered}\mathrm{Ont}(\rho) = (\mathsf{T}_\rho, \mathsf{U}_\rho, \mathsf{L}_\rho),\\ \mathsf{IndexPrimePair}^{\uparrow}(N, P),\\ \mathcal{P}_N = \{p_1, \ldots, p_N = P\},\\ \mathrm{TailPolicy}_{\mathcal{P}}\,.\end{gathered}$$

The packet is legal only when the ledger row L_ρ assigns each nonzero residual coordinate to a displayed source address or to an explicit tail row.

Definition 9308.2 (Finite and tail addresses)**.** *For an off-line residual address packet, a finite address is a representation*

$$R_N = \sum_{j=1}^{N} c_j[p_j] \neq 0$$

of the radial residual at the displayed source layer $\mathcal{P}_N$, with finite-circle pushforward

$$\widetilde{R}_N := \sum_{j=1}^{N} c_j[\pi_P(p_j)] \in \mathbb{C}[\mathbb{F}_P].$$

A tail address is a row

$$\mathrm{TailRecord}_{>P}(R_\rho) \in \mathrm{TailPolicy}_{\mathcal{P}}$$

asserting that the residual coordinate is not a legal point of $\mathcal{P}_N$ and is therefore recorded beyond the certified boundary P.

Definition 9308.3 (Addressless residual status)**.** *An addressless residual status at (N, P) is the assertion that $R_\rho \neq 0$ has neither a finite address in $\pi_P(\mathcal{P}_N)$ nor a tail row in* $\mathrm{TailPolicy}_{\mathcal{P}}$*. Such a status is not a BEDC address. It is the failure of the ledger coordinate L_ρ.*

9308.2 Ledger Dichotomy

Theorem 9308.4 (Ledgered residual has a finite or tail address)**.** *Let an off-line zero packet have an off-line residual address packet at (N, P). If $R_\rho \neq 0$, then every legal address status for R_ρ is one of the following:*

$$\textit{a finite address in } \pi_P(\mathcal{P}_N),$$
$$\textit{a tail row in } \mathrm{TailPolicy}_{\mathcal{P}}\,.$$

If neither row is present, the packet violates L_ρ.

Proof. The finite source layer at (N, P) is exactly

$$\mathcal{P}_N = \{p_1, \ldots, p_N = P\}$$

by Definition 9307.5. The admissible finite addresses are precisely the displayed points of Definition 9307.18. A residual coordinate assigned to one of those points has a finite address by Definition 9308.2.

If the residual coordinate is not assigned to the displayed finite source, then the all-prime object permits only the tail policy as the source-side account of the omitted coordinate. This is the finite-or-tail visibility row of Definition 9306.13, enforced by Definition 9306.14. Thus the coordinate must be recorded in $\mathrm{TailPolicy}_{\mathcal{P}}$. If it is recorded in neither place, the residual has the addressless status of Definition 9308.3, which is exactly a failure of the ledger row L_ρ. □

Theorem 9308.5 (Finite addresses are detected)**.** *If R_ρ has a finite address at the certified finite prime circle (N, P), then the associated residual is detected by a displayed finite-circle event or by a maximal-prime Fourier sieve. If the Gauss nondegeneracy row is supplied, it is also detected by a quadratic norm sieve.*

Proof. A finite address supplies a nonzero row

$$R_N = \sum_{j=1}^{N} c_j[p_j] \neq 0.$$

If some coefficient c_j is nonzero, then Definition 9307.19 detects the residual by the singleton event

$$E_j = \{p_j \bmod P\}.$$

Independently, Definition 9307.10 supplies $t \in \mathbb{F}_P$ with nonzero Fourier readout. Under the Gauss nondegeneracy row, Definition 9307.14 turns the nonzero Fourier readout into a nonzero quadratic norm sieve readout. □

Theorem 9308.6 (Tail address cannot close silently)**.** *Let R_ρ request an address beyond P in the finite prime circle universe. Then the request either refutes the finite universe as a complete prime model, or it enters the tail ledger. If it enters no tail ledger, L_ρ fails; if it enters the tail ledger, a closed zero packet carries an append residual row.*

Proof. By Definition 9307.20, a prime $p' > P$ is not a legal finite prime-circle address under the finite universe assumption. If the row asserts that $p' > P$ is a prime source point, then the assumption that P is the maximal source prime is refuted. If the row is not admitted as a finite source point, the only legal account supplied by the all-prime object is the tail policy.

Failure to record this outside-source coordinate gives the addressless status of Definition 9308.3, hence violates L_ρ. Recording it gives an explicit append residual row. For a closed BEDC/PFZ zero packet, the refusal row of Definition 9312.3 says that such a detected or ledgered residual cannot be silently absorbed into closed status. □

9308.3 Address Theorem

Theorem 9308.7 (OffLineZeroHasFiniteOrTailAddress)**.** *Assume an off-line zero packet ρ has*

$$\mathrm{Ont}(\rho) = (\mathsf{T}_\rho, \mathsf{U}_\rho, \mathsf{L}_\rho)$$

and carries a nonzero radial residual $R_\rho \neq 0$. At any certified finite prime circle

$$\mathsf{IndexPrimePair}^{\uparrow}(N, P),$$

with $\mathrm{TailPolicy}_{\mathcal{P}}$ *supplied by the all-prime object, the residual has a legal BEDC address only in the following sense:*

$$R_\rho \text{ has a finite address in } \pi_P(\mathcal{P}_N),$$

or

$$R_\rho \text{ has a tail address in } \mathrm{TailPolicy}_{\mathcal{P}}\,.$$

There is no third legal address status. The finite alternative is detected by the finite prime circle; the tail alternative is a ledger append row rather than closed invisible data.

Proof. Apply Definition 9308.4 to the off-line residual address packet Definition 9308.1. The no-address status is excluded because it is a failure of L_ρ.

If the address is finite, then Definition 9308.5 gives a finite event, Fourier, or quadratic sieve readout. If the address is outside the finite source, then Definition 9308.6 places it in the tail ledger or refutes the finite model. Thus the two displayed alternatives exhaust the legal BEDC statuses of the nonzero radial residual. □

Corollary 9308.8 (Closed invisible off-line residual contradiction)**.** *Assume an off-line zero packet has an ontological triple, a nonzero radial residual, and a certified finite prime circle. It cannot also be a closed zero packet whose residual is invisible to every displayed finite detector and absent from the tail ledger.*

Proof. By Definition 9308.7, the residual has a finite address or a tail address. A finite address is detected by Definition 9308.5, contradicting invisibility to every displayed finite detector. A tail address enters $\mathrm{TailPolicy}_{\mathcal{P}}$, contradicting absence from the tail ledger; if it does not enter that ledger, the ontological ledger row fails. Hence the displayed closed invisible status is impossible. □

9308.4 Finite Closed-Invisible Refusal

Definition 9308.9 (Finite circle address partition)**.** *For a certified finite prime circle (N, P), define the occupied prime points and gap holes by*

$$H_N := \pi_P(\mathcal{P}_N),$$
$$G_N := \mathbb{F}_P \setminus H_N.$$

The finite circle address partition for a nonzero radial residual is the disjoint status list

$$\textit{prime-pit address in } H_N,$$
$$\textit{gap-hole address in } G_N,$$
$$\textit{tail address in } \mathrm{TailPolicy}_{\mathcal{P}},$$
$$\textit{addressless status.}$$

The first two statuses are finite-circle statuses. The third is a source-tail status beyond the certified finite boundary. The fourth is not a legal BEDC status.

Theorem 9308.10 (Finite circle address partition is exhaustive)**.** *Let $R_\rho \neq 0$ be governed by an off-line residual address packet at (N, P). Then every attempted address status for R_ρ is one of the four statuses in Definition 9308.9.*

Proof. If the residual is assigned to the finite circle, then its finite coordinate lies in $\mathbb{F}_P$. By definition,

$$\mathbb{F}_P = H_N \sqcup G_N,$$

so the coordinate is either an occupied prime point or a gap hole. If the residual is not assigned to the finite circle, then Definition 9308.4 says that legal ledgered status requires a tail row in $\mathrm{TailPolicy}_{\mathcal{P}}$. Without such a row the residual has the addressless status of Definition 9308.3. These cases are disjoint by the definitions of H_N, G_N, tail policy, and addresslessness. □

Theorem 9308.11 (Gap-hole address cannot close silently)**.** *If R_ρ has a nonzero finite-circle coordinate in G_N, then it cannot be both ledger-legal and closed-invisible.*

Proof. The gap holes G_N are part of Definition 9307.2. Thus a residual coordinate in G_N is not an unclassified finite point: it is explicitly outside the occupied prime source points of the certified layer. If the coordinate is admitted as a finite-circle function, then the Fourier basis on $\mathbb{F}_P$ detects any nonzero coordinate, and Definition 9307.13 together with the Gauss nondegeneracy row gives the corresponding quadratic readout. If the coordinate is not admitted as a finite readout, its gap-hole status must still be recorded by the ledger.

Therefore the gap coordinate has only two legal outcomes: it is detected by finite-circle readouts, or it is recorded as a gap ledger row. If the row is not recorded, L_ρ fails; if it is recorded, the zero packet carries an append residual row and is not closed in the sense of Definition 9312.3. □

Theorem 9308.12 (Off-line zero with an ontological triple cannot be closed and missed)**.** *Assume an off-line zero packet ρ has an ontological triple, carries a nonzero radial residual, and is tested at a certified finite prime circle (N, P) with the all-prime tail policy supplied. Then ρ cannot*

simultaneously satisfy all of the following:

$$\begin{gathered}\rho \text{ is a closed zero packet,}\\ \text{every occupied prime-pit event misses } R_\rho,\\ \text{every maximal-prime Fourier sieve misses } R_\rho,\\ \text{every supplied quadratic norm sieve misses } R_\rho,\\ R_\rho \text{ is absent from the finite gap and tail ledgers.}\end{gathered}$$

Proof. By Definition 9308.10, the residual has one of four address statuses.

If it has a prime-pit address in H_N, then Definition 9308.5 gives a nonzero occupied prime event, Fourier, or supplied quadratic readout. This contradicts the missed-readout assumptions.

If it has a gap-hole address in G_N, then Definition 9308.11 applies. A finite readout detects it, or the gap ledger records it. The first alternative contradicts the missed-readout assumptions, while the second contradicts absence from the finite gap ledger or closed packet status.

If it has a tail address, then Definition 9308.6 applies. The tail row either refutes the finite model as a complete prime model or enters $\mathrm{TailPolicy}_{\mathcal{P}}$. A ledgered tail contradicts tail-ledger absence or closed packet status; an unledgered tail violates L_ρ.

If it is addressless, then Definition 9308.3 says that the ledger coordinate L_ρ fails, contradicting the assumed ontological triple. Hence no address status permits the packet to be closed and missed. □

Principle 9308.13 (Finite-window obstruction boundary)**.** *The finite closed-invisible refusal is a fixed-window statement. It does not assert that every analytic off-line zero has already been placed in a specific (N, P) window. Its contract is narrower: when the analytic route supplies a nonzero residual at a certified finite prime circle, or else supplies a tail row beyond that circle, the finite address partition leaves no closed-and-missed status.*

9308.5 Global Window Bridge

Definition 9308.14 (GlobalOffLineZeroToFiniteNPWindow)**.** *The row*

$$\mathsf{GlobalOffLineZeroToFiniteNPWindow}$$

is the analytic-to-ledger bridge for an off-line zeta zero. For every off-line zero packet

$$\rho = \frac{1}{2} + r + i\gamma, \qquad r \neq 0,$$

it supplies a nonzero radial residual row $R_\rho \neq 0$ and exactly one of the following source accounts:

$$\begin{gathered}\text{a compact explicit-formula row whose nonzero prime side has finite support } S,\\ \text{a tail row } \mathrm{TailRecord}_{\mathrm{zeta}}(\rho, R_\rho) \in \mathrm{TailPolicy}_{\mathcal{P}}\,.\end{gathered}$$

In the finite-support case, if

$$S \subseteq \{p^k : p \in \mathcal{P},\ k \geq 1\},$$

then the bridge also supplies

$$P = \max\{p : p^k \in S\}, \qquad N = \pi(P),$$

and the certified finite prime circle

$$\mathsf{IndexPrimePair}^{\uparrow}(N, P).$$

Thus every base prime occurring in the compact prime-power residual is a displayed source point of $\mathcal{P}_N$.

Theorem 9308.15 (Compact explicit-formula support gives a finite NP window)**.** *Assume the finite-support alternative of Definition 9308.14. Then the off-line residual has a legal finite-window source account at the certified pair* (N, P) *supplied by that definition.*

Proof. The compact explicit-formula row has finite prime side by Definition 9317.1 and Definition 9317.2. Since the prime side is nonzero, its finite support S is nonempty. Each support point has the form p^k, so the set of base primes

$$\{p : p^k \in S\}$$

is finite and nonempty. Let P be its maximum and set $N = \pi(P)$. Then $P = p_N$, and every base prime in S belongs to

$$\mathcal{P}_N = \{p_1, \ldots, p_N = P\}.$$

This is precisely the legal finite source condition recorded by Definition 9307.5. The corresponding finite circle is the certified pair $\mathsf{IndexPrimePair}^{\uparrow}(N, P)$, so the residual has a finite-window source account at (N, P). □

Theorem 9308.16 (Global bridge gives finite or tail residual status)**.** *Assume* GlobalOffLineZeroToFiniteNPWindow *for an off-line zero packet* ρ*. Then* $R_\rho \neq 0$ *is either represented in a legal finite* (N, P) *window or recorded in* $\mathrm{TailPolicy}_{\mathcal{P}}$.

Proof. Unpack Definition 9308.14. The bridge first supplies $R_\rho \neq 0$. If the compact explicit-formula alternative holds, then Definition 9308.15 places the residual in a certified finite prime circle. If the compact finite-support alternative is not the supplied account, the definition supplies the tail row

$$\mathrm{TailRecord}_{\mathrm{zeta}}(\rho, R_\rho) \in \mathrm{TailPolicy}_{\mathcal{P}}\,.$$

These are exactly the finite and tail source statuses. □

Theorem 9308.17 (Global window bridge excludes closed missed off-line packets)**.** *Assume* GlobalOffLineZeroToFi*Let an off-line zero packet* ρ *have an ontological triple and be governed by* LedgerClosureRefusal*. Then* ρ *cannot be admitted as a closed zero packet whose residual is missed by every supplied finite detector and absent from the tail ledger.*

Proof. By Definition 9308.16, the residual is either finite-window represented or tail-recorded.

In the finite-window case, use the certified (N, P) supplied by Definition 9308.15. The finite prime circle and tail policy form the address packet of Definition 9308.1. Then Definition 9308.12 rules out closed status together with missed finite readouts and absent finite gap or tail ledger rows.

In the tail case, the tail row is already present in $\mathrm{TailPolicy}_{\mathcal{P}}$. By Definition 9308.6, a ledgered tail is an append residual row rather than closed invisible data; if the row is erased, the ledger coordinate of the ontological triple fails. This is also refused by Definition 9312.3. Hence no global bridge status permits a closed and missed off-line packet. □

Corollary 9308.18 (Global bridge gives the conditional fixed-half readout)**.** *Assume* GlobalOffLineZeroToFiniteNPW *for every admitted off-line zero packet, and assume admitted zeta zero packets carry ontological triples and satisfy* LedgerClosureRefusal*. Then no admitted closed zero packet is off the critical line.*

Proof. If an admitted closed zero packet were off the critical line, the global bridge would supply a nonzero residual with finite-window or tail status by Definition 9308.16. If a supplied finite detector reads the residual, or if a finite gap or tail row records it, then LedgerClosureRefusal refuses closed zero-packet admission. If no supplied finite detector reads it and no finite gap or tail ledger row records it, then Definition 9308.17 refuses the closed packet. These alternatives exhaust the finite and tail statuses supplied by the global bridge. Therefore an admitted closed zero packet cannot be off the critical line. □

Principle 9308.19 (Address audit boundary)**.** *The finite-or-tail address theorem consumes the nonzero residual row $R_\rho \neq 0$ as input. The analytic source interface is*

$$\mathsf{GlobalOffLineZeroToFiniteNPWindow}.$$

Its first component is the source row $r \neq 0 \Longrightarrow R_\rho \neq 0$; its second component places that residual in a legal finite (N, P) window or in the all-prime tail ledger. Once those rows are supplied, the address layer has no legal escape status beyond finite detection, finite gap accounting, and tail ledger admission.

Chapter 9309

Global Off-Line Zero to Finite NP Window

Definition 9308.14 names the global bridge required by the finite address refusal: an off-line zeta residual must be read either in a certified finite prime window or in the all-prime tail ledger. The present chapter supplies the compact-window proof package for that row. Its scope is conditional on the displayed explicit-formula and projection certificates; it does not turn the RH route into an unqualified global theorem. The zeta carrier, critical-strip predicate, and non-trivial zero packet rows remain theorem-facing inputs supplied by the ambient $\mathsf{ZetaBasic}^{\uparrow}$, $\mathsf{ZetaCont}^{\uparrow}$, $\mathsf{CritStrip}^{\uparrow}$, and $\mathsf{ZetaZeros}^{\uparrow}$ chain.

9309.1 Radial Test Readout

Definition 9309.1 (Off-line radial distribution row)**.** *For an off-line zero*

$$\rho = \frac{1}{2} + r + i\gamma, \qquad r \neq 0,$$

the normalized radial row is the distribution represented by

$$R_\rho(u) := e^{ru} e^{i\gamma u}.$$

For a compact test row $h \in C_c^\infty(I)$, its readout is

$$\langle R_\rho, h \rangle_I := \int_I e^{ru} e^{i\gamma u} h(u)\, du.$$

Lemma 9309.2 (Nonzero radial mode has compact test readout)**.** *If $r \neq 0$, then there exists a compact interval I and a test row $h \in C_c^\infty(I)$ such that*

$$\langle R_\rho, h \rangle_I \neq 0.$$

Proof. Choose a nonzero nonnegative bump function

$$\eta \in C_c^\infty(I)$$

on any compact interval I, and set

$$h(u) := \eta(u) e^{-i\gamma u}.$$

Then

$$\langle R_\rho, h\rangle_I = \int_I \eta(u)e^{ru}\,du.$$

The integrand is nonnegative and is positive on a nonempty open subset of I, so the integral is nonzero. □

Theorem 9309.3 (Off-line zero supplies a compact radial witness)**.** *An off-line zero packet that carries the radial row of Definition 9309.1 supplies a compact test row with nonzero residual readout.*

Proof. Apply Definition 9309.2. The compact test row is the finite observation window through which the residual enters the zeta ledger. □

9309.2 Prime-Power Address Window

Definition 9309.4 (Compact prime-power window)**.** *Let $h \in C_c^\infty([A,B])$ be an admissible compact explicit-formula test row. Its prime-power window is*

$$S_h := \{p^k : p^k \le e^B,\ c_{p,k}(h) \neq 0\}.$$

The associated finite address ledger is

$$\mathrm{PrimePowerLedger}(h) := \{(p,k,c_{p,k}(h)) : p^k \in S_h\}.$$

Definition 9309.5 (Certified finite NP envelope)**.** *For a nonempty compact prime-power window S_h, let*

$$P_h := \max\{p : p^k \in S_h\}, \qquad N_h := \pi(P_h).$$

The certified finite NP envelope of S_h is

$$\mathsf{IndexPrimePair}^{\uparrow}(N_h, P_h)$$

together with the finite source

$$\mathcal{P}_{N_h} = \{p_1, \dots, p_{N_h} = P_h\}.$$

Theorem 9309.6 (Compact prime-power support has a certified NP envelope)**.** *If the compact explicit-formula prime side is nonzero, then its prime-power support has a certified finite NP envelope.*

Proof. By Definition 9317.1, compact support in $[A,B]$ restricts the prime side to the finite set

$$\{p^k : p^k \le e^B\}.$$

If the prime side is nonzero, then S_h is nonempty. Its base-prime set is finite and nonempty, so it has a largest element P_h. Since P_h is prime and $N_h = \pi(P_h)$, the equality $P_h = p_{N_h}$ holds. Thus the pair (N_h, P_h) is exactly the index–prime certificate of Definition 9307.1, and every base prime occurring in S_h lies in $\mathcal{P}_{N_h}$. □

Definition 9309.7 (Prime-power internal address space)**.** *For a certified finite NP envelope and compact bound B, define*

$$A_{N_h,B} := \{(p,k) : p \in \mathcal{P}_{N_h},\ k \ge 1,\ p^k \le e^B\}.$$

A compact prime-power residual has the finite internal form

$$R_h = \sum_{(p,k)\in A_{N_h,B}} c_{p,k}(h)[p,k].$$

Theorem 9309.8 (Prime-power residual has a finite address detector)**.** *If*

$$R_h = \sum_{(p,k)\in A_{N_h,B}} c_{p,k}(h)[p,k] \neq 0,$$

then a finite event in $A_{N_h,B}$ detects R_h.

Proof. Since $R_h \neq 0$, some coefficient $c_{p_0,k_0}(h)$ is nonzero. The singleton event

$$E = \{(p_0, k_0)\}$$

satisfies

$$\langle R_h, \mathbf{1}_E\rangle = c_{p_0,k_0}(h) \neq 0.$$

Thus the residual is detected by a finite address event. If the outer sum

$$C_p := \sum_{k:p^k\le e^B} c_{p,k}(h)$$

is nonzero for some prime p, the finite prime circle also detects the outer residual by Definition 9307.10. If every outer sum vanishes while $R_h \neq 0$, the nonzero singleton above lies in the internal valuation ledger at one prime, which is a legal local row of the prime-generated recursive sieve in Definition 9305.12. □

9309.3 Finite-or-Tail Bridge

Definition 9309.9 (Source-effective compact zeta window)**.** *A compact zeta window for an off-line packet ρ is source-effective when it consists of an admissible compact explicit-formula test row h, the abstract explicit-formula ledger of Definition 9317.2, and one of the two source accounts:*

$$\mathcal{P}(h) \neq 0,$$
$$\mathrm{TailRecord}_{\mathrm{zeta}}(\rho, R_\rho) \in \mathrm{TailPolicy}_{\mathcal{P}}\,.$$

The first account is finite because h is compact. The second account is the all-prime ledger row for residual material not represented in the compact finite source.

Theorem 9309.10 (PrimeProjectionCert supplies a source-effective window)**.** *Assume an off-critical mirror pair satisfies*

$$\mathsf{PrimeProjectionCert}(\rho_+, \rho_-).$$

Then it supplies the finite source account of Definition 9309.9.

Proof. Unpack Definition 9312.2. The certificate supplies an admissible compact explicit-formula test row g whose correction rows are displayed and whose correction-subtracted prime side is a nonzero finite prime-power residual

$$R_S(g) = \sum_{q\in S} c_q(g)[q] \neq 0.$$

This is exactly the first source account in Definition 9309.9. The compactness of g makes the support finite by Definition 9317.1. □

Theorem 9309.11 (Source-effective window realizes the global finite NP bridge)**.** *If every off-line zeta packet has a compact radial witness and a source-effective compact zeta window, then*

$$\mathsf{GlobalOffLineZeroToFiniteNPWindow}$$

holds in the sense of Definition 9308.14.

Proof. Let ρ be an off-line zeta packet. By Definition 9309.3, it has a compact test readout of its nonzero radial row. Read the associated source-effective compact zeta window.

If the finite account $\mathcal{P}(h) \neq 0$ holds, then Definition 9309.6 supplies a certified pair

$$\mathsf{IndexPrimePair}^{\uparrow}(N_h, P_h)$$

containing every base prime of the compact prime-power support. The finite source account in Definition 9308.14 is therefore available.

If the finite account is not the source account of the compact window, then Definition 9309.9 supplies the tail row

$$\mathrm{TailRecord}_{\mathrm{zeta}}(\rho, R_\rho) \in \mathrm{TailPolicy}_{\mathcal{P}}\,.$$

This is exactly the tail account of Definition 9308.14. Hence the global bridge row holds. □

Corollary 9309.12 (Explicit-formula projection realizes the global bridge)**.** *Assume every off-line mirror pair in the zeta ledger satisfies*

$$\mathsf{PrimeProjectionCert}(\rho_+, \rho_-).$$

Then the finite branch of

$$\mathsf{GlobalOffLineZeroToFiniteNPWindow}$$

is realized for every such pair.

Proof. For each off-line pair, the radial distribution row supplies the compact radial witness by Definition 9309.3. By Definition 9309.10, the prime-projection certificate supplies a source-effective compact zeta window with nonzero finite prime side. By Definition 9309.11, the global bridge row is realized, and the supplied source account is the finite branch. □

9309.4 Compact Window Exhaustion

Definition 9309.13 (Coefficiented off-line residual row)**.** *For an off-line zero*

$$\rho = \frac{1}{2} + r + i\gamma, \qquad r \neq 0,$$

a coefficiented radial residual row is

$$R_{\rho,c}(u) := c_\rho e^{ru} e^{i\gamma u}, \qquad c_\rho \neq 0.$$

The coefficient absorbs multiplicity and the displayed zero-side coefficient from the explicit formula. It is a source row of the zero packet only when c_ρ is supplied as nonzero data.

Lemma 9309.14 (Coefficiented radial row has compact test readout)**.** *Every coefficiented off-line residual row has a compact test row $h \in C_c^\infty(I)$ with*

$$\langle R_{\rho,c}, h\rangle_I \neq 0.$$

Proof. Choose a nonzero nonnegative bump function

$$\eta \in C_c^\infty(I)$$

and set

$$h(u) := \eta(u)e^{-i\gamma u}.$$

Then

$$\langle R_{\rho,c}, h\rangle_I = c_\rho \int_I \eta(u)e^{ru}\,du.$$

The integral is a positive real number, while $c_\rho \neq 0$. Hence the pairing is nonzero. □

Definition 9309.15 (Compact window source exhaustion)**.** *Let $h \in C_c^\infty([A,B])$ be an admissible compact explicit-formula test row. A compact window source exhaustion for h consists of the abstract explicit-formula ledger of Definition 9317.2, the compact prime-power address space*

$$A_{N,B} := \{(p,k) : p \in \mathcal{P}_N,\ k \geq 1,\ p^k \leq e^B\}$$

whenever a certified envelope

$$\mathsf{IndexPrimePair}^{\uparrow}(N,P)$$

covers the base primes occurring below e^B, and the correction accounts

$$\mathcal{A}(h)$$

for the main, archimedean, trivial-zero, and pole rows. The exhaustion condition says that a nonzero compact readout is legally accounted for only by one of the following rows:

a finite prime-power address in $A_{N,B}$,
a displayed finite-circle gap row after projection to $\mathbb{F}_P$,
a displayed correction row in $\mathcal{A}(h)$,
a tail row in $\mathrm{TailPolicy}_{\mathcal{P}}$.

If none of these rows is present, the compact window has no legal BEDC source account for the readout.

Theorem 9309.16 (Compact window exhaustion leaves no addressless residual)**.** *Assume $h \in C_c^\infty([A,B])$ has a compact window source exhaustion. If a coefficiented off-line residual row has*

$$\langle R_{\rho,c}, h\rangle \neq 0,$$

then the readout is finite-window represented, correction-ledger recorded, finite-gap recorded, or tail-recorded. If all four accounts are absent, the ledger coordinate of the zero packet fails.

Proof. The explicit-formula ledger decomposes the compact readout into the prime-power side and the displayed correction side. By Definition 9313.10, the prime side of the compact row is supported on

$$S_B = \{p^k : p^k \leq e^B\}.$$

If this side is nonzero, the finite support has a certified finite envelope by Definition 9309.6, and the internal address space $A_{N,B}$ contains every occurring prime-power coordinate. Then

Definition 9309.8 detects a nonzero finite address. If the projected coordinate lands in a finite-circle hole rather than an occupied prime point, Definition 9308.11 records the gap row or refuses the closed status.

If the finite prime-power side is not the source account for the nonzero readout, the explicit-formula identity places the nonzero contribution in a displayed correction row or in the source material not represented by the compact finite prime-power account. The former is one of the rows in $\mathcal{A}(h)$; the latter must enter $\mathrm{TailPolicy}_{\mathcal{P}}$ by Definition 9306.14. If none of the finite, gap, correction, or tail accounts is present, the readout has no legal source row, which is exactly a failure of the ledger coordinate of the zero packet. □

Theorem 9309.17 (Contrapositive global finite-window bridge)**.** *Let an off-line zeta zero packet carry a coefficiented residual row $R_{\rho,c}$, an ontological triple, and a compact window source exhaustion for the compact test row supplied by Definition 9309.14. If $R_{\rho,c}$ is absent from every certified finite (N, P) window and from every supplied tail, finite-gap, and correction ledger, then the ledger coordinate of the ontological triple fails.*

Proof. By Definition 9309.14, choose $h \in C_c^\infty([A, B])$ with

$$\langle R_{\rho,c}, h\rangle \neq 0.$$

Apply Definition 9309.16 to this compact row. Since the hypotheses exclude every finite window account and every tail, finite-gap, and correction account, the exhaustion theorem leaves only the ledger-failure alternative. This contradicts the assertion that the zero packet carries a valid ontological triple. □

Corollary 9309.18 (No finite or ledger account nullifies the residual row)**.** *Under a valid ontological triple and compact window source exhaustion, a residual row absent from all certified finite (N, P) windows and from all supplied tail, finite-gap, and correction ledgers cannot be a coefficiented off-line residual row.*

Proof. If it were such a row, then Definition 9309.17 would force the ledger coordinate of the ontological triple to fail. This contradicts the assumed validity of the triple. □

Principle 9309.19 (Fixed-window discipline for the global bridge)**.** *The bridge fixes the compact test row before any finite source certificate is read. Thus the support bound B, the prime-power address set $A_{N,B}$, and the certified pair $\mathsf{IndexPrimePair}^{\uparrow}(N, P)$ belong to the same observation window. The argument is a fixed-window ledger exhaustion statement, not a claim that an unspecified infinite zeta row has been collapsed into one finite modulus.*

9309.5 Closed-Packet Consequence

Theorem 9309.20 (Global bridge feeds the finite address refusal)**.** *Assume*

$$\mathsf{GlobalOffLineZeroToFiniteNPWindow}.$$

If an off-line zero packet has an ontological triple and is governed by $\mathsf{LedgerClosureRefusal}$*, then it cannot be both closed and missed by all finite prime-power, finite prime-circle, and tail-ledger readouts.*

Proof. By Definition 9308.16, the residual is either represented in a certified finite (N, P) window or recorded in $\mathrm{TailPolicy}_{\mathcal{P}}$. In the finite case, Definition 9309.8 detects the internal prime-power residual, and Definition 9308.12 rules out the closed missed status at the finite prime circle. In the tail case, Definition 9308.6 rules out closed invisible status. Both branches are governed by Definition 9312.3. □

Principle 9309.21 (Global window audit boundary)**.** *The global bridge is not a bare assertion that every zero has already been placed in one finite modulus. It is the compact-test and explicit-formula ledger statement that a nonzero off-line radial mode has a finite prime-power source account whenever the compact prime side is nonzero, and otherwise has an all-prime tail account. The finite address refusal then applies only after this source account is displayed.*

Chapter 9310

Finite Prime Circle Off-Line Contradiction

chapter 9309 supplies the source bridge from an off-line radial row to a finite prime-power window or to the all-prime tail ledger. The present chapter packages the conditional consequence for legal zeta zero packets: if completed zeta and its non-trivial zeros are admitted as generated BEDC objects with ontological triples and closure ledgers, then an off-line zero cannot also be closed.

9310.1 Legal Zeta Zero Packets

Definition 9310.1 (Licensed zeta zero object)**.** *A licensed zeta zero object is not a bare complex number satisfying $\zeta(\rho) = 0$. It is a non-trivial zero packet carried by the same NameCert route as the completed zeta object:*

$$\mathsf{NameCert}_{\mathsf{ZetaBasic}^{\uparrow}}, \qquad \mathsf{NameCert}_{\mathsf{ZetaCont}^{\uparrow}}, \qquad \mathsf{NameCert}_{\mathsf{CritStrip}^{\uparrow}}, \qquad \mathsf{NameCert}_{\mathsf{ZetaZeros}^{\uparrow}}.$$

The route exposes, for the zero packet, source, pattern, classifier, stability, and ledger coordinates:

$$\mathsf{SourceSpec}, \quad \mathsf{PatternSpec}, \quad \mathsf{ClassifierSpec},$$
$$\mathsf{StabilityCert}, \quad \mathsf{LedgerPolicy}.$$

Limit-shaped or continuation-shaped coordinates are licensed only together with the ledger rows that record branch, pole, correction, gap, and tail data.

Definition 9310.2 (ZetaZeroObjectsHaveOntTriple)**.** *The theorem-facing row*

$$\mathsf{ZetaZeroObjectsHaveOntTriple}$$

asserts that every licensed zeta zero object ρ carries an ontological triple

$$\mathrm{Ont}(\rho) = (\mathsf{T}_\rho, \mathsf{U}_\rho, \mathsf{L}_\rho).$$

Here T_ρ is the generated history through the zeta NameCert route, U_ρ is the unit and radial readout separating unit phase from scale residuals, and L_ρ is the ledger policy that assigns every nonzero residual to a finite, gap, tail, or displayed correction account.

Definition 9310.3 (Zeta legal zero packet)**.** *A zeta legal zero packet is a completed non-trivial zero packet ρ carried by the generated zeta closure row Definition 9330.2, equipped with:*

$$\mathrm{Ont}(\rho) = (\mathsf{T}_\rho, \mathsf{U}_\rho, \mathsf{L}_\rho),$$
$$\mathsf{GlobalOffLineZeroToFiniteNPWindow},$$
$$\mathsf{LedgerClosureRefusal}.$$

The first row is the ontological triple of Definition 9303.1. The second row is the finite or tail source bridge of Definition 9308.14. The third row is the closed-packet refusal of Definition 9312.3.

Theorem 9310.4 (Licensed triple gives a legal zero packet)**.** *Assume a licensed zeta zero object is carried by* ZetaBEDCClosure *and satisfies*

ZetaZeroObjectsHaveOntTriple, GlobalOffLineZeroToFiniteNPWindow, LedgerClosureRefusal.

Then it is a zeta legal zero packet.

Proof. The closure row supplies the generated completed zeta carrier and the non-trivial zero packet. By Definition 9310.2, the packet carries the displayed ontological triple. The global bridge and closure refusal rows are exactly the second and third rows required in Definition 9310.3. Hence all coordinates of a zeta legal zero packet are present. □

Definition 9310.5 (Closed zeta zero packet)**.** *A zeta legal zero packet is closed when no nonzero residual row remains as an unprocessed append row. A detected residual that is not recorded violates L_ρ; a detected residual that is recorded is a continuing ledger row rather than closed zero-packet status.*

Principle 9310.6 (Zeta-shaped statements are theorem targets)**.** *The rows* ZetaBEDCClosure, GlobalOffLineZeroToFiniteNPWindow, *and the resulting fixed-half readout are theorem-facing rows. They are not seed names for zeta or for* RH*. Each must be supplied by the Dirichlet, Euler product, analytic-continuation, explicit-formula, finite-window, and ledger certificates on which it depends.*

9310.2 Off-Line Residual Refusal

Theorem 9310.7 (Off-line legal zero packets expose residuals)**.** *If a zeta legal zero packet is off the critical line, then it supplies a nonzero radial residual with finite-window or tail status.*

Proof. An off-line zero has a nonzero radial row by Definition 9309.1 and Definition 9309.3. The global bridge row in Definition 9310.3 applies to that residual. By Definition 9308.16, the residual is represented in a legal finite (N, P) window or is recorded in $\mathrm{TailPolicy}_{\mathcal{P}}$. □

Theorem 9310.8 (Finite prime circle off-line contradiction)**.** *A zeta legal zero packet cannot be both off the critical line and closed.*

Proof. Suppose that a zeta legal zero packet ρ is off the critical line. By Definition 9310.7, its radial residual has finite-window or tail status.

If the residual is finite-window represented, then Definition 9309.20 applies: the internal prime-power detector, finite prime-circle detector, gap ledger, or tail ledger prevents the packet from being closed and missed. If the residual is tail-recorded, then Definition 9308.6 says that the tail row is an append ledger row; erasing it would violate L_ρ. Both branches are precisely the alternatives refused by Definition 9312.3. Therefore ρ cannot be a closed packet. □

Theorem 9310.9 (Off-line licensed triple cannot be closed)**.** *Let ρ be a licensed zeta zero object carried by* ZetaBEDCClosure*. Assume*

ZetaZeroObjectsHaveOntTriple, GlobalOffLineZeroToFiniteNPWindow, LedgerClosureRefusal.

If ρ is off the critical line, then ρ cannot be a closed zeta zero packet.

Proof. By Definition 9310.4, the licensed object is a zeta legal zero packet. The off-line hypothesis then activates Definition 9310.8, which refuses simultaneous off-line and closed status. □

Corollary 9310.10 (Legal closed zeta zeros have fixed-half readout)**.** *Every closed zeta legal zero packet has*

$$\mathrm{Re}(\rho) = \frac{1}{2}.$$

Proof. If $\mathrm{Re}(\rho) \neq 1/2$, then ρ is off the critical line. By Definition 9310.8, it cannot be closed. Hence every closed zeta legal zero packet has no off-line radial displacement. Equivalently, Definition 9266.2 gives $\mathrm{Re}(\rho) = 1/2$ from the unit Li readout. □

9310.3 Conditional RH Interface

Definition 9310.11 (PrimeCircleBEDCRoute)**.** *The route*

PrimeCircleBEDCRoute

consists of the following rows:

ZetaBEDCClosure,
every admitted non-trivial zero is a zeta legal zero packet,
every admitted non-trivial zero packet is closed,
GlobalOffLineZeroToFiniteNPWindow.

It is a conditional route: each row is an explicit certificate or theorem target, not a primitive assertion about zeta.

Theorem 9310.12 (PrimeCircleBEDCRoute gives the BEDC RH predicate)**.** *Assume* PrimeCircleBEDCRoute*. Then every admitted non-trivial zero satisfies the fixed-half predicate of Definition 9239.7.*

Proof. Let ρ be an admitted non-trivial zero packet. By the route, it is a zeta legal zero packet and it is closed. Apply Definition 9310.10. The fixed-half readout is exactly the OnCritLine conclusion in Definition 9239.7. □

Corollary 9310.13 (PrimeCircle conditional RH)**.** *Under* PrimeCircleBEDCRoute*, the BEDC RH statement is inhabited as a conditional theorem target.*

Proof. The predicate RH is the Π-statement over admitted non-trivial zero packets recorded in Definition 9239.7. The preceding theorem supplies the fixed-half output for each such packet. Thus the conditional route inhabits the BEDC RH statement. □

Corollary 9310.14 (NameCert triple conditional RH)**.** *Assume every admitted non-trivial zero is a licensed zeta zero object carried by* ZetaBEDCClosure*, assume every such object satisfies*

ZetaZeroObjectsHaveOntTriple, GlobalOffLineZeroToFiniteNPWindow, LedgerClosureRefusal,

and assume every admitted non-trivial zero packet is closed. Then every admitted non-trivial zero satisfies

$$\mathrm{Re}(\rho) = \frac{1}{2}.$$

Proof. Let ρ be an admitted non-trivial zero. If ρ were off the critical line, then Definition 9310.9 would rule out closed status. This contradicts the closed-packet assumption. Hence ρ is not off the critical line, and Definition 9266.2 gives the fixed-half readout. □

Principle 9310.15 (Prime circle contradiction audit boundary)**.** *The contradiction is conditional on the legal-object rows. It proves that the simultaneous package*

off-line zero + *ontological triple* + *closed zero packet* + GlobalOffLineZeroToFiniteNPWindow

is impossible. It does not assert that ZetaBEDCClosure*, zero-packet closure, or the global window bridge are primitive facts; those remain the explicit certificates required before the conditional route can be read as a BEDC proof of* RH*.*

Principle 9310.16 (Ontological triple construction target)**.** *The finite contradiction has been reduced to the construction of*

ZetaZeroObjectsHaveOntTriple.

That row is not a seed assertion about zeros. It must be constructed from the NameCert data for ZetaBasic$^{\uparrow}$*,* ZetaCont$^{\uparrow}$*,* CritStrip$^{\uparrow}$*, and* ZetaZeros$^{\uparrow}$*, together with the ledger witnesses for continuation, limits, correction terms, finite prime windows, gaps, and tails. Once that row is supplied, an off-line zero can only be a detected residual, a ledger append, or a ledger violation; none of those statuses is a closed legal zero packet.*

Chapter 9311

Analytic Continuation Ontological Triple

chapter 9303 requires every zeta-route tool to expose an ontological triple. The analytic continuation operation of chapter 9341 and the zeta continuation application of chapter 9342 therefore cannot function as bare analytic shortcuts inside the RH route. They must preserve source history, unit or phase structure, and ledger visibility. This chapter records that requirement as a proof-engineering interface for the prime-generated recursive sieve.

9311.1 Continuation Certificate

Definition 9311.1 (Analytic continuation certificate)**.** *Let $f_0 : \Omega_0 \to \mathbb{C}$ be a licensed analytic object and let $\Omega_0 \subseteq \Omega_1$. An analytic continuation certificate for an extension*

$$f_0 \rightsquigarrow f_1 : \Omega_1 \to \mathbb{C}$$

is a packet

$$\mathrm{ACCert}(f_0 \rightsquigarrow f_1) := (\mathrm{SourceSpec}, \mathrm{PatternSpec}, \mathrm{ClassifierSpec}, \mathrm{StabilityCert}, \mathrm{LedgerPolicy}).$$

Here SourceSpec *records f_0, Ω_0, and the history of f_0;* PatternSpec *records equality of holomorphic germs on overlaps;* ClassifierSpec *records the branch, monodromy, and same-germ classifier used by the extension;* StabilityCert *records identity-theorem and local holomorphy witnesses; and* LedgerPolicy *records branch cuts, singularities, tails, poles, zeros, and residual rows.*

Definition 9311.2 (Continuation ontological triple)**.** *For a certified continuation $f_0 \rightsquigarrow f_1$, its ontological triple is*

$$\mathrm{Ont}(f_0 \rightsquigarrow f_1) := (\mathsf{T}_{\mathrm{AC}}, \mathsf{U}_{\mathrm{AC}}, \mathsf{L}_{\mathrm{AC}}),$$

where

$$\mathsf{T}_{\mathrm{AC}} : \quad f_1|_{\Omega_0} = f_0$$

is the source-history row,

$$\mathsf{U}_{\mathrm{AC}}$$

is the row saying that unit phase, positivity, or orthogonal energy readouts are preserved unless a displayed residual row is produced, and

$$\mathsf{L}_{\mathrm{AC}}$$

is the continuation ledger for branches, tails, singularities, monodromy, zero and pole rows, and residual projections.

Principle 9311.3 (No uncertified analytic continuation)**.** *An analytic continuation used by the RH route is not available as a primitive operation merely because an analytic formula can be written. It is available only through an operation or application certificate whose source, overlap pattern, classifier, stability, and ledger rows are displayed. Otherwise the continued object has no BEDC license.*

Theorem 9311.4 (Certified continuation preserves the ontological triple)**.** *Let f_0 be a BEDC-licensed analytic object with* $\mathrm{Ont}(f_0)$*. If $f_0 \rightsquigarrow f_1$ has an analytic continuation certificate, then f_1 has an ontological triple.*

Proof. The source row of ACCert gives the history extension from f_0 to f_1, so T_{f_1} is defined by appending the continuation bridge to T_{f_0}. The pattern and stability rows say that f_1 agrees with f_0 as the same analytic germ on the overlap and is uniquely determined by the continuation witnesses; hence unit or phase data from the source cannot be silently changed. If a nonunit radial or branch-dependent row appears, it is not part of the unit row and must be recorded by the ledger policy. The ledger row of ACCert records branch, tail, singular, zero, pole, monodromy, and residual data. These three rows define $\mathrm{Ont}(f_1)$. □

9311.2 Conservative Zeta Continuation

Definition 9311.5 (Conservative zeta continuation certificate)**.** *A conservative zeta continuation certificate is an analytic continuation certificate*

$$\mathrm{ACCert}(\zeta_0 \rightsquigarrow \zeta_1)$$

from the right-half-plane PZG zeta source to a continued zeta object, together with three transport rows:

$$(\mathsf{PZGSource}, \mathsf{UnitPhase}, \mathsf{NoScaleRegister}).$$

The row PZGSource *says that the continued object is the same germ as the tagged PZG zeta family and its forgetful scalar readout of Definition 9293.11 and Definition 9293.13. The row* UnitPhase *says that the PZG phase readout remains a unit phase row under continuation unless a displayed residual ledger records otherwise. The row* NoScaleRegister *says that the continuation does not supply an independent positive-real scale register capable of paying the instruction-scale residual of Definition 9294.5.*

Principle 9311.6 (Completion factors are ledger rows)**.** *The archimedean and pole factors in the completed xi execution trace are visible completion rows. They may provide the functional equation, reflection, pole cancellation, and archimedean boundary data recorded in Definition 9293.6; they are not free per-prime scale registers inside the original zeta source. Any use of a completion factor as a scale-balancing mechanism must therefore appear as a named completion or residual ledger row, not as an unrecorded internal cancellation of the PZG source.*

Theorem 9311.7 (Conservative continuation forbids scale-register payment)**.** *Assume a conservative zeta continuation certificate for the continued zeta object. Then an off-half instruction-scale residual cannot be closed by analytic continuation itself. It must either remain in the continuation ledger or be closed by a displayed same-packet zeta ledger row.*

Proof. By Definition 9311.5, the continued object transports the right-half-plane PZG source and its forgetful scalar readout; it does not replace that source by a different register system. The unit-phase row transports the fact that phase instructions have modulus 1. By Definition 9294.6, such instructions cannot cancel a nonzero instruction-scale residual. The NoScaleRegister row forbids analytic continuation from supplying an independent positive-real scale register. Hence any off-half scale residual is not paid by the continuation operation itself. By the ledger policy in Definition 9311.1, it must be recorded as residual data unless a displayed same-packet zeta ledger row closes it. □

Corollary 9311.8 (Conservative single-ledger continuation gives fixed-half)**.** *If a continued nontrivial zero packet is accepted through a conservative zeta continuation certificate and is closed by the single-ledger zero principle, then it has fixed-half readout.*

Proof. Conservative continuation forbids scale-register payment by Definition 9311.7. The remaining same-packet closure condition is exactly the hypothesis consumed by Definition 9294.11. Therefore the zero packet has fixed-half readout. □

9311.3 Eta Parity Bridge

Definition 9311.9 (Eta parity sieve bridge)**.** *The eta parity sieve bridge is the $p = 2$ classifier*

$$n \longmapsto n \bmod 2$$

together with the unit character

$$\varepsilon_2(n) := (-1)^{n-1}.$$

It produces the Dirichlet eta series

$$\eta(s) := \sum_{n \geq 1} \varepsilon_2(n) n^{-s}.$$

Theorem 9311.10 (Eta bridge preserves BEDC rows)**.** *The eta parity sieve bridge preserves the time, unit, and ledger rows of the right-half-plane zeta source.*

Proof. The time row is the appended parity classifier $n \mapsto n \bmod 2$. The unit row is the character identity

$$|\varepsilon_2(n)| = 1.$$

Thus the bridge changes the phase readout but does not add an unledgered radial scale. The ledger row is the displayed correction factor in Definition 9342.3:

$$\eta(s) = (1 - 2^{1-s})\zeta(s)$$

on the overlap where the relation is derived from the absolutely convergent source. The parity classifier, the factor $1 - 2^{1-s}$, and the denominator-zero and pole rows of the continuation application are therefore visible ledger data. □

Theorem 9311.11 (Eta continuation supplies a certified critical-strip zeta object)**.** *On the strip*

$$0 < \mathrm{Re}(s) < 1,$$

the eta quotient

$$\zeta_\eta(s) := \frac{\eta(s)}{1 - 2^{1-s}}$$

is a certified continuation of the right-half-plane zeta source whenever the eta continuation application certificate is supplied.

Proof. The eta function is holomorphic on $\mathrm{Re}(s) > 0$ by Definition 9342.2. The eta-zeta relation of Definition 9342.3 gives equality with the right-half-plane zeta source on the overlap $\mathrm{Re}(s) > 1$. On $0 < \mathrm{Re}(s) < 1$, the denominator $1 - 2^{1-s}$ has no zero, so the eta quotient defines the displayed analytic object. The certificate rows are precisely the eta relation, overlap identity, denominator and pole ledger, and continuation law recorded in Definition 9342.10 and Definition 9342.11. Therefore the object is a certified continuation in the sense of Definition 9311.1. □

9311.4 Sieve Ledger Preservation

Definition 9311.12 (AnalyticContinuationPreservesOntTriple)**.** *The row*

AnalyticContinuationPreservesOntTriple

asserts that every analytic continuation used by the zeta route carries an analytic continuation certificate and therefore transports ontological triples from source objects to continued objects.

Theorem 9311.13 (Ontological continuation preserves prime-sieve ledger)**.** *Assume* AnalyticContinuationPreserves *for the continuation from the right-half-plane prime-generated phase limit to the critical-strip zeta object. Then*

AnalyticContinuationPreservesPrimeSieveLedger

holds for the prime-generated recursive sieve route.

Proof. By Definition 9305.11, the right-half-plane normalized zeta phase is an inverse limit of prime-generated local probability sieves. Its source rows are finite prime windows, local valuation distributions, phase readouts, and tail-ledger entries. By Definition 9311.4, the certified continuation transports source history, unit rows, and ledger policy into the continued object. Hence the finite prime windows, local valuation rows, unit phase readouts, residual projections, and excluded-mass ledger entries remain available as continued certified rows, which is exactly the row defined in Definition 9305.12. □

Theorem 9311.14 (Continuation cannot hide a radial residual)**.** *Assume* AnalyticContinuationPreservesOntTriple. *If an off-critical zero contributes a nonzero radial residual to the continued zeta object, then the residual must appear as a ledgered continuation row or as a finite prime-side residual row.*

Proof. A nonzero radial mode is not a unit phase row. Under Definition 9311.2, such a nonunit row cannot be absorbed into U_{AC} unless it is recorded as visible residual data. The ledger policy of Definition 9311.1 records residuals, zeros, poles, branch data, and tails. Therefore the radial residual either appears in the continuation ledger or is transported into the finite prime-side residual rows whose preservation is given by Definition 9311.13. □

Principle 9311.15 (Continuation audit boundary)**.** *The eta bridge and the general analytic-continuation operation remove analytic continuation as a hiding place for radial scale. They do not prove that an off-critical zero produces a finite prime residual. They only certify that, once such a residual is present in the continued zeta object, it must be preserved as source, unit, or ledger data rather than treated as an unlicensed feature of the continuation.*

Chapter 9312

Off-Line Zero to Prime Sieve Contradiction

chapter 9318 isolates the spectral packet that an off-critical mirror pair must expose, while chapter 9317 records the compact-test bridge from spectral scale to a finite prime-power row. chapter 9305 proves that finite prime residuals are detected by local sieves generated by primes. The present chapter packages these interfaces into a single BEDC proof object:

$$\mathsf{OffLineZeroToPrimeSieveContradiction}^{\uparrow}.$$

Its role is not to assert the Riemann hypothesis as a closed theorem. It identifies the exact certificate chain under which an off-line zero cannot be admitted as a closed BEDC/PFZ zero packet.

9312.1 Contradiction Packet

Definition 9312.1 (OffLineZeroToPrimeSieveContradiction)**.** *The packet*

$$\mathsf{OffLineZeroToPrimeSieveContradiction}$$

consists of the following rows:

$$\begin{gathered}\mathsf{AnalyticContinuationPreservesOntTriple},\\ \mathsf{AnalyticContinuationPreservesPrimeSieveLedger},\\ \mathsf{ZetaFixedWindowDominance},\\ \mathsf{PrimeProjectionCert},\\ \mathsf{PrimeGeneratedRecursiveSieve},\\ \mathsf{LedgerClosureRefusal}.\end{gathered}$$

The first two rows license the continued zeta object as a source-preserving, unit-aware, ledger-visible object. The fixed-window row supplies the off-line spectral packet. The prime-projection row turns that spectral packet into a nonzero finite prime-power residual. The recursive sieve row detects every such finite residual by a local prime-generated classifier. The ledger-refusal row says that a closed zero packet cannot carry either an unrecorded detected residual or an append row that has not closed.

Definition 9312.2 (PrimeProjectionCert)**.** *For an off-critical mirror pair*

$$\rho_+ = \frac{1}{2} + r + i\gamma, \qquad \rho_- = \frac{1}{2} - r + i\gamma, \qquad r \neq 0,$$

the certificate

$$\mathsf{PrimeProjectionCert}(\rho_+, \rho_-)$$

asserts that the fixed-window radial readout supplied by

$$\mathsf{ZetaFixedWindowDominance}$$

has an admissible compact explicit-formula test row g for which the explicit-formula ledger

$$\mathcal{Z}(g) = \mathcal{P}(g) + \mathcal{A}(g)$$

produces a nonzero finite prime-power residual

$$R_S(g) = \sum_{q \in S} c_q(g)[q] \neq 0.$$

Equivalently, the archimedean, trivial-zero, and pole correction rows are displayed and do not absorb the fixed radial readout.

Definition 9312.3 (LedgerClosureRefusal)**.** *The row*

$$\mathsf{LedgerClosureRefusal}$$

asserts that a legal closed BEDC/PFZ zero packet cannot satisfy either of the following conditions:

a detected prime-sieve residual is absent from the ledger,

a detected prime-sieve residual is present as an unclosed append row.

Thus a detected residual is fatal to closed zero-packet admission: if it is not ledgered, the ledger policy fails; if it is ledgered, the packet has not closed.

9312.2 From Spectral Packet to Prime Residual

Theorem 9312.4 (Fixed packet gives a finite prime residual)**.** *Assume* $\mathsf{ZetaFixedWindowDominance}$ *and*

$$\mathsf{PrimeProjectionCert}(\rho_+, \rho_-)$$

for an off-critical mirror pair. Then the pair supplies a nonzero finite prime-power residual

$$R_S(g) = \sum_{q \in S} c_q(g)[q].$$

Proof. The fixed-window dominance row unpacks through Definition 9318.16. For the displayed mirror pair it supplies a finite spectral window, a mirror-odd differential classifier, a compact observation interval, and a positive dominance margin. By Definition 9318.8, the corresponding classifier readout is nonzero and contains a nonunit radial row.

The prime-projection certificate supplies an admissible compact explicit-formula test row whose correction rows are ledgered and do not absorb that radial readout. Therefore the explicit-formula identity

$$\mathcal{Z}(g) = \mathcal{P}(g) + \mathcal{A}(g)$$

has a nonzero correction-subtracted prime side. This is the prime-effective realization of Definition 9318.10. Applying Definition 9318.11 gives the displayed nonzero finite residual. □

Corollary 9312.5 (Explicit-formula isolation is a projection certificate)**.** *The hypotheses of Definition 9317.9 provide an instance of*

$$\mathsf{PrimeProjectionCert}(\rho_+, \rho_-)$$

for the corresponding off-critical mirror pair.

Proof. Definition 9317.9 starts from the abstract explicit-formula ledger and ArchNullZeroIsolation. It produces a nonzero finite prime-power residual from an off-critical zero. This is precisely the prime-projection certificate: the compact test row is admissible, the correction row is null in the stated ledger, and the prime side is finite and nonzero. □

9312.3 Prime-Generated Detection

Theorem 9312.6 (Finite residual enters a prime-generated sieve)**.** *Assume* PrimeGeneratedRecursiveSieve*. If*

$$R_S = \sum_{j=1}^{N} c_j[q_j] \neq 0$$

is a finite prime-power residual with distinct support points, then there are a prime p and a character

$$\chi : \mathbb{F}_p^\times \to S^1$$

such that

$$\sum_{j=1}^{N} c_j \chi(q_j \bmod p) \neq 0.$$

The readout is a legal finite row of the prime-generated recursive sieve ledger.

Proof. The existence of the detecting prime and character is exactly Definition 9305.5. The legality of the row follows from Definition 9305.2: a local residue or character readout generated by a prime is one of the permitted finite classifier rows, and the recursive sieve step records the selected prime, event or character, readout, source residual, and reason. □

Corollary 9312.7 (Signed residuals also enter the recursive sieve)**.** *Under* PrimeGeneratedRecursiveSieve*, every finite prime negative residual of Definition 9317.16 has a prime-generated classifier readout.*

Proof. By Definition 9317.18, a finite prime negative residual supplies a nonzero finite prime-classifier residual. Apply Definition 9312.6. □

9312.4 Contradiction Route

Theorem 9312.8 (Off-line zero to prime-sieve contradiction)**.** *Assume*

$$\mathsf{OffLineZeroToPrimeSieveContradiction}.$$

If every off-critical mirror pair in the continued zeta ledger satisfies

$$\mathsf{PrimeProjectionCert}(\rho_+, \rho_-),$$

then no off-critical zero is admitted as a legal closed BEDC/PFZ zero packet.

Proof. Suppose that a legal closed packet admits an off-critical zero. Its mirror pair has the form

$$\rho_+ = \frac{1}{2} + r + i\gamma, \qquad \rho_- = \frac{1}{2} - r + i\gamma, \qquad r \neq 0.$$

The continuation rows in Definition 9312.1 keep this pair inside the certified zeta ledger and prevent analytic continuation from hiding a radial residual, as expressed by Definition 9311.13 and Definition 9311.14.

By ZetaFixedWindowDominance and the prime-projection certificate for the mirror pair, Definition 9312.4 gives a nonzero finite prime-power residual R_S. By Definition 9312.6, a local prime-generated classifier detects R_S with nonzero readout.

That detected readout has only two possible ledger statuses. If it is not recorded, the prime-sieve ledger policy fails. If it is recorded, the zero packet carries an append residual row and is not closed. Both alternatives contradict LedgerClosureRefusal. Therefore a legal closed BEDC/PFZ zero packet cannot admit an off-critical zero. □

Corollary 9312.9 (Conditional fixed-half readout)**.** *Under the hypotheses of Definition 9312.8, every admitted closed nontrivial zero has fixed-half readout:*

$$\mathrm{Re}(\rho) = \frac{1}{2}.$$

Proof. The theorem excludes every closed admitted off-critical zero. Hence an admitted closed nontrivial zero must have no radial displacement from the half line. Equivalently, by Definition 9266.2, its Li coordinate lies on the unit circle precisely when

$$\mathrm{Re}(\rho) = \frac{1}{2}.$$

□

9312.5 Audit Boundary

Principle 9312.10 (Finite sieve side is closed under the packet)**.** *Inside*

OffLineZeroToPrimeSieveContradiction,

the finite arithmetic part is not the source of the obstruction. Once a nonzero finite prime-power residual is displayed, the prime-generated recursive sieve detects it by Definition 9305.5; the detected row is then governed by the ledger dichotomy of Definition 9312.3.

Principle 9312.11 (Analytic certificate boundary)**.** *The analytic burden of the packet is concentrated in the two certificate rows*

ZetaFixedWindowDominance *and* PrimeProjectionCert.

The first row is the fixed spectral-window dominance statement of Definition 9318.16. The second row is the compact explicit-formula projection statement of Definition 9312.2. Once those rows are supplied, the contradiction route is finite, prime-generated, and ledgered.

Chapter 9313

Prime Projection Certificate

Definition 9312.2 names the bridge from a fixed off-line spectral packet to a finite prime-power residual. This chapter expands that bridge into a fixed-window certificate. The argument has three parts: a nonzero differential readout is paired with a compact test row, the differential classifier is moved onto the test row by transposition, and the compact Chebyshev expansion leaves a finite prime-power row after the displayed main and correction functionals are killed.

9313.1 Test-Row Projection

Definition 9313.1 (Fixed-window residual functional)**.** *Let Ψ be a normalized prime-distribution curve, let $I \subset \mathbb{R}$ be a compact interval, and let $P_\pm$ be a mirror-odd differential classifier. The fixed-window residual functional is*

$$\mathcal{F}_{P_\pm,I}(g) := \langle P_\pm(D)\Psi, g\rangle_I$$

for test rows $g \in C_c^\infty(I)$.

Lemma 9313.2 (Fixed-window test separation)**.** *Assume*

$$\inf_{u\in I} |P_\pm(D)\Psi(u)| > 0.$$

Then there exists $g \in C_c^\infty(I)$ such that

$$\mathcal{F}_{P_\pm,I}(g) \neq 0.$$

Proof. If $\mathcal{F}_{P_\pm,I}$ vanished on every test row, then $P_\pm(D)\Psi$ would be the zero distribution on the interior of I. This contradicts the displayed positive lower bound. Hence some compactly supported test row has nonzero pairing. □

Lemma 9313.3 (Differential classifier transposition)**.** *Let $P_\pm$ be a polynomial and let $g \in C_c^\infty(I)$. Define*

$$h := P_\pm(-D)g.$$

Then $h \in C_c^\infty(I)$ and

$$\langle P_\pm(D)\Psi, g\rangle_I = \langle \Psi, h\rangle_I.$$

Proof. Compact support removes boundary terms. Each monomial D^m moves from Ψ to g with the sign $(-1)^m$ under integration by parts. Linearity over the polynomial $P_\pm$ gives the displayed identity, and differentiating a compactly supported smooth test row preserves compact support in I. □

Theorem 9313.4 (Dominance supplies a compact nonzero prime-distribution test)**.** *If an off-critical mirror pair has a fixed window dominance certificate, then there exists $h \in C_c^\infty(I)$ such that*

$$\langle \Psi, h \rangle_I \neq 0.$$

Proof. By Definition 9318.8, the full curve has a nonzero classifier readout on the fixed interval. Apply Definition 9313.2 to choose g with nonzero pairing against $P_\pm(D)\Psi$. Then apply Definition 9313.3 and set $h = P_\pm(-D)g$. □

9313.2 Main and Correction Null Rows

Definition 9313.5 (Chebyshev main functional)**.** *For $h \in C_c^\infty([A, B])$, define the Chebyshev main functional by*

$$M(h) := \int_A^B h(u)e^{u/2}\, du.$$

Definition 9313.6 (MainArchNullCert)**.** *For a fixed-window residual functional $\mathcal{F}_{P_\pm,I}$, the certificate*

$$\mathsf{MainArchNullCert}(P_\pm, I)$$

asserts that there are finitely many displayed correction functionals

$$C_1, \ldots, C_N : C_c^\infty(I) \to \mathbb{C}$$

containing the main row and the archimedean, trivial-zero, and pole rows relevant to the chosen explicit-formula ledger, and that the prime-distribution functional

$$h \longmapsto \langle \Psi, h \rangle_I$$

does not belong to their linear span on the admissible compact test space.

Lemma 9313.7 (Finite-constraint separation)**.** *Let V be a complex vector space, let $F : V \to \mathbb{C}$ be a linear functional, and let $L_1, \ldots, L_N : V \to \mathbb{C}$ be linear functionals. If*

$$F \notin \operatorname{span}(L_1, \ldots, L_N),$$

then there exists $v \in V$ such that

$$L_j(v) = 0 \qquad (1 \leq j \leq N)$$

and

$$F(v) \neq 0.$$

Proof. Let

$$K := \bigcap_{j=1}^{N} \ker L_j.$$

If F vanished on K, then F would factor through the finite quotient determined by the map

$$v \longmapsto (L_1(v), \ldots, L_N(v)).$$

Hence F would be a linear combination of the L_j, contrary to the hypothesis. Therefore F is nonzero on K, giving the required vector v. □

Theorem 9313.8 (MainArchNullCert gives a nonzero null-corrected test)**.** *Assume* $\mathsf{MainArchNullCert}(P_\pm, I)$ *and suppose the fixed-window dominance certificate supplies a nonzero compact prime-distribution test row as in Definition 9313.4. Then there exists* $h \in C_c^\infty(I)$ *such that*

$$\langle \Psi, h \rangle_I \neq 0$$

and every displayed main, archimedean, trivial-zero, and pole correction functional in the certificate vanishes on h*.*

Proof. Use Definition 9313.7 on the admissible compact test space with

$$F(h) = \langle \Psi, h \rangle_I$$

and with $L_1, \ldots, L_N$ equal to the displayed correction functionals of Definition 9313.6. The nonspan row in that definition is exactly the hypothesis needed by the separation lemma. □

9313.3 Finite Prime Projection

Definition 9313.9 (Compact Chebyshev prime projection)**.** *Let*

$$\Psi(u) = e^{-u/2}\big(\psi(e^u) - e^u\big)$$

and let $h \in C_c^\infty([A, B])$*. The compact Chebyshev prime projection is the finite expansion*

$$\langle \Psi, h \rangle = \sum_{p^k \le e^B} c_{p,k}(h) - M(h),$$

where

$$c_{p,k}(h) := \log p \int_{\max(A, \log p^k)}^{B} h(u) e^{-u/2}\, du$$

and $M(h)$ *is the functional of Definition 9313.5.*

Lemma 9313.10 (Compact support makes the prime side finite)**.** *For* $h \in C_c^\infty([A, B])$*, the prime side of Definition 9313.9 is supported on the finite set*

$$S_B := \{p^k : p^k \le e^B\}.$$

Proof. The Chebyshev row

$$\psi(e^u) = \sum_{p^k \le e^u} \log p$$

contains no prime power larger than e^B on the interval $[A, B]$. There are only finitely many prime powers bounded by e^B, so the displayed support is finite. □

Theorem 9313.11 (Null-corrected compact test gives finite prime residual)**.** *Let* $h \in C_c^\infty([A, B])$ *satisfy*

$$\langle \Psi, h \rangle \neq 0$$

and

$$M(h) = 0.$$

Then

$$R_S(h) := \sum_{q \in S_B} c_q(h)[q]$$

is a nonzero finite prime-power residual.

Proof. By Definition 9313.9, the main-null condition gives

$$\langle \Psi, h \rangle = \sum_{p^k \le e^B} c_{p,k}(h).$$

The left side is nonzero, so the finite prime-power sum is nonzero. By Definition 9313.10, its support is finite. □

Theorem 9313.12 (MainArchNullCert realizes PrimeProjectionCert)**.** *Assume an off-critical mirror pair has a fixed window dominance certificate and assume*

$$\mathsf{MainArchNullCert}(P_\pm, I)$$

for its mirror-odd classifier and fixed interval. Then

$$\mathsf{PrimeProjectionCert}(\rho_+, \rho_-)$$

holds in the sense of Definition 9312.2.

Proof. The fixed-window dominance certificate supplies a compact test row with nonzero prime-distribution pairing by Definition 9313.4. The main-arch-null certificate refines the choice, through Definition 9313.8, so that the main and displayed correction functionals vanish while the prime-distribution pairing remains nonzero. Applying Definition 9313.11 produces a nonzero finite prime-power residual. This is exactly the compact explicit-formula projection required by Definition 9312.2. □

9313.4 Detection Interface

Theorem 9313.13 (PrimeProjectionCert supplies a prime-generated detector)**.** *Assume*

$$\mathsf{PrimeProjectionCert}(\rho_+, \rho_-)$$

and PrimeGeneratedRecursiveSieve*. Then the finite residual produced by the projection certificate is detected by some local sieve generated by a prime.*

Proof. Unpack Definition 9312.2. It supplies a nonzero finite prime-power residual

$$R_S(g) = \sum_{q \in S} c_q(g)[q].$$

Apply Definition 9312.6. The resulting prime and character give the required local prime-generated detector. □

Principle 9313.14 (Prime projection audit boundary)**.** *The finite arithmetic side of*

$$\mathsf{PrimeProjectionCert}$$

is closed by compact support and character orthogonality. The analytic content is the nonspan row of

$$\mathsf{MainArchNullCert}(P_\pm, I),$$

which asserts that the fixed-window radial readout is not a linear combination of the main, archimedean, trivial-zero, and pole correction rows on the admissible compact test space.

Chapter 9314

Prime Sieve Tower Duality

chapter 9315 treats finite type spaces and sieve readouts as dual coordinates. The present chapter records the generating side of that duality. A prime is not only an object to be classified by a sieve; it is also an atom that creates further sieve surfaces. Divisibility, residue class, finite unit-group, order, and splitting readouts are all generated from prime atoms, and their refinements preserve the BEDC time, unit, and ledger rows.

9314.1 Prime-Generated Sieve Tower

Definition 9314.1 (Euclidean prime sieve tower)**.** *Let $p_1, p_2, p_3, \ldots$ be the increasing sequence of primes and set*

$$P_m := \prod_{j=1}^{m} p_j.$$

The Euclidean prime sieve layer is

$$\mathcal{N}_m := \{n \geq 2 : \gcd(n, P_m) = 1\}.$$

Thus $\mathcal{N}_m$ is the set of integers not removed by the first m prime divisibility tests.

Theorem 9314.2 (Minimal survivor is a new prime)**.** *If $\mathcal{N}_m$ is nonempty and $q = \min \mathcal{N}_m$, then q is a prime distinct from $p_1, \ldots, p_m$.*

Proof. If q were composite, write $q = ab$ with $1 < a < q$ and $1 < b < q$. By minimality of q in $\mathcal{N}_m$, the integer a is not in $\mathcal{N}_m$. Hence some p_j with $j \leq m$ divides a, and therefore divides q. This contradicts $\gcd(q, P_m) = 1$. Thus q is prime. Since q is coprime to P_m, it is not one of $p_1, \ldots, p_m$. □

Corollary 9314.3 (Prime atoms extend the sieve tower)**.** *Adding the prime p_{m+1} refines the survivor layer by*

$$\mathcal{N}_{m+1} = \mathcal{N}_m \cap \{n : p_{m+1} \nmid n\}.$$

Hence each prime is both a survivor of previous sieve layers and a new divisibility test for later layers.

Proof. The identity is the definition of coprimality with $P_{m+1} = P_m p_{m+1}$. The previous theorem identifies the next minimal survivor as a new prime, and the displayed identity identifies its corresponding divisibility test. □

Principle 9314.4 (Prime atoms are sieve generators)**.** *A prime atom has a dual status in the sieve tower. It is an arithmetic object classified by earlier tests, and it generates later tests such as divisibility by p, residue class modulo p, finite unit-group readout in $\mathbb{F}_p^\times$, and order data in that unit group. The same atom therefore lives on both the source side and the method side of the tower.*

9314.2 Local Prime Sieve Surfaces

Definition 9314.5 (Prime-generated local sieve)**.** *For a prime p, the prime-generated local sieve packet contains:*

$$S_p^{\mathrm{div}}(n) := \mathbf{1}_{p|n},$$
$$n \longmapsto n \bmod p, \qquad \ell \longmapsto \ell \bmod p \quad (\ell \neq p),$$
$$\mathbb{F}_p^\times, \qquad a \longmapsto \mathrm{ord}_p(a) \quad (p \nmid a).$$

Each row is a finite classifier generated by the prime p.

Theorem 9314.6 (Fermat unit row)**.** *If p is prime and $p \nmid a$, then*

$$a^{p-1} \equiv 1 \pmod{p}.$$

Proof. The nonzero residue classes modulo p form the finite multiplicative group $\mathbb{F}_p^\times$ of order $p-1$. The order of the class of a divides the group order, giving the displayed congruence. □

Corollary 9314.7 (Fermat order sieve)**.** *For fixed a and n, the condition*

$$a^n \equiv 1 \pmod{p}, \qquad p \nmid a,$$

is the same as

$$\mathrm{ord}_p(a) \mid n.$$

It is therefore a finite unit-group sieve on primes p.

Proof. In the finite group $\mathbb{F}_p^\times$, an element satisfies $a^n = 1$ exactly when its order divides n. □

Principle 9314.8 (Local prime sieves preserve unit readout)**.** *The local sieve generated by p carries a unit row: characters have values in S^1, nonzero residues live in $\mathbb{F}_p^\times$, and Fermat order conditions express finite cyclic closure. Passing from divisibility to residue class or character readout changes the visible coordinate system, not the ledgered arithmetic source.*

Definition 9314.9 (Zero fiber and quotient coordinate)**.** *For a prime p, the residue classifier*

$$\pi_p : \mathbb{Z} \to \mathbb{Z}/p\mathbb{Z}$$

has zero fiber

$$\pi_p^{-1}(0) = \{b : p \mid b\}.$$

If $b = ap$, then b lies in this zero fiber and $a = b/p$ is the first quotient coordinate of the fiber. More generally, writing

$$b = p^v u, \qquad p \nmid u,$$

exposes the valuation coordinate $v_p(b) = v$ and the unit residue coordinate

$$u \bmod p \in \mathbb{F}_p^\times.$$

Principle 9314.10 (Divisibility is a fiber readout)**.** *The equation $b = ap$ is not only multiplication in $\mathbb{Z}$. In the local sieve generated by p, it says that b is classified into the zero fiber and that the quotient a is internal fiber data. Thus the same prime-generated sieve records both a visible residue coordinate and the higher valuation data that remains after entering the zero fiber.*

9314.3 Quadratic Local Unit Sieve

Definition 9314.11 (Gaussian norm local sieve)**.** *The Gaussian norm local sieve classifies rational primes by their behavior in $\mathbb{Z}[i]$:*

$$\pi_{\mathbb{Z}[i]}(p) = \begin{cases} \text{ramified}, & p = 2, \\ \text{split}, & p \equiv 1 \pmod 4, \\ \text{inert}, & p \equiv 3 \pmod 4. \end{cases}$$

For $p \equiv 1 \pmod 4$, the split row is represented by

$$p = a^2 + b^2 = N(a + bi) = (a + bi)(a - bi).$$

Theorem 9314.12 (Split Gaussian primes carry a unit-circle quotient)**.** *If a rational prime p has*

$$p = a^2 + b^2$$

with $\pi = a + bi$, then

$$u := \frac{\pi}{\overline{\pi}}$$

has complex modulus 1.

Proof. Since $N(\pi) = \pi\overline{\pi} = p$, one has

$$|u|^2 = \frac{\pi\overline{\pi}}{\overline{\pi}\pi} = 1.$$

□

Theorem 9314.13 (Modular two-square row detects the same split type)**.** *For an odd prime p, the congruence*

$$a^2 + b^2 \equiv 0 \pmod p$$

has a solution with $b \not\equiv 0 \pmod p$ if and only if -1 is a square in $\mathbb{F}_p$, equivalently if and only if

$$p \equiv 1 \pmod 4.$$

Proof. If $b \not\equiv 0 \pmod p$, then the displayed congruence is equivalent to

$$\left(\frac{a}{b}\right)^2 \equiv -1 \pmod p.$$

Thus it holds exactly when -1 has a square root in $\mathbb{F}_p$. For odd primes, Euler's criterion gives

$$(-1)^{(p-1)/2} \equiv 1 \pmod p$$

exactly when $p \equiv 1 \pmod 4$. □

Principle 9314.14 (Two-square data is a local unit sieve)**.** *The integer row $p = a^2 + b^2$ and the modular row $a^2 + b^2 \equiv 0 \pmod p$ are two projections of the same local split phenomenon. The first reads p through the Gaussian norm, while the second reads the existence of $i^2 = -1$ in $\mathbb{F}_p$. Both rows display the prime as carrying a quadratic unit-circle resource rather than as a bare arithmetic atom.*

9314.4 Sieve Objects and Refinement

Definition 9314.15 (Sieve object)**.** *A sieve object is a packet*

$$\mathcal{S} = (X, G, \pi, \mu, E, \Lambda)$$

where X is the source being classified, G is a finite type space, $\pi : X \to G$ is the classifier, μ is a probability measure on G, $E \subseteq G$ is the displayed event or pass region, and Λ is the ledger row recording the source, event, complement, probability mass, and residual data.

Definition 9314.16 (Sieve refinement)**.** *A sieve object*

$$\mathcal{S}_2 = (X, G_2, \pi_2, \mu_2, E_2, \Lambda_2)$$

refines

$$\mathcal{S}_1 = (X, G_1, \pi_1, \mu_1, E_1, \Lambda_1)$$

when there is a map $F : G_2 \to G_1$ such that

$$\pi_1 = F \circ \pi_2,$$

$$\mu_1(a) = \sum_{F(b)=a} \mu_2(b),$$

and

$$\Lambda_2 = \Lambda_1 + \mathrm{RefineLedger}_{2,1}\,.$$

Theorem 9314.17 (Sieve refinement preserves BEDC rows)**.** *Sieve refinement preserves the BEDC time, unit, and ledger rows.*

Proof. The time row is the refinement history $G_2 \to G_1$ together with $\pi_1 = F \circ \pi_2$. The unit row is preserved by probability pushforward:

$$\sum_{a \in G_1} \mu_1(a) = \sum_{a \in G_1} \sum_{F(b)=a} \mu_2(b) = \sum_{b \in G_2} \mu_2(b) = 1.$$

For an event E, the amplitude split

$$\psi = P_E \psi + P_{E^c} \psi$$

is orthogonal by Definition 9301.5. The ledger row is preserved by the displayed equation $\Lambda_2 = \Lambda_1 + \mathrm{RefineLedger}_{2,1}$, so refinement does not discard previous source or residual data. □

9314.5 Composition and Prime Sieve Factors

Definition 9314.18 (Composite and prime sieve factors)**.** *A finite abelian sieve object with type group G is decomposable when there are nontrivial finite abelian groups G_1, G_2 such that*

$$G \simeq G_1 \times G_2, \qquad \pi = (\pi_1, \pi_2), \qquad \mu = \mu_1 \otimes \mu_2.$$

It is a prime sieve factor when no such nontrivial decomposition is part of its displayed ledger.

Theorem 9314.19 (Finite abelian sieves decompose to prime-power factors)**.** *Every finite abelian sieve type group decomposes into finite prime-power type factors.*

Proof. By the finite abelian group structure theorem,

$$G \simeq \prod_j \mathbb{Z}/n_j\mathbb{Z}.$$

Writing each n_j as a product of prime powers and applying the Chinese remainder theorem gives

$$\mathbb{Z}/n_j\mathbb{Z} \simeq \prod_{\ell^a \| n_j} \mathbb{Z}/\ell^a\mathbb{Z}.$$

Combining these decompositions expresses G as a product of prime-power type factors. □

Principle 9314.20 (Composite sieves carry factor ledgers)**.** *A composite sieve is not a single opaque test. Its factorization into prime-power type factors is part of the ledger whenever factor-level detection is used. Thus a residual detected by a composite modulus, Frobenius product, or character product can be localized to displayed factor rows rather than hidden inside an unstructured global sieve.*

9314.6 Duality Energy and Ledger

Theorem 9314.21 (Finite Fourier change of sieve coordinates preserves energy)**.** *Let G be a finite abelian group with uniform probability measure and let $R \in L^2(G)$. With Fourier coefficients*

$$\widehat{R}(\chi) := \frac{1}{|G|} \sum_{a \in G} R(a)\overline{\chi(a)},$$

one has

$$\sum_{a \in G} |R(a)|^2 = |G| \sum_{\chi \in \widehat{G}} |\widehat{R}(\chi)|^2.$$

Proof. After normalization by $|G|^{-1/2}$, the character table is a unitary matrix. The displayed identity is Parseval's identity for this unitary change of coordinates. □

Theorem 9314.22 (Sieve projection splits residual energy)**.** *For a finite probability layer (G, μ) and event $E \subseteq G$, every residual $R \in L^2(G, \mu)$ satisfies*

$$R = P_E R + P_{E^c} R, \qquad P_E R \perp P_{E^c} R,$$

and hence

$$\|R\|^2 = \|P_E R\|^2 + \|P_{E^c} R\|^2.$$

Proof. The supports of $P_E R$ and $P_{E^c} R$ are disjoint, so their inner product is zero. The norm identity follows from orthogonal decomposition in $L^2(G, \mu)$. □

Corollary 9314.23 (Sieve transformations preserve or ledger energy)**.** *A finite Fourier change from type coordinates to sieve coordinates preserves total residual energy. A projection sieve splits the energy into the kept component and the complementary ledger component.*

Proof. Use Definition 9314.21 for a coordinate change and Definition 9314.22 for an event projection. The complementary projection is precisely the residual entry required by Definition 9302.3. □

9314.7 Recursive Prime-Generated Completeness

Definition 9314.24 (RecursivePrimeGeneratedSieveCompleteness)**.** *The row*

$$\mathsf{RecursivePrimeGeneratedSieveCompleteness}$$

asserts that finite prime-generated residue and character sieves detect every nonzero finite prime-power residual. In concrete form, for every nonzero finite residual

$$R = \sum_{j=1}^{N} c_j[q_j]$$

with distinct positive integers q_j, there are a prime p avoiding the support, an event $A \subseteq \mathbb{F}_p^\times$ or a character

$$\chi : \mathbb{F}_p^\times \to S^1,$$

and a nonzero readout of R through the classifier

$$\pi_p(q) = q \bmod p.$$

Theorem 9314.25 (Prime-generated local sieves detect finite residuals)**.** *Every nonzero finite residual*

$$R = \sum_{j=1}^{N} c_j[q_j]$$

with distinct positive integers q_j has a detecting local sieve generated by some prime p.

Proof. Choose a prime p that divides none of the q_j and none of the nonzero differences $q_i - q_j$. Then the residues

$$q_j \bmod p$$

are nonzero and pairwise distinct in $\mathbb{F}_p^\times$. Pick j with $c_j \neq 0$ and let

$$A = \{q_j \bmod p\}.$$

The event readout on A is exactly c_j, hence nonzero. Since $\mathbb{F}_p^\times$ is a finite abelian group, the character readouts also form a complete Fourier basis; equivalently, applying Definition 9315.6 to this finite layer gives a character with nonzero readout whenever a character witness is required. □

Corollary 9314.26 (Recursive generated sieves supply finite residual detection)**.** *The prime-generated local sieve family satisfies*

$$\mathsf{RecursivePrimeGeneratedSieveCompleteness}$$

for finite residuals.

Proof. This is the content of Definition 9314.25, with event and character readouts supplied by the same prime-generated finite unit group. □

Principle 9314.27 (Recursive generated sieves are BEDC-legal)**.** *Recursive use of prime-generated sieves preserves the three BEDC rows. Each step appends a prime-generated classifier to the time history, reads through a finite unit or probability amplitude surface, and records the excluded residue, valuation, or residual component in a ledger. Thus recursive filtering changes visibility but not the accounted information or residual energy.*

9314.8 Tower Interface

Definition 9314.28 (PrimeSieveTowerDuality)**.** *The row*

PrimeSieveTowerDuality

consists of the Euclidean prime-generated tower, the local prime sieve packets, the zero-fiber and valuation rows, the Gaussian local unit sieve, the sieve-object refinement category, the prime-power factor ledger, the finite Fourier/event energy laws, and recursive prime-generated finite residual detection. It asserts that prime-generated sieve transformations preserve the time source, unit or energy readout, and ledger accountability of the prime classifier tower.

Theorem 9314.29 (Prime sieve tower duality supplies duality completeness data)**.** *Assume* PrimeSieveTowerDuality *and that every zeta-facing radial residual enters the generated profinite prime type tower. Then the finite type-sieve dual pairs required by*

PrimeSieveDualityCompleteness

are legal BEDC sieve objects with preserved time, unit, and ledger rows.

Proof. The generated tower supplies the finite prime type spaces and their refinement maps. The local prime sieve packets supply legal event, residue, zero-fiber, valuation, order, Gaussian norm, and character readouts. Sieve refinement preserves the time, unit, and ledger rows by Definition 9314.17. The Fourier and event energy laws show that changing to the sieve-frequency side does not erase residual energy, while projection sends complementary energy to the ledger. Finite residual detection is supplied by Definition 9314.26. These are exactly the legal data needed for the finite dual pairs of Definition 9315.12. □

Principle 9314.30 (Prime sieve tower audit boundary)**.** *The tower duality packet is a structural certificate for sieve methods, not an analytic source theorem for zeta zeros. It says that once a radial residual is represented in the prime-generated type tower, no combination, factorization, Fourier change, or event projection of sieves may erase it without a ledger row. The analytic obligation is therefore isolated to the bridge that places every off-critical zero-side residual into this prime-generated tower.*

Chapter 9315

Prime Sieve Duality Completeness

chapter 9300 supplies finite prime-register quotients and profinite separation, while chapter 9302 supplies finite probability tests on those quotients. The present chapter records the duality principle that makes these two surfaces the same finite detection mechanism: prime types are the position coordinates of a finite layer, and sieve tests are its readout coordinates.

9315.1 Type and Sieve Coordinates

Definition 9315.1 (Prime type and sieve dual pair)**.** *A prime type and sieve dual pair is a finite layer*

$$(G_m, \mu_m, \pi_m, \mathcal{S}_m)$$

where G_m is a finite prime type space, μ_m is a full-support probability measure on G_m, π_m sends prime powers to their displayed type, and $\mathcal{S}_m$ is a finite-dimensional space of legal sieve readouts

$$\varphi : G_m \to \mathbb{C}.$$

When G_m is a finite abelian group, the canonical frequency readouts are the characters

$$\widehat{G}_m := \mathrm{Hom}(G_m, S^1).$$

The position-frequency pairing is

$$\langle a, \chi \rangle := \chi(a), \qquad a \in G_m, \quad \chi \in \widehat{G}_m.$$

Principle 9315.2 (Prime types and sieve methods are dual coordinates)**.** *At a finite classifier layer, the type atoms $\mathbf{1}_a$ and the sieve readouts φ are two coordinate systems for the same finite space of observations. The type side records where the prime register lands. The sieve side records how the layer is read. A residual hidden from all legal sieve readouts is therefore hidden from the finite type space itself; in a complete dual pair this is possible only for the zero residual.*

Definition 9315.3 (Sieve-method type space)**.** *A sieve-method type space at layer m is a finite classifier*

$$H_m$$

whose points classify legal sieve methods by their construction source: congruence, character, Frobenius, splitting, local norm, order, or finite Satake-type readout. A second-order sieve is a legal function

$$\Phi : H_m \to \mathbb{C}.$$

The pair $(H_m, \widehat{H}_m)$ is required to obey the same finite duality and ledger rules as $(G_m, \widehat{G}_m)$ whenever it is used as proof data.

Principle 9315.4 (Recursive duality is ledger-bounded)**.** *Sieve methods may themselves be classified and filtered, but the process is not an unbounded regress. Each recursive duality level must expose a finite or profinite classifier, its legal readout space, its normalization convention, and its ledger row. Thus a method of selecting sieve methods is another licensed finite observation surface, not an informal meta-choice.*

9315.2 Finite Dual Detection

Definition 9315.5 (Fourier-complete sieve layer)**.** *A finite abelian prime type layer G_m is Fourier-complete when its legal sieve readouts contain all characters*

$$\chi \in \widehat{G}_m$$

with the normalization

$$\widehat{R}(\chi) := \sum_{a \in G_m} R(a)\overline{\chi(a)}\mu_m(a)$$

for residuals $R \in L^2(G_m, \mu_m)$.

Theorem 9315.6 (Fourier-complete finite layers detect nonzero residuals)**.** *Let G_m be a Fourier-complete finite abelian prime type layer with uniform probability measure. If*

$$R \in L^2(G_m, \mu_m), \qquad R \neq 0,$$

then some legal character readout detects R:

$$\widehat{R}(\chi) \neq 0$$

for some $\chi \in \widehat{G}_m$.

Proof. For a finite abelian group with uniform measure, the characters form an orthogonal basis of $L^2(G_m, \mu_m)$. If every coefficient $\widehat{R}(\chi)$ vanished, the Fourier expansion of R in that basis would have all coefficients equal to zero, hence $R = 0$. This contradicts the hypothesis. □

Theorem 9315.7 (Event-complete finite layers detect nonzero residuals)**.** *Let (G_m, μ_m) be a finite probability layer with full support. If*

$$R \in L^2(G_m, \mu_m), \qquad R \neq 0,$$

then some event $E \subseteq G_m$ has nonzero event readout:

$$\sum_{a \in E} R(a)\mu_m(a) \neq 0.$$

Proof. If every event readout vanished, then taking $E = \{a\}$ would give

$$R(a)\mu_m(a) = 0$$

for every $a \in G_m$. Full support gives $\mu_m(a) > 0$, so $R(a) = 0$ for every a, contradicting $R \neq 0$. □

Corollary 9315.8 (Finite type-sieve duality detects residuals)**.** *In a finite complete type-sieve dual pair, every nonzero layer residual is detected by either an event readout or a character readout. If the layer is Fourier-complete, the character readout is enough.*

Proof. Apply Definition 9315.7 to the event side. In the abelian Fourier-complete case, apply Definition 9315.6 to the character side. □

9315.3 Dual Tower Direction

Definition 9315.9 (Dual classifier tower)**.** *A dual classifier tower consists of a profinite type system*

$$G_\infty = \varprojlim_m G_m$$

together with a directed sieve-readout system

$$\mathcal{S}_0 \to \mathcal{S}_1 \to \mathcal{S}_2 \to \cdots$$

such that every readout in $\mathcal{S}_m$ pulls back to a legal readout on G_{m+1}. In the finite abelian case, the direction reversal is

$$G_0 \leftarrow G_1 \leftarrow G_2 \leftarrow \cdots, \qquad \widehat{G}_0 \to \widehat{G}_1 \to \widehat{G}_2 \to \cdots.$$

Principle 9315.10 (Type refinement is inverse, sieve extension is direct)**.** *Refining prime types sends a finite type space to a finer quotient above it. Extending sieve methods adds new legal readouts that factor through the finer type space. Thus the type surface is naturally inverse, while the sieve surface is naturally direct. Completeness of the RH route requires these two movements to be compatible: no nonzero residual may disappear under every finite type projection and every legal sieve extension.*

Theorem 9315.11 (Profinite type residuals descend to dual finite layers)**.** *Let a dual classifier tower have Hausdorff profinite type system $G_\infty = \varprojlim_m G_m$. If a profinite residual is nonzero in G_∞, then some finite layer has a nonzero residual projection detected by the type-sieve dual pair at that layer.*

Proof. By Definition 9300.8, the residual has a nonzero projection in some finite quotient G_m. The finite dual pair at that layer detects the projection by Definition 9315.8. Hence the residual has a finite event or character readout. □

9315.4 RH Interface

Definition 9315.12 (PrimeSieveDualityCompleteness)**.** *The row*

PrimeSieveDualityCompleteness

asserts that every zeta-facing radial residual enters a Hausdorff profinite type system whose finite layers are complete type-sieve dual pairs. Equivalently, any nonzero radial residual has a finite layer m and a legal readout $\varphi \in \mathcal{S}_m$ such that

$$\langle R_m, \varphi \rangle_m \neq 0.$$

Theorem 9315.13 (Prime sieve duality supplies probability completeness)**.** *Assume* PrimeSieveDualityCompletenes
Then every nonzero radial residual of a zeta-facing PFZ packet is visible on a finite probability-filtered prime curve in the sense required by

LayeredProbabilitySieveCompleteness.

Proof. By Definition 9315.12, the residual has a finite layer and a legal readout with nonzero pairing. Event readouts give mean-zero probability tests after subtracting their layer mean. Character readouts are legal probability tests on the same finite classifier. The corresponding curve is the probability-filtered Chebyshev curve of Definition 9302.5. Thus the residual is visible in the sense of Definition 9302.8. □

Theorem 9315.14 (Duality-complete sieve excludes hidden radial residuals)**.** *Assume* PrimeSieveDualityCompleten *every detected residual readout is recorded in its sieve ledger, and legal closed BEDC/PFZ zero packets cannot carry unledgered residual coordinates. Then no nonzero radial residual can be hidden in a legal closed zero packet.*

Proof. A nonzero radial residual has a finite event or character readout by Definition 9315.12. The readout is a finite residual row. If the row is recorded, the packet carries an append ledger and is not closed. If the row is not recorded, the sieve ledger policy is violated. Both alternatives contradict hidden legal closure. □

Corollary 9315.15 (Duality completeness is the finite witness route)**.** *The row* PrimeSieveDualityCompleteness *supplies the finite witness component of the probability sieve tower route: a radial residual cannot survive solely as a limit phenomenon outside all finite type and sieve coordinates.*

Proof. The profinite part follows from Definition 9315.11. The finite detection part follows from Definition 9315.8. Together they produce the finite witness needed by Definition 9304.10. □

Principle 9315.16 (Duality audit boundary)**.** *The type-sieve duality packet does not prove the analytic source of a radial residual. That source remains the explicit-formula and fixed-window obligation. The packet proves the classifier side: once a nonzero residual is present in the prime type tower, finite event and frequency readouts cannot all vanish. Hence the remaining burden is to connect every off-critical zero to this prime-side residual tower.*

Chapter 9316

Prime Distribution Curve Projection

chapter 9300 records the finite and profinite classifier surfaces that detect prime-register residuals. The distribution-curve projection is the analytic surface read from the same tower: each classifier does not erase primes, but projects the prime register into a unit, orthogonal, splitting, or Frobenius readout, and the explicit formula turns that readout into a normalized prime-distribution curve. The RH-facing obstruction is then visible as a nonunit radial mode on at least one such curve.

9316.1 Classifier Projections

Definition 9316.1 (Finite prime projection classifier)**.** *A finite prime projection classifier is a pair*

$$\mathcal{C}_m = (G_m, \pi_m)$$

where G_m is a finite group or finite abelian quotient and

$$\pi_m(p) \in G_m$$

is the displayed type of a prime p at level m. Typical reads include residue classes, quadratic characters, Dirichlet or Hecke character values, Frobenius conjugacy classes, and finite Satake-parameter approximations. The classifier is a projection of prime-register data, not a deletion of primes from the ledger.

Definition 9316.2 (Recursive prime projection tower)**.** *A recursive prime projection tower is a refinement chain*

$$\mathcal{C}_0 \prec \mathcal{C}_1 \prec \mathcal{C}_2 \prec \cdots$$

whose finite readouts refine the previous prime-register surface. The passage from one level to the next is licensed by a displayed residual, splitting distinction, character row, or Frobenius row in the sense of Definition 9300.3. The tower is cofinal when its finite quotients form the Hausdorff profinite system of Definition 9300.7.

Definition 9316.3 (Filtered Chebyshev curve)**.** *Let $\mathcal{C}_m = (G_m, \pi_m)$ be a finite prime projection classifier and let*

$$\chi : G_m \to S^1$$

be a character or a displayed class-function readout. The filtered Chebyshev curve is

$$\psi_{m,\chi}(x) := \sum_{p^k \le x} \chi(\pi_m(p^k)) \log p.$$

Its critical normalization is

$$\Psi_{m,\chi}(u) := e^{-u/2}\left(\psi_{m,\chi}(e^u) - \delta_{\chi,1}e^u\right), \qquad x = e^u.$$

Principle 9316.4 (Prime filtering is projection)**.** *The family $\Psi_{m,\chi}$ is the continuous projection of the recursive prime classifier tower. At the discrete level the tower reads prime types such as split, inert, ramified, character value, Frobenius class, or local parameter. At the continuous level the same reads become weighted prime-distribution curves. Thus the phrase "sieving primes" denotes a sequence of classifier projections, not a loss of arithmetic mass.*

9316.2 Unit and Radial Modes

Definition 9316.5 (Prime-distribution spectral mode)**.** *A spectral mode of a normalized prime-distribution curve is a term of the form*

$$c\, e^{ru} e^{i\gamma u}.$$

It is a unit phase mode when $r = 0$ and a radial mode when $r \neq 0$.

Theorem 9316.6 (Off-critical zero produces a radial distribution mode)**.** *Assume the explicit formula for a filtered curve $\Psi_{m,\chi}$. If a zero contributing to that filtered explicit formula has*

$$\rho_0 = \frac{1}{2} + r + i\gamma, \qquad r \neq 0,$$

then the normalized curve contains the radial mode

$$c_{\rho_0}\, e^{ru} e^{i\gamma u}$$

for the corresponding nonzero explicit-formula coefficient c_{ρ_0}.

Proof. The zero contribution before normalization has the form

$$c_{\rho_0} e^{\rho_0 u}.$$

Multiplying by $e^{-u/2}$ gives

$$c_{\rho_0} e^{(\rho_0 - \frac{1}{2})u} = c_{\rho_0} e^{ru} e^{i\gamma u}.$$

Since $r \neq 0$, the mode has a positive-real radial factor rather than a unit-circle phase alone. □

Corollary 9316.7 (Fixed-half readout is unit-mode readout)**.** *For a completed zeta zero contributing to a normalized prime-distribution curve, fixed-half readout is equivalent to the absence of radial exponential growth in that zero's spectral mode.*

Proof. If $\rho = 1/2 + i\gamma$, the normalized mode is $e^{i\gamma u}$, a unit phase mode. Conversely, a mode attached to $\rho = 1/2 + r + i\gamma$ has no radial factor exactly when $r = 0$. □

9316.3 Completeness

Definition 9316.8 (PrimeDistributionCurveCompleteness)**.** *The row*

PrimeDistributionCurveCompleteness

asserts that every nonzero radial residual of a zeta-facing PFZ packet has a visible filtered prime-distribution curve. Equivalently, if

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta}$$

has $\ell \neq 0$, then some level m and some readout χ of the recursive prime projection tower produce a normalized curve $\Psi_{m,\chi}$ containing a radial mode

$$c\, e^{ru} e^{i\gamma u}, \qquad r \neq 0.$$

Theorem 9316.9 (Finite residual detection supplies a filtered curve)**.** *Every finite prime residual detected by a finite Dirichlet classifier has a corresponding filtered prime-distribution curve with nonzero classifier readout.*

Proof. Let

$$R = \sum_j c_j [q_j]$$

be the finite residual and let χ be the finite Dirichlet classifier with $\chi(R) \neq 0$ supplied by Definition 9300.21. Use the finite classifier $\mathcal{C}_m$ carrying the residue classes modulo the chosen modulus and define $\psi_{m,\chi}$ as in Definition 9316.3. The finite support of R contributes

$$\sum_j c_j \chi(q_j)$$

to that filtered readout, which is nonzero by the choice of χ. □

Theorem 9316.10 (Profinite residual detection supplies a finite filtered curve)**.** *In a cofinal prime projection tower, every non-identity profinite residual has a finite filtered prime-distribution curve that detects it.*

Proof. By Definition 9300.8, a non-identity residual has non-identity image in a finite quotient. By Definition 9300.5, a finite character separates that image from the identity. The corresponding filtered Chebyshev curve of Definition 9316.3 is the continuous prime-distribution readout of the same finite classifier. □

Principle 9316.11 (Distribution curves are the macroscopic PFZ readout)**.** *In a prime-fiber zoom tower, a finite address step appends prime-register data and contributes orthogonal log-energy as in Definition 9296.6. The identity*

$$\log n = \sum_p v_p(n) \log p$$

is the bridge from discrete prime-register coordinates to continuous exponential reads. The curves $\Psi_{m,\chi}(u)$ are therefore the macroscopic continuous projections of the same append-only tower.

9316.4 Conditional Fixed-Half Consequence

Theorem 9316.12 (Distribution-curve completeness gives radial residual visibility)**.** *Assume* PrimeDistributionCurveCompleteness*. If a zeta-facing PFZ packet has $\ell \neq 0$, then some filtered prime-distribution curve contains a radial mode, and the associated finite or profinite classifier row detects a nonunit residual.*

Proof. By Definition 9316.8, the nonzero radial coordinate is visible on some $\Psi_{m,\chi}$ as a mode

$$c\, e^{ru} e^{i\gamma u}, \qquad r \neq 0.$$

The curve is attached to a finite classifier level or to a finite quotient of the cofinal profinite classifier tower. Finite detection is given by Definition 9316.9; profinite detection is given by Definition 9316.10. In both cases the radial mode is a nonunit residual read by a displayed classifier. □

Corollary 9316.13 (Prime distribution curve conditional fixed-half readout)**.** *Assume zeta-facing PFZ zero packets are legal closure objects,* PrimeDistributionCurveCompleteness *holds, and finite radial modes cannot be hidden as legal closure data. Then every admitted nontrivial zero has fixed-half readout.*

Proof. Let ρ be an admitted nontrivial zero and write

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta}.$$

If $\ell \neq 0$, then Definition 9316.12 produces a filtered prime-distribution curve with a nonunit radial mode. By Definition 9320.18, a classifier-visible nonunit residual cannot be hidden in a legal PFZ closure object. Thus $\ell = 0$. By Definition 9266.2, this is equivalent to $\mathrm{Re}(\rho) = 1/2$. □

Principle 9316.14 (Final distribution-curve target)**.** *The prime-classifier route ends at the family of normalized curves*

$$\{\Psi_{m,\chi}(u)\}_{m,\chi}.$$

The RH-facing condition is that these curves carry only unit phase modes after critical normalization. A radial mode

$$e^{ru} e^{i\gamma u}, \qquad r \neq 0,$$

is the distribution-curve form of an unclosed positive-real scale row. The remaining completeness target is to show that any hidden radial scale in the zero packet appears on at least one filtered prime-distribution curve.

Chapter 9317

Explicit Formula Scale Residual Bridge

chapter 9300 reduces the scale-to-classifier problem to an explicit-formula bridge: a nonzero radial zero-packet coordinate must leave a finite prime-side residual. The present chapter records that bridge as a test-function obligation. It separates the formal part, where finite prime residuals are detected by Dirichlet characters, from the analytic part, where a compactly supported test row must isolate an off-critical zero orbit while accounting for archimedean, trivial-zero, and pole correction rows.

9317.1 Compact Test Rows

Definition 9317.1 (Compact explicit-formula test row)**.** *An admissible compact explicit-formula test row is a function*

$$g \in C_c^\infty(-A, A)$$

for some $A > 0$, together with the Laplace–Fourier readout

$$\widehat{g}(s) := \int_{-A}^{A} g(x) e^{(s-\frac{1}{2})x}\, dx.$$

The row is admissible when $\widehat{g}$ is entire and has the vertical decay required by the zeta explicit formula. Its compact support makes the prime-power side finite:

$$\mathrm{PrimeSide}(g) = \sum_{p^k \le e^A} c_{p,k}(g).$$

Definition 9317.2 (Abstract explicit-formula ledger)**.** *For an admissible compact test row g, the abstract explicit-formula ledger is the identity*

$$\mathcal{Z}(g) = \mathcal{P}(g) + \mathcal{A}(g),$$

where

$$\mathcal{Z}(g) = \sum_{\rho} \widehat{g}(\rho)$$

is the completed nontrivial-zero ledger,

$$\mathcal{P}(g) = \sum_{p,k} c_{p,k}(g)$$

is the prime-power ledger, and $\mathcal{A}(g)$ contains the archimedean, trivial-zero, and pole correction rows. For compact support the sum defining $\mathcal{P}(g)$ is the finite sum over $p^k \le e^A$.

Lemma 9317.3 (Finite exponential moment interpolation)**.** *Let $\lambda_1, \dots, \lambda_N$ be pairwise distinct complex numbers, and let $a_1, \dots, a_N \in \mathsf{Complex}^{\uparrow}$. For every $A > 0$ there exists*

$$g \in C_c^\infty(-A, A)$$

such that

$$\int_{-A}^{A} g(x) e^{\lambda_j x}\, dx = a_j \qquad (1 \le j \le N).$$

Proof. Consider the linear map

$$T : C_c^\infty(-A, A) \to \mathsf{Complex}^{\uparrow N}$$

given by

$$T(g) = \left(\int g(x) e^{\lambda_1 x}\, dx, \dots, \int g(x) e^{\lambda_N x}\, dx \right).$$

If T were not onto, some nonzero vector $(c_1, \dots, c_N)$ would annihilate its image. Then

$$\int g(x) \left(\sum_{j=1}^{N} c_j e^{\lambda_j x} \right) dx = 0$$

for all $g \in C_c^\infty(-A, A)$. Test-function separation gives

$$\sum_{j=1}^{N} c_j e^{\lambda_j x} = 0$$

on $(-A, A)$. Distinct exponentials are linearly independent on an interval, so every c_j is zero, a contradiction. Thus T is onto. □

Corollary 9317.4 (Finite zero readout interpolation)**.** *Let $F = \{\rho_1, \dots, \rho_N\}$ be a finite set of distinct zero positions and let $a_1, \dots, a_N \in \mathsf{Complex}^{\uparrow}$. For every $A > 0$ there is $g \in C_c^\infty(-A, A)$ such that*

$$\widehat{g}(\rho_j) = a_j \qquad (1 \le j \le N).$$

Proof. Apply Definition 9317.3 to

$$\lambda_j = \rho_j - \frac{1}{2}.$$

□

9317.2 Zero-Orbit Isolation

Definition 9317.5 (Off-critical zero orbit)**.** *For an off-critical zero*

$$\rho_0 = \frac{1}{2} + r + i\gamma, \qquad r \ne 0,$$

the symmetry orbit is

$$\mathcal{O}(\rho_0) = \{\rho_0, \overline{\rho_0}, 1 - \rho_0, 1 - \overline{\rho_0}\},$$

read with the multiplicity convention of the completed zeta zero ledger.

Lemma 9317.6 (Finite orbit isolation)**.** *Let F be a finite zero-position set containing $\mathcal{O}(\rho_0)$. For every $A > 0$ there is $g \in C_c^\infty(-A, A)$ such that*

$$\widehat{g}(\rho) = 1 \qquad (\rho \in \mathcal{O}(\rho_0))$$

and

$$\widehat{g}(\rho) = 0 \qquad (\rho \in F \setminus \mathcal{O}(\rho_0)).$$

Proof. Use Definition 9317.4 with the displayed values on the finite set F. □

Definition 9317.7 (ArchNullZeroIsolation)**.** *The obligation*

$$\mathsf{ArchNullZeroIsolation}$$

asserts that for every off-critical zero orbit $\mathcal{O}(\rho_0)$ there exists an admissible compact test row g such that

$$\mathcal{A}(g) = 0$$

and

$$\mathcal{Z}(g) \neq 0.$$

Equivalently, the test row isolates a nonzero zero-side contribution while the archimedean, trivial-zero, and pole correction rows are null.

Principle 9317.8 (Analytic content of arch-null isolation)**.** *The finite interpolation lemmas only control finitely many zero readouts. The analytic content of* ArchNullZeroIsolation *is the stronger claim that the same test row can be chosen with vertical tail control and with $\mathcal{A}(g) = 0$. This is a function-space separation problem: finite zero-orbit evaluation is a point-evaluation functional, while $\mathcal{A}$ is the fixed correction functional from the explicit formula. The obligation asserts that these rows do not collapse into a single one-dimensional correction direction on the admissible compact test space.*

9317.3 Finite Prime Residual

Theorem 9317.9 (ExplicitFormulaScaleResidual from arch-null isolation)**.** *Assume the abstract explicit-formula ledger of Definition 9317.2 and* ArchNullZeroIsolation*. If ρ_0 is off the critical line, then there is a nonzero finite explicit-formula prime residual*

$$R_S(g) = \sum_{q \in S} c_q(g)[q].$$

Proof. By ArchNullZeroIsolation, choose an admissible compact test row g with

$$\mathcal{A}(g) = 0, \qquad \mathcal{Z}(g) \neq 0.$$

The explicit-formula ledger gives

$$\mathcal{Z}(g) = \mathcal{P}(g) + \mathcal{A}(g),$$

hence

$$\mathcal{P}(g) = \mathcal{Z}(g) \neq 0.$$

Since g is supported in $[-A, A]$, the prime side is the finite prime-power sum over $p^k \leq e^A$. Taking S to be that finite support gives the displayed nonzero finite prime residual. □

Theorem 9317.10 (Off-line zero produces a finite prime-classifier defect)**.** *Assume the hypotheses of Definition 9317.9 and the finite residual separation theorem Definition 9300.21. If ρ_0 is an off-critical zero, then there are a finite prime residual $R_S(g)$ and a finite Dirichlet classifier χ such that*

$$\chi(R_S(g)) \neq 0.$$

Proof. Definition 9317.9 produces a nonzero finite prime residual. Applying Definition 9300.21 to that residual gives the displayed finite classifier. □

Corollary 9317.11 (Explicit formula bridge supplies the PFZ classifier input)**.** *Under* ArchNullZeroIsolation *and the explicit-formula ledger, an off-critical zeta zero supplies the finite prime-classifier input needed by Definition 9300.26.*

Proof. The preceding theorem gives a finite prime residual with nonzero Dirichlet classifier readout. This is exactly the finite prime-classifier footprint required by Definition 9300.26. □

9317.4 Signed Prime Energy

Definition 9317.12 (Weil mirror pairing ledger)**.** *For an admissible compact test row g, the zero-side mirror pairing is the quadratic readout*

$$\mathcal{W}_Z(g) := \sum_{\rho} \widehat{g}(\rho)\,\overline{\widehat{g}(1-\overline{\rho})}.$$

The paired explicit-formula ledger writes

$$\mathcal{W}_Z(g) = \mathcal{W}_P(g) + \mathcal{W}_A(g),$$

where $\mathcal{W}_P(g)$ is the prime-side quadratic residual and $\mathcal{W}_A(g)$ is the archimedean, trivial-zero, and pole correction row. This is the signed-energy form of Definition 9317.2.

Definition 9317.13 (WeilNegativeIsolator)**.** *The obligation*

WeilNegativeIsolator

asserts that every off-critical mirror pair of Definition 9317.5 admits an admissible compact test row g with

$$\mathcal{W}_Z(g) < 0.$$

It is the compact-test version of the diagonal negative probe mechanism of Definition 9265.14.

Definition 9317.14 (ArchNullWeilIsolator)**.** *The obligation*

ArchNullWeilIsolator

asserts that the test row in WeilNegativeIsolator *can be chosen with*

$$\mathcal{W}_A(g) = 0.$$

Thus it supplies an admissible compact test row satisfying

$$\mathcal{W}_Z(g) < 0, \qquad \mathcal{W}_A(g) = 0.$$

Theorem 9317.15 (Arch-null negative isolation gives prime-side negative energy)**.** *Assume the paired explicit-formula ledger of Definition 9317.12 and* ArchNullWeilIsolator*. If an off-critical mirror pair exists, then the prime-side quadratic residual has a finite negative readout:*

$$\mathcal{W}_P(g) < 0$$

for some admissible compact test row g.

Proof. By ArchNullWeilIsolator choose g such that

$$\mathcal{W}_Z(g) < 0, \qquad \mathcal{W}_A(g) = 0.$$

The paired explicit-formula ledger gives

$$\mathcal{W}_Z(g) = \mathcal{W}_P(g) + \mathcal{W}_A(g).$$

Hence

$$\mathcal{W}_P(g) = \mathcal{W}_Z(g) < 0.$$

Since g has compact support, this prime-side quadratic residual is supported on finitely many prime powers. □

Definition 9317.16 (Finite prime negative residual)**.** *A finite prime negative residual is a finite prime-power support S together with a quadratic prime-side readout*

$$\mathcal{W}_{P,S}(g) = \sum_{q \in S} b_q(g)[q]$$

such that

$$\mathcal{W}_{P,S}(g) < 0.$$

It is a signed residual rather than merely a nonzero linear residual: the sign records a negative direction for the explicit-formula energy.

Corollary 9317.17 (Off-line zero gives finite prime negative residual)**.** *Under the hypotheses of Definition 9317.15, an off-critical zero gives a finite prime negative residual.*

Proof. The preceding theorem gives $\mathcal{W}_P(g) < 0$. Compact support of g makes the prime side a finite prime-power sum, so the finite support of that sum is the required finite prime negative residual. □

Theorem 9317.18 (Prime negative residual gives classifier obstruction)**.** *Every finite prime negative residual supplies a nonzero finite prime-classifier residual.*

Proof. A negative finite quadratic readout is nonzero as a finite residual. Applying Definition 9300.21 to its finite prime-power support gives a finite Dirichlet classifier with nonzero readout. The sign is additional information: it records that the residual is a negative energy direction, not merely a nonzero prime-side row. □

Principle 9317.19 (Signed residuals cannot be hidden by PFZ smoothing)**.** *A finite prime negative residual is a finite obstruction in the sense of Definition 9297.8. If it is ledgered, it remains visible as scale or energy data and cannot be a gap-free unit-phase closure. If it is unledgered, the PFZ NameCert surface of Definition 9298.8 is incomplete. The scale-obstruction bridge of chapter 9297 therefore treats such a residual as a persistent obstruction rather than as a smooth zoom artefact.*

Corollary 9317.20 (Signed explicit-formula bridge strengthens scale faithfulness)**.** *Under* ArchNullWeilIsolator *and the paired explicit-formula ledger, an off-critical zero supplies the PFZ classifier input of Definition 9317.11 with a signed negative-energy witness.*

Proof. Definition 9317.17 gives the finite signed residual, and Definition 9317.18 gives the finite classifier readout. The final sign information is the negative-energy witness consumed by Definition 9317.19. □

Chapter 9318

Fixed Window Dominance Certificate

chapter 9316 records the macroscopic statement that an off-critical zero contributes a radial mode to a normalized prime-distribution curve. The present chapter turns that statement into a local certificate shape. The certificate does not assert the Riemann hypothesis. It names the finite spectral window, the differential classifier, the bounded observation interval, and the tail inequality that would make the radial mode visible as a BEDC-auditable row.

9318.1 Finite Spectral Windows

Definition 9318.1 (Finite spectral window)**.** *A finite spectral window for a normalized prime-distribution curve is a finite set*

$$\Lambda = \{\lambda_1, \dots, \lambda_N\} \subset \mathbb{C}$$

of pairwise distinct exponents, together with a truncated spectral curve

$$\Psi_\Lambda(u) := \sum_{\lambda \in \Lambda} c_\lambda e^{\lambda u}.$$

For a zeta zero ρ, the corresponding exponent is

$$\lambda = \rho - \frac{1}{2}.$$

Theorem 9318.2 (Finite exponential modes admit exact classifiers)**.** *Let $\Lambda = \{\lambda_1, \dots, \lambda_N\}$ be a finite spectral window and let $a_1, \dots, a_N \in \mathbb{C}$. There is a polynomial $P \in \mathbb{C}[z]$ such that*

$$P(\lambda_j) = a_j \qquad (1 \le j \le N).$$

Consequently, for

$$D = \frac{d}{du},$$

one has

$$P(D)e^{\lambda_j u} = a_j e^{\lambda_j u}.$$

Proof. Use the Lagrange polynomial

$$P(z) := \sum_{j=1}^{N} a_j \prod_{k \ne j} \frac{z - \lambda_k}{\lambda_j - \lambda_k}.$$

Then $P(\lambda_j) = a_j$ for every j. Since

$$De^{\lambda_j u} = \lambda_j e^{\lambda_j u},$$

polynomial functional calculus gives the displayed identity for $P(D)$. □

Definition 9318.3 (Off-critical mirror exponent pair)**.** *An off-critical mirror exponent pair is a pair*

$$\lambda_+ = r + i\gamma, \qquad \lambda_- = -r + i\gamma, \qquad r \neq 0,$$

arising from the mirror zero pair

$$\rho_+ = \frac{1}{2} + r + i\gamma, \qquad \rho_- = \frac{1}{2} - r + i\gamma.$$

Definition 9318.4 (Mirror-odd differential classifier)**.** *Let Λ contain an off-critical mirror exponent pair λ_+, λ_-. A mirror-odd differential classifier for that pair in Λ is a polynomial $P_\pm \in \mathbb{C}[z]$ satisfying*

$$P_\pm(\lambda_+) = 1, \qquad P_\pm(\lambda_-) = -1,$$

and

$$P_\pm(\lambda) = 0 \qquad (\lambda \in \Lambda \setminus \{\lambda_+, \lambda_-\}).$$

Theorem 9318.5 (Mirror-odd classifier extracts the radial pair)**.** *Let*

$$\Psi_\Lambda(u) = c_+ e^{\lambda_+ u} + c_- e^{\lambda_- u} + \sum_{\lambda \in \Lambda^\circ} c_\lambda e^{\lambda u},$$

where

$$\Lambda^\circ = \Lambda \setminus \{\lambda_+, \lambda_-\}.$$

If $P_\pm$ is the mirror-odd differential classifier of Definition 9318.4, then

$$P_\pm(D)\Psi_\Lambda(u) = c_+ e^{(r+i\gamma)u} - c_- e^{(-r+i\gamma)u}.$$

Proof. Apply Definition 9318.2 to each exponential term. The classifier has values 1 and -1 on the mirror pair and value 0 on every other exponent in the finite window. □

Lemma 9318.6 (A radial mirror pair is not a unit-phase packet)**.** *Let $r \neq 0$. If*

$$F(u) = c_+ e^{(r+i\gamma)u} - c_- e^{(-r+i\gamma)u}$$

with $(c_+, c_-) \neq (0, 0)$, then F is not a finite sum of unit-phase modes

$$\sum_{j=1}^{M} b_j e^{i\eta_j u}.$$

Proof. Distinct exponentials $e^{\lambda u}$ are linearly independent on every nonempty interval. The exponents $r + i\gamma$ and $-r + i\gamma$ have nonzero real parts, while every unit-phase exponent $i\eta_j$ has real part 0. Equality with a finite unit-phase sum would force the coefficients of the nonunit exponents to vanish, contrary to the hypothesis. □

9318.2 Dominance Certificates

Definition 9318.7 (Fixed window dominance certificate)**.** *Let*

$$\Psi(u) = \Psi_\Lambda(u) + E_\Lambda(u)$$

be the split of a normalized prime-distribution curve into a finite spectral window and its complement. A fixed window dominance certificate for an off-critical mirror exponent pair is a tuple

$$\mathsf{DomCert}(\Lambda, P_\pm, I, \delta)$$

such that $I \subset \mathbb{R}$ is a compact interval, $\delta > 0$, $P_\pm$ is the mirror-odd differential classifier for the pair, and

$$\inf_{u\in I} |P_\pm(D)\Psi_\Lambda(u)| \geq \delta,$$

while

$$\sup_{u\in I} |P_\pm(D)E_\Lambda(u)| < \frac{\delta}{2}.$$

Theorem 9318.8 (Dominance certificate gives an audited radial readout)**.** *Assume* $\mathsf{DomCert}(\Lambda, P_\pm, I, \delta)$ *for an off-critical mirror exponent pair. Then the full curve has a nonzero classifier readout on the fixed interval:*

$$\inf_{u\in I} |P_\pm(D)\Psi(u)| > 0.$$

Moreover the certified main component is a nonunit radial row, and the tail inequality records that this component is not cancelled on the displayed interval.

Proof. For $u \in I$,

$$P_\pm(D)\Psi(u) = P_\pm(D)\Psi_\Lambda(u) + P_\pm(D)E_\Lambda(u).$$

The triangle inequality and the two certificate bounds give

$$|P_\pm(D)\Psi(u)| \geq \delta - \frac{\delta}{2} = \frac{\delta}{2}.$$

By Definition 9318.5, the finite-window main readout is the mirror radial pair. By Definition 9318.6, that finite-window component is not a finite unit-phase packet. The strict tail inequality shows that this component is not cancelled on the displayed interval. □

Principle 9318.9 (Dominance is the fixed-window audit row)**.** *The certificate of Definition 9318.7 is the BEDC form of a dominant-branch argument. The finite window carries the selected branch pair, the polynomial classifier removes the other displayed branches, the interval I is the observation window, and the tail inequality records that undisplayed modes cannot cancel the selected radial readout. The object is local and finite: it does not by itself claim a global zero theorem.*

9318.3 Prime-Side Realization

Definition 9318.10 (Prime-effective dominance realization)**.** *A prime-effective realization of a fixed window dominance certificate is an admissible compact explicit-formula test row h whose zero-side readout is the scalar audit of the dominated interval and whose archimedean, trivial-zero,*

and pole correction row is displayed in the ledger of Definition 9317.2. It is prime-effective when the correction-subtracted prime side is nonzero:

$$\mathcal{P}(h) = \mathcal{Z}(h) - \mathcal{A}(h) \neq 0.$$

For compact support in $[-A, A]$, this prime side has finite support:

$$\mathcal{P}(h) = \sum_{p^k \leq e^A} c_{p,k}(h)[p^k].$$

Theorem 9318.11 (Prime-effective dominance gives a finite prime residual)**.** *If an off-critical mirror exponent pair admits a fixed window dominance certificate with a prime-effective realization, then there is a nonzero finite prime-power residual*

$$R_S(h) = \sum_{q \in S} c_q(h)[q].$$

Proof. By Definition 9318.10, the correction-subtracted prime side is nonzero. Compact support of h makes the explicit-formula prime ledger a finite sum over $p^k \leq e^A$. Taking S to be that finite support gives the displayed nonzero finite residual. □

Theorem 9318.12 (Fixed-window dominance supplies filtered prime detection)**.** *Assume an off-critical mirror exponent pair admits a fixed window dominance certificate with a prime-effective realization. Then there is a finite Dirichlet classifier whose filtered prime-distribution curve detects the corresponding nonunit residual.*

Proof. Definition 9318.11 supplies a nonzero finite prime-power residual. The finite Dirichlet separation theorem Definition 9300.21 supplies a finite character with nonzero readout on that residual. Then Definition 9316.9 turns the finite classifier readout into the corresponding filtered prime-distribution curve. □

Definition 9318.13 (SpectralPacketCert)**.** *Let*

$$\rho_+ = \frac{1}{2} + r + i\gamma, \qquad \rho_- = \frac{1}{2} - r + i\gamma, \qquad r \neq 0$$

be an off-critical mirror zero pair, and set

$$\lambda_\pm = \rho_\pm - \frac{1}{2}.$$

The certificate

$$\mathsf{SpectralPacketCert}(\rho_+, \rho_-)$$

asserts that there exist a finite spectral window Λ, a mirror-odd differential classifier $P_\pm$, a compact interval $I \subset \mathbb{R}$, a margin $\delta > 0$, and an admissible compact explicit-formula test row h such that $\lambda_+, \lambda_- \in \Lambda$,

$$\mathsf{DomCert}(\Lambda, P_\pm, I, \delta)$$

holds, and h is a prime-effective realization of that fixed window dominance certificate.

Theorem 9318.14 (Spectral packet certificate gives filtered prime detection)**.** *If* $\mathsf{SpectralPacketCert}(\rho_+, \rho_-)$ *holds for an off-critical mirror zero pair, then some finite Dirichlet classifier detects the corresponding nonunit residual on a filtered prime-distribution curve.*

Proof. Unpack Definition 9318.13. It supplies a fixed window dominance certificate together with a prime-effective realization. Apply Definition 9318.12. □

9318.4 Zeta Target

Definition 9318.15 (UniversalSpectralPacketCert)**.** *The row*

$$\mathsf{UniversalSpectralPacketCert}$$

asserts that every off-critical mirror pair in the completed zeta zero ledger admits its certificate

$$\mathsf{SpectralPacketCert}(\rho_+, \rho_-).$$

Definition 9318.16 (ZetaFixedWindowDominance)**.** *The row*

$$\mathsf{ZetaFixedWindowDominance}$$

is the zeta-facing interface exported by

$$\mathsf{UniversalSpectralPacketCert}.$$

Unpacked at a single mirror pair, it consists of the finite spectral window, mirror-odd classifier, fixed observation interval, positive dominance margin, tail inequality, and prime-effective explicit-formula row carried by $\mathsf{SpectralPacketCert}(\rho_+, \rho_-)$.

Theorem 9318.17 (Universal spectral packets supply fixed-window dominance)**.** *If* UniversalSpectralPacketCert *holds, then* ZetaFixedWindowDominance *holds.*

Proof. This is the interface translation of Definition 9318.15 through Definition 9318.16: each off-critical mirror pair receives the finite packet required by the zeta fixed-window row. □

Theorem 9318.18 (ZetaFixedWindowDominance supplies PrimeDistributionCurveCompleteness)**.** *Assume* ZetaFixedWindowDominance*. Then every off-critical zeta mirror pair has a filtered prime-distribution curve on which its nonunit radial residual is visible. In the terminology of Definition 9316.8, the fixed window certificate supplies the local witness required by*

$$\mathsf{PrimeDistributionCurveCompleteness}.$$

Proof. Apply Definition 9318.16 to the off-critical mirror pair. The unpacked $\mathsf{SpectralPacketCert}(\rho_+, \rho_-)$ gives filtered prime detection by Definition 9318.14. This is precisely the visible filtered curve required by Definition 9316.8. □

Corollary 9318.19 (Fixed-window route to the conditional fixed-half readout)**.** *Assume* ZetaFixedWindowDominan *and the hypotheses of Definition 9316.13. Then every admitted nontrivial zero has fixed-half readout.*

Proof. By Definition 9318.18, the required instance of PrimeDistributionCurveCompleteness is available. Apply Definition 9316.13. □

Corollary 9318.20 (Universal spectral packets give the conditional fixed-half readout)**.** *Assume* UniversalSpectralPacketCert *and the hypotheses of Definition 9316.13. Then every admitted nontrivial zero has fixed-half readout.*

Proof. By Definition 9318.17, ZetaFixedWindowDominance holds. Apply Definition 9318.19. □

Definition 9318.21 (TailDominance)**.** *For an off-critical mirror pair, the row*

$$\mathsf{TailDominance}(\rho_+, \rho_-)$$

asserts that there are a finite spectral window Λ, its mirror-odd classifier $P_\pm$, a compact interval I, and a margin $\delta > 0$ such that

$$\inf_{u \in I} |P_\pm(D)\Psi_\Lambda(u)| \geq \delta$$

and

$$\sup_{u \in I} |P_\pm(D)E_\Lambda(u)| < \frac{\delta}{2}.$$

It is the analytic dominance part of $\mathsf{SpectralPacketCert}(\rho_+, \rho_-)$*, separated from the finite Lagrange projector and from the prime-effective explicit-formula realization.*

Theorem 9318.22 (Tail dominance packages the spectral certificate)**.** *If* $\mathsf{TailDominance}(\rho_+, \rho_-)$ *holds and the displayed dominance row has a prime-effective compact explicit-formula realization, then*

$$\mathsf{SpectralPacketCert}(\rho_+, \rho_-)$$

holds.

Proof. The tail-dominance row supplies the finite spectral window, mirror-odd classifier, interval, margin, main-term lower bound, and tail upper bound. These rows are exactly $\mathsf{DomCert}(\Lambda, P_\pm, I, \delta)$. Adding the prime-effective compact explicit-formula realization supplies the last row required by Definition 9318.13. □

Principle 9318.23 (Audit boundary for the fixed-window route)**.** *The proof obligation is concentrated in*

$$\mathsf{UniversalSpectralPacketCert}.$$

For each off-critical mirror pair one must display the finite spectral window, the mirror-odd polynomial classifier, the compact interval, the positive dominance margin, the tail bound, and the compact explicit-formula row whose prime side is nonzero after the recorded correction rows. The finite-window and Lagrange-projector rows are already local certificate data; the unresolved analytic core is the tail-dominance inequality for the selected zeta spectral packet.

Chapter 9319

Damped Spectral Packet Certificate

chapter 9318 isolates the remaining fixed-window burden as a spectral packet certificate with tail dominance. The damped packet route keeps the same local pair and finite Lagrange projector, but appends an entire damping factor. The resulting filter is exact on the selected off-critical mirror pair, vanishes on the displayed finite local packet, and suppresses remote zero rows by vertical exponential decay rather than by a growing interpolation window.

9319.1 Damped Mirror Filter

Definition 9319.1 (Local mirror spectral packet)**.** *Let*

$$\rho_+ = \frac{1}{2} + r + i\gamma, \qquad \rho_- = \frac{1}{2} - r + i\gamma, \qquad r \neq 0$$

be an off-critical mirror zero pair, and set

$$\lambda_\pm = \rho_\pm - \frac{1}{2} = \pm r + i\gamma.$$

A local mirror spectral packet is a finite set

$$\Lambda = \{\lambda_+, \lambda_-\} \cup \Lambda^\circ$$

of zero exponents. The finite subset Λ° records the local zero rows to be killed exactly by the packet projector.

Definition 9319.2 (Mirror Lagrange packet projector)**.** *For a local mirror spectral packet Λ, define the Lagrange basis polynomials*

$$L_+(z) := \prod_{\lambda \in \Lambda, \lambda \neq \lambda_+} \frac{z - \lambda}{\lambda_+ - \lambda},$$

and

$$L_-(z) := \prod_{\lambda \in \Lambda, \lambda \neq \lambda_-} \frac{z - \lambda}{\lambda_- - \lambda}.$$

The mirror Lagrange packet projector is

$$P_\pm(z) := L_+(z) - L_-(z).$$

It satisfies

$$P_\pm(\lambda_+) = 1, \qquad P_\pm(\lambda_-) = -1,$$

and

$$P_\pm(\lambda) = 0 \qquad (\lambda \in \Lambda^\circ).$$

Definition 9319.3 (Damped mirror packet filter)**.** *For $\mu > 0$, define*

$$G_\mu(z) := \exp\left(-\mu\left((z - i\gamma)^2 - r^2\right)^2\right),$$

and

$$\Phi_\mu(z) := P_\pm(z) G_\mu(z).$$

The factor G_μ is normalized on the selected mirror pair:

$$G_\mu(\lambda_+) = G_\mu(\lambda_-) = 1.$$

Therefore

$$\Phi_\mu(\lambda_+) = 1, \qquad \Phi_\mu(\lambda_-) = -1,$$

and

$$\Phi_\mu(\lambda) = 0 \qquad (\lambda \in \Lambda^\circ).$$

Theorem 9319.4 (Damped packet filter has vertical decay)**.** *Fix $C > 0$. On the strip*

$$|\operatorname{Re} z| \le C$$

there are constants $c > 0$ and $C_{\mu,P} > 0$ such that, for sufficiently large $|\operatorname{Im} z - \gamma|$,

$$|\Phi_\mu(z)| \le C_{\mu,P}(1 + |z|)^{\deg P_\pm} \exp\left(-c\mu|\operatorname{Im} z - \gamma|^4\right).$$

Proof. Write

$$w = z - i\gamma = a + it, \qquad t = \operatorname{Im} z - \gamma,$$

with a bounded on the fixed strip. Then

$$w^2 - r^2 = (a^2 - t^2 - r^2) + 2iat.$$

The real part of $(w^2 - r^2)^2$ is

$$(a^2 - t^2 - r^2)^2 - (2at)^2.$$

For large $|t|$, the leading term is t^4, while the negative part is quadratic in t with bounded coefficient. Hence

$$\operatorname{Re}\left((w^2 - r^2)^2\right) \ge c|t|^4$$

outside a compact set. Thus

$$|G_\mu(z)| \le \exp(-c\mu|t|^4).$$

Since $P_\pm$ is a fixed polynomial,

$$|P_\pm(z)| \le C_P(1 + |z|)^{\deg P_\pm}.$$

Multiplying these estimates gives the claimed bound. □

9319.2 Negative Zero-Side Packet

Definition 9319.5 (Exponent mirror quadratic readout)**.** *For a spectral filter Φ on the zero-exponent ledger, define*

$$\mathcal{W}_Z^\lambda(\Phi) := \sum_{\lambda_\rho} \Phi(\lambda_\rho)\overline{\Phi(-\overline{\lambda_\rho})},$$

where $\lambda_\rho = \rho - 1/2$ and the completed zeta multiplicity convention is used.

Definition 9319.6 (DampedSpectralPacketCert)**.** *For an off-critical mirror zero pair ρ_+, ρ_-, the certificate*

$$\mathsf{DampedSpectralPacketCert}(\rho_+, \rho_-)$$

asserts that there are a local mirror spectral packet Λ and a parameter $\mu > 0$ such that the damped mirror packet filter Φ_μ of Definition 9319.3 is admissible for the zero-side quadratic readout and satisfies

$$\mathcal{W}_Z^\lambda(\Phi_\mu) < 0.$$

Theorem 9319.7 (Damped packet gives a negative zero-side readout)**.** *Assume the zero-exponent ledger satisfies the standard zero-counting bound*

$$N(T) = O(T \log T)$$

in vertical strips and that the local packet Λ contains every zero exponent in a fixed bounded height window centered at λ_+, λ_- except the selected pair. Then, for sufficiently large μ,

$$\mathcal{W}_Z^\lambda(\Phi_\mu) < 0.$$

Proof. The selected mirror pair contributes

$$\Phi_\mu(\lambda_+)\overline{\Phi_\mu(\lambda_-)} + \Phi_\mu(\lambda_-)\overline{\Phi_\mu(\lambda_+)} = -2.$$

Every other zero exponent in the displayed local packet is killed by the Lagrange projector. The remaining contribution is the remote tail

$$\mathrm{Tail}_\mu := \sum_{\lambda_\rho \notin \Lambda} \Phi_\mu(\lambda_\rho)\overline{\Phi_\mu(-\overline{\lambda_\rho})}.$$

By Definition 9319.4, the summands have quartic exponential decay in vertical height, up to a fixed polynomial factor. The zero-counting bound makes the tail absolutely convergent and gives

$$\mathrm{Tail}_\mu \to 0$$

as $\mu \to \infty$ by dominated convergence on the dyadic zero ledger. Choose μ so that

$$|\,\mathrm{Tail}_\mu\,| < 1.$$

Then

$$\mathcal{W}_Z^\lambda(\Phi_\mu) = -2 + \mathrm{Tail}_\mu < 0.$$

□

Corollary 9319.8 (Off-critical mirrors supply damped spectral packets)**.** *Under the hypotheses of Definition 9319.7, every off-critical mirror zero pair admits*

$$\mathsf{DampedSpectralPacketCert}(\rho_+, \rho_-).$$

Proof. Use the local packet and the parameter μ supplied by Definition 9319.7. The resulting filter is admissible for the zero-side quadratic readout and has negative value, which is precisely Definition 9319.6. □

9319.3 Prime Residual Interface

Definition 9319.9 (AdmissibleDampedPacketApproximation)**.** *The row*

$$\mathsf{AdmissibleDampedPacketApproximation}$$

asserts that the damped filters Φ_μ can be represented by, or approximated by, admissible Weil explicit-formula test rows while preserving the strict negative zero-side inequality

$$\mathcal{W}_Z^\lambda(\Phi_\mu) < 0.$$

Definition 9319.10 (Damped arch non-cancellation)**.** *The row*

$$\mathsf{DampedArchNonCancellation}$$

asserts that, for at least one admissible damped packet associated to an off-critical mirror pair, the archimedean, trivial-zero, and pole correction terms do not cancel the negative zero-side readout. In the paired explicit-formula notation of Definition 9317.12, the resulting full prime side is nonzero.

Theorem 9319.11 (Damped packet gives a finite prime residual)**.** *Assume*

$$\mathsf{DampedSpectralPacketCert}(\rho_+, \rho_-), \qquad \mathsf{AdmissibleDampedPacketApproximation}, \qquad \mathsf{DampedArchNonCancellation}.$$

Then there is a nonzero finite prime-power residual

$$R_S = \sum_{q \in S} a_q[q].$$

Proof. The damped packet supplies a negative zero-side readout. The admissibility row transfers it to the paired explicit-formula test space, and the arch non-cancellation row makes the corresponding prime-side readout nonzero. If the prime-side expansion is finite, take its support. If it is an absolutely convergent weighted prime-power series, choose a finite subset whose partial sum is nonzero; otherwise all finite partial sums would force the total readout to vanish. This gives the displayed finite residual. □

Theorem 9319.12 (Damped packet supplies filtered prime detection)**.** *Under the hypotheses of Definition 9319.11, some finite Dirichlet classifier detects the damped packet residual on a filtered prime-distribution curve.*

Proof. Definition 9319.11 supplies a nonzero finite prime-power residual. Apply the finite Dirichlet separation theorem Definition 9300.21 and then the filtered-curve realization of Definition 9316.9. □

Theorem 9319.13 (Damped packet route gives conditional fixed-half readout)**.** *Assume every off-critical mirror pair admits a damped spectral packet, the admissible approximation and arch non-cancellation rows hold for those packets, zeta-facing PFZ zero packets are legal closure objects, and classifier-visible nonunit residuals cannot be hidden in legal PFZ closure data. Then every admitted nontrivial zero has fixed-half readout.*

Proof. If an admitted zero were off the critical line, it would determine an off-critical mirror pair. By the damped packet hypothesis and Definition 9319.12, some filtered prime-distribution curve would detect a nonunit residual. The no-hidden-residual hypothesis excludes such a residual from a legal PFZ closure object. Therefore the radial coordinate is zero, and Definition 9266.2 gives fixed-half readout. □

Principle 9319.14 (Damped packet audit boundary)**.** *The damped packet route uses a local exact projector plus a vertical damping estimate. The spectral side supplies a negative mirror direction once zero-counting controls the remote tail. The remaining analytic interfaces are admissibility for the Weil explicit formula and non-cancellation by the archimedean, trivial-zero, and pole correction ledger.*

Chapter 9320

Negative Weil Isolator

chapter 9317 records a signed explicit-formula bridge under the arch-null isolator. The negative-Weil package uses a sharper separation surface: an off-critical mirror pair is required to produce a negative direction for the full Weil form, not merely a nonzero prime-side residual. The remaining analytic content is thereby localized in two obligations: Paley–Wiener tail control for the selected zero pair, and independence of the fixed archimedean, trivial-zero, and pole correction rows from that negative mirror direction.

9320.1 Mirror Pair Geometry

Definition 9320.1 (Weil mirror involution)**.** *The Weil mirror involution on the completed zeta zero ledger is*

$$\iota(\rho) := 1 - \overline{\rho}.$$

An off-critical mirror pair is a pair

$$\rho_+ = \frac{1}{2} + r + i\gamma, \qquad \rho_- = \iota(\rho_+) = \frac{1}{2} - r + i\gamma,$$

with $r \neq 0$.

Lemma 9320.2 (Li radius reverses across the mirror)**.** *Let*

$$z(\rho) := 1 - \frac{1}{\rho}.$$

If $z(\rho_+) = e^{\ell + i\theta}$ *for an off-critical mirror pair, then*

$$z(\rho_-) = e^{-\ell + i\theta}.$$

In particular, $r \neq 0$ *is equivalent to* $\ell \neq 0$.

Proof. For $\rho_- = \iota(\rho_+) = 1 - \overline{\rho_+}$,

$$z(\rho_-) = 1 - \frac{1}{1 - \overline{\rho_+}} = \frac{\overline{\rho_+}}{\overline{\rho_+} - 1} = \frac{1}{\overline{z(\rho_+)}}.$$

Thus $z(\rho_+) = e^{\ell + i\theta}$ gives

$$z(\rho_-) = e^{-\ell + i\theta}.$$

The equivalence between $\ell = 0$ and the fixed-half condition follows from Definition 9266.2; hence $r \neq 0$ is equivalent to $\ell \neq 0$. □

Principle 9320.3 (Mirror scale is quadratic residual data)**.** *The linear radial coordinates of an off-critical mirror pair are ℓ and $-\ell$. Their signed sum can disappear from a first-order scale ledger, but their quadratic energy cannot:*

$$\ell^2 + (-\ell)^2 = 2\ell^2 > 0.$$

The mirror pair is therefore not a harmless cancellation. It is a displayed scale-energy row, and any zeta-facing PFZ packet that admits the pair must either ledger this row or violate the no-hidden-radial surface of Definition 9297.14.

9320.2 Zero-Side Negative Direction

Definition 9320.4 (Mirror quadratic zero readout)**.** *For an admissible compact test row g, the mirror quadratic zero readout is*

$$\mathcal{W}_Z(g) := \sum_{\rho} \widehat{g}(\rho)\,\overline{\widehat{g}(\iota(\rho))}.$$

This is the zero-side row of the paired explicit-formula ledger of Definition 9317.12.

Definition 9320.5 (Finite mirror negative interpolation)**.** *Let F be a finite zero-position set containing an off-critical mirror pair ρ_+, ρ_-. A finite mirror negative interpolation row for F is an admissible compact test row g satisfying*

$$\widehat{g}(\rho_+) = 1, \qquad \widehat{g}(\rho_-) = -1,$$

and

$$\widehat{g}(\rho) = 0 \qquad (\rho \in F \setminus \{\rho_+, \rho_-\}).$$

Lemma 9320.6 (Finite mirror negative interpolation exists)**.** *For every finite zero-position set F containing an off-critical mirror pair and every $A > 0$, a finite mirror negative interpolation row exists in $C_c^\infty(-A, A)$.*

Proof. Apply Definition 9317.4 to the finite set F, assigning the values 1 and -1 to the mirror pair and 0 to all other entries of F. □

Lemma 9320.7 (Mirror interpolation gives local negative contribution)**.** *For a finite mirror negative interpolation row, the contribution of the selected mirror pair to $\mathcal{W}_Z(g)$ is*

$$-2.$$

Proof. The two ordered mirror terms are

$$\widehat{g}(\rho_+)\overline{\widehat{g}(\rho_-)} + \widehat{g}(\rho_-)\overline{\widehat{g}(\rho_+)} = 1 \cdot (-1) + (-1) \cdot 1 = -2.$$

□

Definition 9320.8 (PWZeroPairTailControl)**.** *The obligation*

$$\mathsf{PWZeroPairTailControl}$$

asserts that for every off-critical mirror pair ρ_+, ρ_- there is an admissible compact test row g with

$$\widehat{g}(\rho_+) = 1, \qquad \widehat{g}(\rho_-) = -1,$$

such that the remaining zero-side mirror contribution satisfies

$$\left| \sum_{\rho \notin \{\rho_+, \rho_-\}} \widehat{g}(\rho)\, \overline{\widehat{g}(\iota(\rho))} \right| < \frac{1}{2}.$$

Principle 9320.9 (Tail-control analytic content)**.** *Definition 9320.6 supplies the finite interpolation part of* PWZeroPairTailControl*. The analytic part is the simultaneous choice of interpolation row and vertical decay. In Paley–Wiener terms, one must retain the two prescribed point values while making the zero tail small against the standard zero-counting ledger. This is a test-function construction problem, not a BEDC ledger convention.*

Theorem 9320.10 (Tail-controlled mirror pair gives negative zero-side readout)**.** *Assume* PWZeroPairTailControl*. Every off-critical mirror pair admits an admissible compact test row g such that*

$$\mathcal{W}_Z(g) < -\frac{3}{2}.$$

Proof. Choose g by Definition 9320.8. The selected mirror pair contributes -2 by Definition 9320.7. The remaining zero-side contribution has absolute value less than $1/2$. Therefore

$$\mathcal{W}_Z(g) < -2 + \frac{1}{2} = -\frac{3}{2}.$$

□

9320.3 Archimedean Independence

Definition 9320.11 (Admissible Weil test Hilbert space)**.** *An admissible Weil test Hilbert space is a completion $\mathcal{H}$ of the compact explicit-formula test rows with the following structure. For every zero row ρ, the evaluation*

$$E_\rho(g) := \widehat{g}(\rho)$$

extends to a continuous linear functional on $\mathcal{H}$. Finite zero readout interpolation rows remain represented in $\mathcal{H}$. The archimedean, trivial-zero, and pole correction row of the paired explicit formula extends to a continuous quadratic form

$$\mathcal{W}_A : \mathcal{H} \to \mathsf{Real}^{\uparrow}.$$

Definition 9320.12 (Mirror affine interpolation plane)**.** *For an off-critical mirror pair, the mirror affine interpolation plane is*

$$\mathcal{I}_{\rho_\pm} := \left\{ g \in \mathcal{H} : E_{\rho_+}(g) = 1,\ E_{\rho_-}(g) = -1 \right\}.$$

Definition 9320.13 (ArchIndependence)**.** *The obligation*

$$\mathsf{ArchIndependence}$$

asserts that for every off-critical mirror pair, the fixed correction quadratic form does not dominate the negative mirror direction on $\mathcal{I}_{\rho_\pm}$. In the normalized form used here, this means that the test row supplied by PWZeroPairTailControl *may be chosen so that*

$$|\mathcal{W}_A(g)| < \frac{1}{2}.$$

Equivalently, the off-critical point-evaluation direction is not in the closure of the archimedean, trivial-zero, and pole correction directions.

Principle 9320.14 (Arch independence is weaker than arch-null isolation)**.** *The obligation* ArchNullWeilIsolator *of Definition 9317.14 asks for*

$$\mathcal{W}_A(g) = 0.$$

Definition 9320.13 asks only that the fixed correction row cannot force cancellation of the negative mirror direction. It is therefore a separation statement about the admissible test space, rather than a nulling statement for every archimedean correction component.

Theorem 9320.15 (NegativeWeilIsolator)**.** *Assume* PWZeroPairTailControl *and* ArchIndependence*. If an off-critical mirror pair exists, then there is an admissible compact test row g for which the full paired Weil form satisfies*

$$\mathcal{W}(g) < 0.$$

Proof. By PWZeroPairTailControl and ArchIndependence, choose an admissible compact row g satisfying both the tail-controlled mirror interpolation and the correction bound. The tail-controlled estimate is

$$\mathcal{W}_Z(g) < -\frac{3}{2}.$$

The correction estimate is

$$|\mathcal{W}_A(g)| < \frac{1}{2}.$$

For the full paired Weil form

$$\mathcal{W}(g) = \mathcal{W}_Z(g) - \mathcal{W}_A(g),$$

one has

$$\mathcal{W}(g) < -\frac{3}{2} + \frac{1}{2} = -1 < 0.$$

□

9320.4 Prime-Side Negative Residual

Theorem 9320.16 (Negative Weil direction gives finite prime negative residual)**.** *Assume the paired explicit-formula ledger of Definition 9317.12. If an admissible compact test row satisfies*

$$\mathcal{W}(g) < 0,$$

then it supplies a finite prime negative residual in the sense of Definition 9317.16.

Proof. The paired explicit formula identifies the full Weil form with the prime-side quadratic residual after the archimedean, trivial-zero, and pole correction rows have been accounted for:

$$\mathcal{W}(g) = \mathcal{W}_P(g).$$

Thus $\mathcal{W}_P(g) < 0$. If g is supported in $[-A, A]$, the prime-power side is supported on

$$p^k \leq e^A.$$

Hence the negative prime-side readout is a finite prime negative residual. □

Corollary 9320.17 (Negative isolator gives classifier-visible residual)**.** *Assume* PWZeroPairTailControl*,* ArchIndependence*, and the paired explicit-formula ledger. If an off-critical mirror pair exists, then there is a finite Dirichlet classifier with nonzero readout on the associated prime-side residual.*

Proof. Definition 9320.15 supplies g with $\mathcal{W}(g) < 0$. By Definition 9320.16 this gives a finite prime negative residual. A negative residual is nonzero, so Definition 9300.21 supplies a finite Dirichlet classifier with nonzero readout. □

Principle 9320.18 (Negative residuals are PFZ-visible obstructions)**.** *The classifier-visible residual of Definition 9320.17 is a finite obstruction in the sense of Definition 9297.8. If it is entered into the PFZ ledger, the packet is still carrying a negative energy row and is not a unit-phase triangle closure. If it is omitted, the zeta-facing NameCert admission surface is incomplete. If a zoom step attempts to dilute it across scales, the self-substitution and reflection-positive persistence rows of Definition 9297.4 and Definition 9297.7 preserve the finite defect as scale-stable data.*

9320.5 Fixed-Half Consequence

Theorem 9320.19 (Off-critical zero gives unhideable negative residual)**.** *Assume the paired explicit-formula ledger,* PWZeroPairTailControl*,* ArchIndependence*, and the PFZ obstruction bridge of Definition 9320.18. Then every off-critical zero produces a classifier-visible finite prime negative residual that cannot be hidden by legal PFZ zoom, smoothing, or branch selection.*

Proof. An off-critical zero supplies the mirror pair of Definition 9320.1. The two analytic obligations and Definition 9320.15 give an admissible compact test row with negative full Weil form. The paired explicit formula and Definition 9320.16 turn this into a finite prime negative residual. The finite Dirichlet classifier of Definition 9320.17 detects the residual, while Definition 9320.18 prevents the detected finite obstruction from being hidden as zoom noise, solenoid phase, or a smooth branch artefact. □

Corollary 9320.20 (Negative-Weil conditional fixed-half readout)**.** *Assume that every completed zeta zero packet admitted by the zeta-facing PFZ surface is a legal closure object, and assume the hypotheses of Definition 9320.19. Then every admitted nontrivial zero has fixed-half readout.*

Proof. Let ρ be an admitted nontrivial zero and write

$$z(\rho) = 1 - \frac{1}{\rho} = e^{\ell + i\theta}.$$

If $\ell \neq 0$, then Definition 9320.2 places ρ in an off-critical mirror pair. By Definition 9320.19, that pair produces a classifier-visible finite prime negative residual that legal PFZ closure cannot hide. This contradicts the assumption that the admitted zero packet is a legal closure object. Therefore

$$\ell = 0.$$

By Definition 9266.2, this is equivalent to

$$\Re(\rho) = \frac{1}{2}.$$

□

Principle 9320.21 (Remaining analytic frontier)**.** *The negative-Weil route concentrates the remaining analytic frontier in the two obligations*

PWZeroPairTailControl *and* ArchIndependence.

The finite interpolation, the sign calculation, the finite prime residual passage, the Dirichlet classifier detection, and the PFZ visibility consequence are separated from these analytic obligations. Thus the route is not a general appeal to explicit-formula positivity; it is a precise request for a compact test row that isolates an off-critical mirror pair as a negative full Weil direction.

Chapter 9321

Paley–Wiener Zero Pair Tail Control

chapter 9320 isolates the first analytic row in the negative-Weil route as PWZeroPairTailControl. This chapter resolves the finite part of that row and states the precise uniform tail condition needed for the infinite zero ledger. The construction is local at an off-critical mirror pair: a mirror-odd bump gives exact values $(1, -1)$ on the pair, finite exponential interpolation removes every other zero in a bounded window, and a uniform Paley–Wiener tail row then converts the finite negative block into a negative zero-side Weil readout.

9321.1 Mirror-Odd Local Isolator

Definition 9321.1 (Mirror-odd bump)**.** *Let $r \in \mathsf{Real}^{\uparrow}$ with $r \neq 0$. A mirror-odd bump for r is a real-valued function*

$$\phi \in C_c^\infty(-A, A)$$

such that

$$\phi(-x) = -\phi(x)$$

and

$$I_r(\phi) := \int_{\mathbb{R}} \phi(x) \sinh(rx)\, dx \neq 0.$$

Lemma 9321.2 (Mirror-odd bumps exist)**.** *For every $A > 0$ and every $r \neq 0$, there is a mirror-odd bump for r supported in $(-A, A)$.*

Proof. Choose a nonzero nonnegative bump

$$\psi \in C_c^\infty((0, A)).$$

Set

$$\phi(x) := \psi(x) - \psi(-x).$$

Then ϕ is smooth, compactly supported in $(-A, A)$, and odd. The function $\sinh(rx)$ is also odd, so $\phi(x)\sinh(rx)$ is even. On the positive support of ψ, its sign is constant and nonzero after possibly replacing ϕ by $-\phi$. Hence

$$I_r(\phi) = 2\int_0^A \psi(x) \sinh(rx)\, dx \neq 0.$$

□

Definition 9321.3 (Mirror-odd zero-pair row)**.** *For an off-critical mirror pair*

$$\rho_+ = \frac{1}{2} + r + i\gamma, \qquad \rho_- = \frac{1}{2} - r + i\gamma,$$

and a mirror-odd bump ϕ for r, define

$$f_{\rho_+,\phi}(x) := \frac{e^{-i\gamma x}\phi(x)}{I_r(\phi)}.$$

Theorem 9321.4 (Mirror-odd row separates the zero pair)**.** *For the row of Definition 9321.3,*

$$\widehat{f}_{\rho_+,\phi}(\rho_+) = 1, \qquad \widehat{f}_{\rho_+,\phi}(\rho_-) = -1.$$

Proof. At ρ_+ one has

$$\widehat{f}_{\rho_+,\phi}(\rho_+) = \frac{1}{I_r(\phi)} \int_{\mathbb{R}} \phi(x) e^{rx}\, dx.$$

Since

$$e^{rx} = \cosh(rx) + \sinh(rx),$$

the product $\phi(x)\cosh(rx)$ is odd and has integral zero. Therefore

$$\int_{\mathbb{R}} \phi(x) e^{rx}\, dx = \int_{\mathbb{R}} \phi(x)\sinh(rx)\, dx = I_r(\phi),$$

which gives $\widehat{f}_{\rho_+,\phi}(\rho_+) = 1$.

At ρ_- the same cancellation gives

$$\widehat{f}_{\rho_+,\phi}(\rho_-) = \frac{1}{I_r(\phi)} \int_{\mathbb{R}} \phi(x) e^{-rx}\, dx.$$

Using

$$e^{-rx} = \cosh(rx) - \sinh(rx),$$

the odd part again integrates to zero and the remaining term is

$$-I_r(\phi).$$

Hence $\widehat{f}_{\rho_+,\phi}(\rho_-) = -1$. □

Corollary 9321.5 (Mirror-odd row gives a local negative block)**.** *The selected mirror pair contributes*

$$-2$$

to the zero-side mirror quadratic readout of Definition 9320.4.

Proof. By Definition 9321.4, the two ordered mirror terms are

$$1 \cdot \overline{-1} + (-1) \cdot \overline{1} = -2.$$

□

9321.2 Finite Window Cancellation

Definition 9321.6 (Centered nontrivial zero window)**.** *For an off-critical mirror pair at height γ and a width $T > 0$, the centered nontrivial zero window is the finite zero-position set*

$$\mathcal{F}_T(\gamma) := \{\rho : \ \rho \text{ is nontrivial and } |\operatorname{Im}\rho - \gamma| \le T\},$$

with the completed zeta multiplicity convention. Its punctured window is

$$\mathcal{F}_T^\circ(\gamma) := \mathcal{F}_T(\gamma) \setminus \{\rho_+, \rho_-\}.$$

Theorem 9321.7 (Finite window mirror-negative interpolation)**.** *Let $\mathcal{F}_T(\gamma)$ be a centered nontrivial zero window containing the off-critical mirror pair ρ_+, ρ_-. For every $A > 0$ there is a compact smooth row*

$$g_T \in C_c^\infty(-A, A)$$

such that

$$\widehat{g}_T(\rho_+) = 1, \qquad \widehat{g}_T(\rho_-) = -1,$$

and

$$\widehat{g}_T(\rho) = 0 \qquad (\rho \in \mathcal{F}_T^\circ(\gamma)).$$

Proof. The centered nontrivial zero window is finite because the completed zeta nontrivial-zero ledger is discrete in bounded vertical strips. Apply Definition 9317.4 to this finite set, assigning the values 1 and -1 to ρ_+ and ρ_- and assigning 0 to every point in the punctured window. □

Corollary 9321.8 (Finite window contribution is exactly negative)**.** *For g_T as in Definition 9321.7, the contribution of $\mathcal{F}_T(\gamma)$ to $\mathcal{W}_Z(g_T)$ is*

$$-2.$$

Proof. The mirror pair contributes -2 by the same calculation as Definition 9321.5. Every other zero in the centered window has prescribed readout 0, so the remaining finite-window terms vanish. □

9321.3 Uniform Tail Row

Definition 9321.9 (UniformPWInterpolationTailControl)**.** *The row*

$$\mathsf{UniformPWInterpolationTailControl}$$

asserts that for every off-critical mirror pair and every $\varepsilon > 0$ there are $T > 0$, $A > 0$, and a compact smooth row $g_T \in C_c^\infty(-A, A)$ satisfying the finite window interpolation of Definition 9321.7 and

$$\left| \sum_{\rho \notin \mathcal{F}_T(\gamma)} \widehat{g}_T(\rho)\, \overline{\widehat{g}_T(\iota(\rho))} \right| < \varepsilon.$$

Equivalently, the finite interpolation rows can be chosen with enough uniform Paley–Wiener decay to make the complement of the centered window arbitrarily small in the zero-side mirror quadratic form.

Lemma 9321.10 (Dyadic zero-tail estimate)**.** *Let g be an admissible compact row whose transform satisfies, in the critical strip,*

$$|\widehat{g}(\sigma + it)| \le C_N(1 + |t|)^{-N}$$

for some $N > 1$. If the zero-counting row has the standard dyadic bound

$$\#\{\rho : \ 2^j T < |\operatorname{Im}\rho - \gamma| \le 2^{j+1}T\} \le C\, 2^j T \log(2^j T + 2)$$

for $T \ge 1$, then

$$\sum_{\rho \notin \mathcal{F}_T(\gamma)} |\widehat{g}(\rho)|\, |\widehat{g}(\iota(\rho))| \le C'_N C_N^2 T^{1-2N} \log(T + 2)$$

for a constant C'_N independent of T and g except through C_N.

Proof. The involution $\iota(\rho) = 1 - \overline{\rho}$ preserves the imaginary part of ρ. On the dyadic annulus

$$2^j T < |\operatorname{Im}\rho - \gamma| \le 2^{j+1}T,$$

both $\widehat{g}(\rho)$ and $\widehat{g}(\iota(\rho))$ are bounded by the same vertical decay estimate. The annulus contribution is therefore bounded by

$$C\, 2^j T \log(2^j T + 2)\, C_N^2 (2^j T)^{-2N}.$$

Summing over $j \ge 0$ gives

$$C C_N^2 T^{1-2N} \sum_{j \ge 0} 2^{j(1-2N)} \log(2^j T + 2).$$

Since $N > 1$, the displayed dyadic series is bounded by a constant multiple of $\log(T + 2)$. This gives the claimed estimate. □

Principle 9321.11 (Uniformity is the analytic load)**.** *Definition 9321.10 shows that rapid vertical decay controls the zero tail once the relevant constants are uniform along the finite interpolation rows. The non-formal analytic issue is therefore not finite interpolation itself, but the selection of the finite interpolation solution with Sobolev or Paley–Wiener constants that remain controlled as the centered window expands.*

Theorem 9321.12 (Uniform tail row gives PWZeroPairTailControl)**.** *If* UniformPWInterpolationTailControl *holds, then* PWZeroPairTailControl *holds.*

Proof. Apply Definition 9321.9 with

$$\varepsilon = \frac{1}{2}.$$

The resulting row has

$$\widehat{g}_T(\rho_+) = 1, \qquad \widehat{g}_T(\rho_-) = -1,$$

and its complement outside the centered window has mirror contribution of absolute value less than 1/2. The punctured window contributes zero by Definition 9321.7. Hence the same row satisfies the definition of PWZeroPairTailControl in Definition 9320.8. □

Corollary 9321.13 (Uniform tail row gives a negative zero-side Weil readout)**.** *If* UniformPWInterpolationTailContr *holds and an off-critical mirror pair exists, then there is an admissible compact row g such that*

$$\mathcal{W}_Z(g) < 0.$$

Proof. By Definition 9321.12, PWZeroPairTailControl holds. Then Definition 9320.10 gives

$$\mathcal{W}_Z(g) < -\frac{3}{2} < 0.$$

□

Principle 9321.14 (Zero-side boundary of the negative-Weil route)**.** *The zero-side part of the negative-Weil route is reduced to a single uniform Paley–Wiener selection problem:*

$$\mathsf{UniformPWInterpolationTailControl} \Longrightarrow \mathsf{PWZeroPairTailControl} \Longrightarrow \exists g,\ \mathcal{W}_Z(g) < 0.$$

No archimedean, trivial-zero, pole, or prime-side correction row is used in this implication. Those rows enter only in the independent ArchIndependence *surface of Definition 9320.13.*

Chapter 9322

Paley–Wiener Condition Number Bridge

chapter 9321 reduces the zero-side part of the negative-Weil route to uniform control of compact test rows that interpolate a finite zero window. The present chapter expresses that uniform control as a condition-number estimate. The analytic target is no longer an unspecified global test function. It is the growth rate of the least vertical-decay cost of the finite Paley–Wiener interpolation problem, with optional finite archimedean null constraints.

9322.1 Vertical Decay Cost

Definition 9322.1 (Vertical Paley–Wiener seminorm)**.** *Fix a vertical strip*

$$\sigma_0 \le \mathrm{Re}(s) \le \sigma_1$$

containing the critical strip, and let $N \ge 1$. For a compact explicit-formula test row f, define

$$|f|_{A,N} := \sup_{\sigma\in[\sigma_0,\sigma_1]} \sup_{t\in\mathbb{R}} (1+|t|)^N |\widehat{f}(\sigma+it)|.$$

Thus

$$|\widehat{f}(\sigma+it)| \le |f|_{A,N}(1+|t|)^{-N}$$

throughout the strip.

Definition 9322.2 (Symmetric height zero window)**.** *For $T > 0$, let*

$$\mathcal{Z}_T := \{\rho : \ \rho \text{ is a nontrivial completed zeta zero and } |\operatorname{Im}\rho| \le T\}$$

with the completed zeta multiplicity convention. For an off-critical mirror pair ρ_+, ρ_- contained in $\mathcal{Z}_T$, define the mirror target row

$$b_T(\rho_+) := 1, \qquad b_T(\rho_-) := -1, \qquad b_T(\rho) := 0 \quad (\rho \in \mathcal{Z}_T \setminus \{\rho_+, \rho_-\}).$$

Definition 9322.3 (Paley–Wiener interpolation condition number)**.** *For $N \ge 1$, the finite zero-window interpolation condition number is*

$$\mathfrak{K}_N(T) := \inf\left\{|f|_{A,N} : f \in C_c^\infty(-A,A),\ \widehat{f}(\rho) = b_T(\rho) \text{ for all } \rho \in \mathcal{Z}_T\right\},$$

where the infimum is taken over compact supports and compact test rows admissible for the explicit-formula ledger.

Lemma 9322.4 (Finite condition number is finite)**.** *For every finite zero window $\mathcal{Z}_T$ containing an off-critical mirror pair and every $N \geq 1$,*

$$\mathfrak{K}_N(T) < \infty.$$

Proof. The finite interpolation row Definition 9317.4 gives a compact smooth f realizing the target values b_T on $\mathcal{Z}_T$. Its Laplace–Fourier transform is rapidly decaying in every fixed vertical strip, so $|f|_{A,N} < \infty$. Hence the displayed infimum is finite. □

9322.2 Condition Number Tail Estimate

Definition 9322.5 (Symmetric zero tail)**.** *For a row f realizing the mirror target on $\mathcal{Z}_T$, the symmetric zero tail is*

$$\mathrm{Tail}_T(f) := \sum_{\rho \notin \mathcal{Z}_T} \widehat{f}(\rho)\, \overline{\widehat{f}(\iota(\rho))}.$$

Theorem 9322.6 (Condition-number zero-tail bound)**.** *Assume the standard nontrivial-zero counting bound*

$$\#\{\rho : \ Y < |\operatorname{Im}\rho| \leq 2Y\} \leq C\, Y \log(Y+2)$$

for $Y \geq 1$. Let $N > 1$. If f realizes the mirror target on $\mathcal{Z}_T$ and

$$|f|_{A,N} \leq K,$$

then

$$|\,\mathrm{Tail}_T(f)| \leq C_N K^2 T^{1-2N} \log(T+2),$$

where C_N is independent of T and of f except through the displayed seminorm bound.

Proof. The mirror involution preserves imaginary height. For every zero outside $\mathcal{Z}_T$,

$$|\widehat{f}(\rho)|\,|\widehat{f}(\iota(\rho))| \leq K^2(1+|\operatorname{Im}\rho|)^{-2N}.$$

Apply dyadic decomposition to the ranges

$$2^j T < |\operatorname{Im}\rho| \leq 2^{j+1}T.$$

The contribution of the jth range is bounded by

$$C\, 2^j T \log(2^j T + 2)\, K^2 (2^j T)^{-2N}.$$

Summing in j gives

$$C K^2 T^{1-2N} \sum_{j \geq 0} 2^{j(1-2N)} \log(2^j T + 2).$$

Since $N > 1$, the dyadic series is bounded by a constant multiple of $\log(T+2)$. This gives the required estimate. □

Theorem 9322.7 (Condition growth gives UniformPWInterpolationTailControl)**.** *Suppose there are $N > 1$ and a sequence $T \to \infty$ such that*

$$\mathfrak{K}_N(T)^2 T^{1-2N} \log(T+2) \to 0.$$

Then UniformPWInterpolationTailControl *holds for the off-critical mirror pair.*

Proof. For each T, choose a compact interpolation row f_T realizing b_T and satisfying

$$|f_T|_{A,N} \le 2\mathfrak{K}_N(T).$$

The factor 2 only records a near-minimizer for the infimum. By Definition 9322.6,

$$|\operatorname{Tail}_T(f_T)| \le 4C_N\mathfrak{K}_N(T)^2T^{1-2N}\log(T+2).$$

The right side tends to zero. Given $\varepsilon > 0$, choose T in the sequence so that the displayed bound is less than ε. The row f_T realizes the finite window interpolation and has the required tail bound, which is UniformPWInterpolationTailControl. □

Corollary 9322.8 (Condition growth gives negative zero-side readout)**.** *Under the condition-growth hypothesis of Definition 9322.7, an off-critical mirror pair admits an admissible compact row f with*

$$\mathcal{W}_Z(f) < 0.$$

Proof. Apply Definition 9322.7 and then Definition 9321.13. □

9322.3 Archimedean Condition Number

Definition 9322.9 (Finite archimedean null row)**.** *A finite archimedean null row is a finite family of continuous linear test-function functionals*

$$L_1, \dots, L_J$$

representing a finite truncation of the archimedean, trivial-zero, and pole correction ledger. A test row is J-arch-null when

$$L_j(f) = 0 \qquad (1 \le j \le J).$$

Definition 9322.10 (Arch-null interpolation condition number)**.** *For a finite archimedean null row, define*

$$\mathfrak{K}^{\mathrm{arch}}_{N,J}(T) := \inf\left\{|f|_{A,N} : \widehat{f}(\rho) = b_T(\rho) \text{ for all } \rho \in \mathcal{Z}_T,\ L_j(f) = 0 \text{ for } 1 \le j \le J\right\}.$$

Lemma 9322.11 (Finite arch-null interpolation is finite under independence)**.** *Assume the functionals*

$$\{\widehat{(\cdot)}(\rho) : \rho \in \mathcal{Z}_T\} \cup \{L_1, \dots, L_J\}$$

are linearly independent on $C_c^\infty(-A, A)$. Then

$$\mathfrak{K}^{\mathrm{arch}}_{N,J}(T) < \infty.$$

Proof. Consider the linear map sending f to the vector of zero evaluations and archimedean reads:

$$f \mapsto \left((\widehat{f}(\rho))_{\rho\in\mathcal{Z}_T}, L_1(f), \dots, L_J(f)\right).$$

If this map were not onto, a nonzero linear functional on the finite target space would annihilate its range, giving a nontrivial linear relation among the displayed source functionals. This contradicts the independence hypothesis. Hence the target values b_T and the zero arch reads can be prescribed simultaneously. The resulting compact smooth row has finite $|\cdot|_{A,N}$ seminorm. □

Definition 9322.12 (ArchLimitControl)**.** *The row*

$$\mathsf{ArchLimitControl}$$

asserts that the full archimedean, trivial-zero, and pole correction quadratic form is approximated by finite archimedean null rows on the near-minimizing interpolation family. In the normalized form used here, there are J and a sequence $T \to \infty$ such that for the chosen near-minimizers f_T,

$$|\mathcal{W}_A(f_T)| \to 0.$$

Theorem 9322.13 (Arch condition growth gives NegativeWeilIsolator)**.** *Assume there are $N > 1$, a finite archimedean null row J, and a sequence $T \to \infty$ such that*

$$\left(\mathfrak{K}^{\mathrm{arch}}_{N,J}(T)\right)^2 T^{1-2N} \log(T+2) \to 0,$$

and assume ArchLimitControl *for the corresponding near-minimizing rows. Then an off-critical mirror pair gives a compact test row f satisfying*

$$\mathcal{W}(f) < 0.$$

Proof. Choose near-minimizing rows f_T satisfying the zero interpolation and the finite arch-null constraints, with

$$|f_T|_{A,N} \le 2\mathfrak{K}^{\mathrm{arch}}_{N,J}(T).$$

The zero-tail estimate gives

$$|\operatorname{Tail}_T(f_T)| \to 0.$$

The finite zero window contributes exactly -2: the mirror pair has values 1 and -1, while every other zero in $\mathcal{Z}_T$ has value 0. The finite arch rows vanish by construction, and the remaining arch correction tends to zero by ArchLimitControl. For T sufficiently large,

$$|\operatorname{Tail}_T(f_T)| < \frac{1}{4}, \qquad |\mathcal{W}_A(f_T)| < \frac{1}{4}.$$

Thus

$$\mathcal{W}(f_T) < -2 + \frac{1}{4} + \frac{1}{4} = -\frac{3}{2} < 0.$$

□

9322.4 Condition-Number RH Interface

Definition 9322.14 (PWInterpolationConditionBound)**.** *The row*

$$\mathsf{PWInterpolationConditionBound}$$

asserts that for every off-critical mirror pair there are $N > 1$, a finite archimedean null row J, and a sequence $T \to \infty$ for which

$$\left(\mathfrak{K}^{\mathrm{arch}}_{N,J}(T)\right)^2 T^{1-2N} \log(T+2) \to 0$$

and ArchLimitControl *holds on the associated near-minimizing rows.*

Theorem 9322.15 (Condition-number negative residual theorem)**.** *Assume* PWInterpolationConditionBound *and the paired explicit-formula ledger. If an off-critical mirror pair exists, then it produces a finite prime negative residual detected by a finite Dirichlet classifier.*

Proof. Definition 9322.14 supplies the hypotheses of Definition 9322.13, so there is f with $\mathcal{W}(f) < 0$. The paired explicit formula and Definition 9320.16 turn this into a finite prime negative residual. The classifier readout is then supplied by Definition 9320.17. □

Corollary 9322.16 (Condition-number PFZ fixed-half readout)**.** *Assume* PWInterpolationConditionBound*, the paired explicit-formula ledger, and the PFZ rule that finite negative residuals cannot be hidden as legal closure data. Then every zeta-facing PFZ legal zero packet has fixed-half readout.*

Proof. If a legal zero packet had $\ell \neq 0$, then Definition 9320.2 would place it in an off-critical mirror pair. By Definition 9322.15, that pair produces a finite prime negative residual detected by a finite classifier. By Definition 9320.18, the residual cannot be hidden in a legal PFZ closure object. Hence $\ell = 0$, and Definition 9266.2 gives fixed-half readout. □

Principle 9322.17 (Polynomial condition-number target)**.** *The analytic frontier can be attacked through the growth of* $\mathfrak{K}^{\mathrm{arch}}_{N,J}(T)$*. A polynomial estimate*

$$\mathfrak{K}^{\mathrm{arch}}_{N,J}(T) = O(T^M)$$

would be enough after choosing $N > M + \frac{1}{2}$*, because then*

$$\left(\mathfrak{K}^{\mathrm{arch}}_{N,J}(T)\right)^2 T^{1-2N} \log(T+2) \to 0.$$

Thus the remaining zero-isolation problem is a finite-dimensional Paley–Wiener interpolation condition-number estimate, rather than an unstructured request for a global separating test function.

Chapter 9323

Circle-Triangle Projection Dictionary

chapter 9290 isolates the common generator behind the RH-facing route: generated time, unit-circle phase, orthogonal triangle readout, Zeckendorf–prime ledger, Li scale-phase coordinates, and hidden-scale refusal. The present chapter records how the familiar RH criteria are read as projections of that one generator. The point is not to replace their analytic content with a name. It is to prevent the proof search from treating Li positivity, Weil positivity, Nyman exhaustion, Lee–Yang boundary stability, branch dominance, and tower cofinality as unrelated obligations.

9323.1 Common Generator

Definition 9323.1 (RH circle-triangle-register generator)**.** *An RH circle-triangle-register generator is a certificate packet*

$$\mathcal{R}_\zeta := (\mathcal{G}, \mathsf{PrimeReg}, \mathsf{ZeroRead}, \mathsf{LiRead}, \mathsf{OrthRead}, \mathsf{NoScale})$$

whose rows are as follows. The row $\mathcal{G}$ is a circle-triangle generation packet in the sense of Definition 9290.1. The prime-register row is the source ledger of Definition 9290.5. The zero-read row carries completed non-trivial zero packets. The Li-read row carries $z_\rho = 1 - 1/\rho$. The orthogonal-read row carries the scale-phase defect split of Definition 9290.17. The no-scale row is $\mathsf{NoHiddenScaleFromBEDC}(\mathcal{G})$.

Principle 9323.2 (Projection discipline for RH criteria)**.** *A classical RH criterion is accepted into this dictionary only as a projection of $\mathcal{R}_\zeta$ with a declared visible surface, a declared hidden fiber or residual ledger, and a declared transport back to the zero-read row. A projection may expose time coefficients, energy forms, approximation containers, finite thermal boundaries, branch dominance, or cofinal tower exhaustion. It may not erase the radial scale residual unless the no-scale row has been supplied.*

Definition 9323.3 (Projection row)**.** *A projection row of $\mathcal{R}_\zeta$ is a tuple*

$$\Pi := (V_\Pi, \pi_\Pi : \mathcal{R}_\zeta \to V_\Pi, \Lambda_\Pi, \mathsf{Back}_\Pi).$$

Here V_Π is the visible criterion surface, π_Π is the readout, Λ_Π is the residual ledger retained by that readout, and Back_Π is the transport that converts a violation or positivity certificate on V_Π back into a statement about the zero-read row.

9323.2 Classical Projections

Definition 9323.4 (Li time projection)**.** *The Li time projection reads the iterates*

$$z_\rho^n$$

of the Li coordinate. Its visible surface is the time sequence of defects

$$1 - z_\rho^n.$$

Under a scale-phase read

$$z_\rho = e^{\ell + i\theta},$$

the defect norm splits as

$$|1 - z_\rho^n|^2 = (e^{n\ell} - 1)^2 + 2e^{n\ell}(1 - \cos(n\theta)).$$

Thus the Li surface is the time projection of hidden radial scale.

Principle 9323.5 (Li positivity is a time-facing no-scale test)**.** *Li positivity asks whether the time projection can detect a radial scale leg. If $\ell\#0$, the factor $e^{n\ell}$ is amplified along the append order. Any Li-side positivity theorem that rules out the resulting negative or unbounded time witness is therefore a projection of* NoHiddenScaleFromBEDC*, not an independent source of the unit circle.*

Definition 9323.6 (Weil energy projection)**.** *The Weil energy projection reads the zero packet through a quadratic test form*

$$\mathcal{W}(f)$$

whose visible surface is an energy pairing of zero-side probes. Its residual ledger records which mirror-paired zero packets and test functions were used. An off-line mirror pair supplies an energy channel whose sign can be reversed by an appropriate probe; the projection therefore detects the same radial leg as an energy defect.

Principle 9323.7 (Weil positivity is an energy-facing no-scale test)**.** *Weil positivity is the energy projection of the no-hidden-scale row. A nonzero radial coordinate creates a separated mirror-pair channel, and a test function can read that separation as negative energy. A positive Weil form closes precisely the projection route that would otherwise let radial scale appear as a hidden energy defect.*

Definition 9323.8 (Nyman container projection)**.** *The Nyman container projection reads the zero packet through a closed linear span of scaling correctors in a function space on $(0, 1)$. Its visible surface is the approximation of the target container row, and its residual ledger records separating functionals. If an off-line zero survives, it produces a functional that annihilates the displayed generators while not annihilating the target row. The unexhausted functional is the container-side residue of hidden radial scale.*

Principle 9323.9 (Nyman exhaustion is a container-facing no-scale test)**.** *Nyman exhaustion asks whether the legal scaling generators fill the container without leaving a residual functional. In the dictionary, such a residual functional is the projection of $\ell\#0$ into the container surface. Closing the Nyman span is therefore a container-facing form of the no-hidden-scale obligation.*

Definition 9323.10 (Lee–Yang unit-boundary projection)**.** *The Lee–Yang unit-boundary projection reads finite thermal or algebraic models whose zero sets are forced to a unit circle by a finite positivity or ferromagnetic monotonicity row. Its visible surface is a unit boundary in the finite model. Its residual ledger records which finite interactions, variables, and specialization maps preserve the unit-boundary statement.*

Principle 9323.11 (Lee–Yang boundary is a finite unit model)**.** *Lee–Yang boundary stability is a finite model of the same constraint as $\ell = 0$: zeros may occur only on the unit boundary licensed by the finite packet. It does not by itself prove the zeta zero statement; it supplies a projection pattern showing how finite positivity can enforce unit-circle localization without adding an independent radial register.*

9323.3 Dominance and Cofinality Projections

Definition 9323.12 (Dominant-strand projection)**.** *The dominant-strand projection records which branch, strand, or finite-window carrier actually controls the visible zero-relevant surface. Its residual ledger records branch choices, comparison windows, and maximal-modulus or endpoint dominance rows. A branch point or spectral component is not accepted as the controlling observation merely because it is visible; dominance must be certified as part of the projection row.*

Principle 9323.13 (Dominance prevents false projection collapse)**.** *Dominant-branch theorems are projection-correctness tests. They prevent a visible but non-dominant strand from being mistaken for the zero-relevant generator. In the circle-triangle route, such theorems ensure that the scale-phase leg being tested is the controlling observation vector rather than a discarded or subordinate branch.*

Definition 9323.14 (Tower cofinality projection)**.** *The tower cofinality projection reads a growing family of finite observation spaces*

$$\mathcal{H}_0 \subset \mathcal{H}_1 \subset \cdots$$

with orthogonal residuals

$$v_{m+1} = P_m v_{m+1} + \eta_{m+1}, \qquad \eta_{m+1} \perp \mathcal{H}_m.$$

The visible invariant is

$$|v_{m+1}|^2 = |P_m v_{m+1}|^2 + |\eta_{m+1}|^2.$$

Cofinality asserts that the legal tower exhausts the zero-relevant observation surface rather than leaving a residual functional.

Principle 9323.15 (Tower cofinality is the infinite no-scale test)**.** *The infinite part of the RH route is not a search through unrelated criteria. It is the question whether the fixed generator and its finite observation windows are cofinal. If a nonzero residual remains outside the tower, it is read as a separating functional, an unexhausted scale leg, or a missing source row. The finite Pick tower and the xi Hausdorff moment audit are analytic implementations of this cofinality projection.*

9323.4 Minimal Proof Package

Definition 9323.16 (Prime-register completeness)**.** *Prime-register completeness is the source statement that every zeta oscillation frequency used by the Dirichlet row is generated by the prime*

exponent ledger:

$$n = \prod_p p^{v_p(n)}, \qquad \log n = \sum_p v_p(n) \log p.$$

It supplies the arithmetic part of the generator and prevents zeta phase from being treated as an unledgered continuous frequency.

Definition 9323.17 (Circular-triangular observation completeness)**.** *Circular-triangular observation completeness is the statement that every zero-relevant completed zeta observation has the Li coordinate and orthogonal defect split of Definition 9290.15 and Definition 9290.17, with the source ledgers of $\mathcal{R}_\zeta$ still attached.*

Definition 9323.18 (No hidden radial register)**.** *No hidden radial register is the specialization of Definition 9290.13 to zero-relevant zeta observations. A nonzero radial coordinate*

$$\ell \# 0$$

is neither a unit-circle phase, nor a prime-exponent gauge, nor a free continuous coordinate. It must either enter the ledger as a residual scale row, in which case the object is not pure phase closure, or remain unavailable, in which case the object is not legal.

Theorem 9323.19 (Minimal generator package is conditionally RH-sufficient)**.** *Assume prime-register completeness, circular-triangular observation completeness, no hidden radial register, and the located readback needed to turn absence of radial apartness into equality. Then the BEDC RH section target is inhabited.*

Proof. Let ρ be a completed non-trivial zero packet. Circular-triangular observation completeness supplies

$$z_\rho = 1 - \frac{1}{\rho} = e^{\ell + i\theta}$$

and the defect split

$$|1 - z_\rho^n|^2 = (e^{n\ell} - 1)^2 + 2e^{n\ell}(1 - \cos(n\theta)).$$

If $\ell \# 0$, the radial term is a nonzero scale leg. By no hidden radial register, that leg cannot be absorbed into unit phase or into the prime-register row supplied by prime-register completeness. If it is recorded, the object is not pure phase closure; if it is not recorded, the object is not legal. Thus the radial coordinate is not apart from zero. The located readback gives $\ell = 0$, hence $|z_\rho| = 1$. By Definition 9290.16, $\Re(\rho) = 1/2$. Since the zero packet was arbitrary, the section target is inhabited. □

Principle 9323.20 (Status of the projection dictionary)**.** *The projection dictionary identifies a common source mechanism for the major RH-facing criteria. It does not claim that any of the projected analytic theorems has already been discharged. The remaining proof load is the construction of the generator packet $\mathcal{R}_\zeta$, the no-hidden-radial-register theorem, and a cofinal analytic implementation such as the finite Pick tower or the xi Hausdorff moment audit.*

Chapter 9324

Unresolved Projection Obligation Ledger

chapter 9323 gives the projection dictionary for Li, Weil, Nyman, Lee–Yang, dominance, and cofinal tower readings. The present chapter records only the remaining obligations. The algebraic Li coordinate criterion, the scale-phase defect identity, the orthogonal norm split, and the prime-factorization ledger are treated as background rows supplied by earlier chapters. They are not repeated here as open tasks.

9324.1 Open Projection Obligations

Definition 9324.1 (Zeta BEDC embedding obligation)**.** *The obligation*

$$\mathsf{ZetaBEDCEmbedding}$$

asks for a single BEDC observation certificate for each completed non-trivial zeta zero packet. The certificate must package the carrier, classifier, ledger, boundary, and stability rows for completed zeta, zero readout, functional-equation transport, explicit-formula transport, Li readout, Weil pairing, Nyman container rows, and the prime-register source ledger. The prime-register phase source is already visible; the open part is the unified observation certificate.

Definition 9324.2 (No hidden scale obligation)**.** *The obligation*

$$\mathsf{NoHiddenScaleFromBEDC}$$

asks for an internal BEDC theorem that a nonzero radial scale leg cannot be used as a hidden component of a legal pure zeta closure. The theorem must distinguish unit phase, prime-register data, finite encodable residue, and noncompact positive-real scale. Its target is a ledger statement, not a physical analogy.

Definition 9324.3 (Projection faithfulness obligation)**.** *The obligation*

$$\mathsf{TriProjectionFaithfulness}$$

asks for a commutative projection certificate showing that Li time readout, Weil energy readout, and Nyman container readout detect the same radial scale leg when it exists. The open content is not the individual criterion statements; it is the shared source witness and the transport between the three readouts.

Definition 9324.4 (Dominant observation strand obligation)**.** *The obligation*

$$\mathsf{DominantObservationStrand}$$

asks for a source-side certificate selecting the zero-relevant observation strand. A visible branch, local model, or finite carrier is not enough; the selected strand must be certified as controlling the zero-relevant boundary through a dominance, Rouché, energy, or ledger comparison row.

Definition 9324.5 (Unit-boundary transport obligation)**.** *The obligation*

$$\mathsf{UnitBoundaryTransport}$$

asks for a stable transport from the dominant zeta observation strand to a unit-boundary container such as a Lee–Yang, unitary, compact, or Pick positive model. The transport must expose its boundary nonvanishing and ledger compatibility rows; it may not pass through an unrecorded radial scale.

Definition 9324.6 (Cofinal triangular tower obligation)**.** *The obligation*

$$\mathsf{CofinalTriangularTower}$$

asks for a tower of finite triangular observation spaces whose nondegenerate residual legs are PZG-supported in the sense of Definition 9291.15, and whose residuals are exhausted in the limit. Finite orthogonal residual rows and finite Pick positivity are already reduction rows; the open content is the cofinal exhaustion statement, together with the layerwise source-ledger condition of Definition 9291.16, that prevents a radial residual from being hidden at the far end.

Definition 9324.7 (Cofinal prime-class triangular tower obligation)**.** *The obligation*

$$\mathsf{CofinalPrimeClassTriangularTower}$$

asks for a cofinal family of prime-classifier containers in the sense of Definition 9290.7. For every zero-relevant radial scale witness $\ell\#0$, some finite stage of the family must display a container $\mathcal{C}$ whose register, unit, triangular norm, or boundary row reads the scale as a nonzero obstruction:

$$\mathsf{Obstruction}_{\mathcal{C}}(\ell)\#0.$$

The obstruction may be a visible inert parity boundary, a nonunit normalized phase parameter, a negative energy or pairing row, or a separating residual functional. The obligation is the cofinal prime-class form of NoHiddenRadialRegister: a radial leg may fail to be unit phase, but it may not escape every displayed prime-classifier container.

Definition 9324.8 (Layerwise prime cofinality obligation)**.** *The obligation*

$$\mathsf{LayerwisePrimeCofinality}$$

is the layerwise source form of Definition 9324.7. It asks for a tower of primality-supported layers

$$\Pi_0 \subseteq \Pi_1 \subseteq \Pi_2 \subseteq \cdots$$

as in Definition 9291.12, together with container-relative split, inert, and ramified reads at the finite stages, such that every zero-relevant radial scale witness $\ell\#0$ is detected at some stage:

$$\exists m \quad \mathsf{Obstruction}_{\Pi_m}(\ell)\#0.$$

This is the constructive form of cofinal prime-class detection: the obstruction must be found by a displayed atom layer and its classifier, not by an unledgered prohibition after the zero packet has been inspected.

Definition 9324.9 (Diagonal safety obligation)**.** *The obligation*

DiagonalSafety

asks that the proof system be source-generated and append-only. It forbids a local oracle strategy that first detects a bad zero-side direction and then modifies the certificate to cover that direction. Negative Li witnesses, Weil probes, and Nyman separating functionals must be excluded by the source-side construction itself.

Definition 9324.10 (No hidden radial register obligation)**.** *The obligation*

NoHiddenRadialRegister

is the strengthened gauge form of Definition 9324.2. It asks for a theorem that a nonzero radial coordinate is not unit phase, not a prime-register gauge, not freely erasable finite data, and not an admissible tower tail. A recorded radial coordinate changes the object into a scale-ledgered row; an unrecorded radial coordinate violates ledger completeness.

Definition 9324.11 (Triangular projection equivalence obligation)**.** *The obligation*

TriangularProjectionEquivalence

asks for the converse direction of the projection dictionary: any Li, Weil, or Nyman defect relevant to the completed zeta zero packet must come from the same radial scale witness, and the three projection defects must share a common source certificate. This is the diagrammatic equivalence row tying time, unit, and ledger projections together.

9324.2 Conditional Package

Theorem 9324.12 (Projection obligation package is conditionally sufficient)**.** *Assume the obligations*

ZetaBEDCEmbedding, NoHiddenScaleFromBEDC, TriProjectionFaithfulness, DominantObservationStrand, Ur

Then the BEDC RH section target is inhabited.

Proof. The embedding obligation places each completed non-trivial zero packet in the BEDC observation system. If a radial scale witness were present, the faithfulness and equivalence obligations would expose it through the Li, Weil, and Nyman projections as the same source-side defect. Dominance ensures that the defect belongs to the zero-relevant strand; unit-boundary transport prevents it from passing through a legal unit container; cofinal triangular exhaustion prevents it from escaping to the tower tail; cofinal prime-class detection prevents it from escaping all prime-classifier containers; diagonal safety prevents posterior repair. The hidden-scale and hidden-radial-register obligations then rule out the radial witness inside a legal closure. The zero packet is therefore forced onto the unit Li boundary, and the earlier Li criterion transports that row to the critical-line section. □

9324.3 Compressed Core

Principle 9324.13 (Minimal open core)**.** *The preceding package compresses to three core proof tasks:*

$$\mathsf{ZetaBEDCEmbedding}, \qquad \mathsf{NoHiddenRadialRegister}, \qquad \mathsf{LayerwisePrimeCofinality}.$$

The first supplies the legal observation object, the second forbids a nonzero radial scale as a hidden gauge or ledger-free residual, and the third supplies a cofinal atom-layer tower whose prime classifiers detect any nonzero radial leg at some finite or tower stage. Cofinal prime-class triangular detection, cofinal triangular exhaustion, tri-projection faithfulness, dominant-strand selection, unit-boundary transport, diagonal safety, and projection equivalence are support rows that make these three tasks usable in the completed zeta carrier.

Principle 9324.14 (Status of the unresolved projection ledger)**.** *This ledger lists open obligations only. The already displayed algebraic identities, coordinate criteria, finite factorization rows, and moment reductions are not counted as remaining proof load here. The route to RH through this ledger is conditional on constructing the listed source-side certificates.*

Chapter 9325

Triadic Solenoid Pick Tower

chapter 9289 isolates the source-side obligation behind the phase-prime-triangle reading: completed zeta must enter as a certificate-bearing object, and its Pick positivity must be produced from source data rather than from a posteriori zero information. The present chapter records the finite tower that makes that obligation concrete. Each finite layer builds a positive Pick kernel from a finite solenoid source, positive spectral atoms, and a Hilbert factorization. The remaining unclosed content is the convergence of this finite tower to the completed zeta kernel.

9325.1 Finite Solenoid Sources

Definition 9325.1 (Triadic solenoid Pick layer)**.** *A triadic solenoid Pick layer is a finite packet*

$$\mathcal{T}_m := (S_m, \Sigma_{S_m}, (\gamma_{m,j})_{j=1}^{N_m}, (\alpha_{m,j})_{j=1}^{N_m}, (c_{m,j})_{j=1}^{N_m})$$

with the following rows:

$$S_m \subset \mathsf{Prime}^{\uparrow}$$

is a finite prime window;

$$\Sigma_{S_m} \to \mathbb{T}$$

is the finite solenoid phase projection of Definition 9413.779;

$$\gamma_{m,j}$$

are displayed finite source roles or active modes over the same window;

$$\alpha_{m,j} \in \mathsf{Real}^{\uparrow}_{>0}$$

are their positive frequency readouts; and

$$c_{m,j} \in \mathsf{Real}^{\uparrow}_{>0}$$

are positive spectral weights. The packet contains no independent $\mathsf{Real}^{\uparrow}_{>0}$ *source fiber; positive real numbers occur only as frequency and weight readouts certified by the finite layer.*

Principle 9325.2 (Triadic role of a finite layer)**.** *The layer* $\mathcal{T}_m$ *separates the three BEDC roles:*

$$\mathsf{P}_m := \textit{finite prime ledger and solenoid phase fiber},$$

$$\mathsf{T}_m := \textit{finite active-mode phase flow},$$

and

$$\mathsf{U}_m := \textit{positive spectral weight ledger}.$$

The positivity used below is therefore a finite source row, not an untyped assumption that a limiting positive kernel exists.

Definition 9325.3 (Cofinal finite solenoid tower)**.** *A cofinal finite solenoid Pick tower is a sequence*

$$\mathcal{T}_1, \mathcal{T}_2, \dots$$

such that

$$S_1 \subset S_2 \subset \cdots \subset \mathsf{Prime}^{\uparrow}, \qquad \bigcup_m S_m = \mathsf{Prime}^{\uparrow}$$

at the declared source-ledger scope. The cofinality row states only that every displayed prime row eventually appears in a finite window; it does not assert convergence to the completed zeta kernel.

9325.2 Finite Herglotz Kernels

Definition 9325.4 (Finite positive spectral measure)**.** *For a layer $\mathcal{T}_m$, the finite positive spectral measure is*

$$\nu_m := \sum_{j=1}^{N_m} c_{m,j} \delta_{\alpha_{m,j}^2}.$$

It is a finite source-side measure because each support point $\alpha_{m,j}^2$ and each weight $c_{m,j}$ is displayed in the layer packet and satisfies positivity at that layer.

Definition 9325.5 (Finite Stieltjes and Herglotz readouts)**.** *The finite Stieltjes readout is*

$$S_m(x) := \int_0^\infty \frac{1}{x+t}\, d\nu_m(t) = \sum_{j=1}^{N_m} \frac{c_{m,j}}{x + \alpha_{m,j}^2}.$$

For a centered half-plane coordinate w, define

$$H_m(w) := 2wS_m(w^2) = \sum_{j=1}^{N_m} \frac{2c_{m,j}w}{w^2 + \alpha_{m,j}^2}.$$

Theorem 9325.6 (Finite layer is Herglotz on the right half-plane)**.** *If $\Re(w) > 0$, then*

$$\Re H_m(w) \geq 0.$$

Proof. It is enough to check one summand. For $\alpha > 0$ and $\Re(w) > 0$,

$$\Re \frac{w}{w^2 + \alpha^2} = \frac{\Re(w)(|w|^2 + \alpha^2)}{|w^2 + \alpha^2|^2} \geq 0.$$

Multiplication by the positive coefficient $2c_{m,j}$ preserves nonnegativity, and a finite sum of nonnegative real parts has nonnegative real part. □

Definition 9325.7 (Finite right-half-plane Pick kernel)**.** *The right-half-plane Pick kernel of the finite layer is*

$$P_m(w,\eta) := \frac{H_m(w) + \overline{H_m(\eta)}}{w + \overline{\eta}}.$$

Definition 9325.8 (Finite Hilbert feature map)**.** *For each active mode set*

$$\phi_{m,j}(w) := \sqrt{2c_{m,j}}\,\frac{(w,\alpha_{m,j})}{w^2+\alpha_{m,j}^2} \in \mathbb{C}^2.$$

Let

$$\mathcal{H}_m := \bigoplus_{j=1}^{N_m} \mathbb{C}^2, \qquad \Phi_m(w) := \bigoplus_{j=1}^{N_m} \phi_{m,j}(w).$$

Theorem 9325.9 (Finite Pick kernel has an explicit Hilbert factorization)**.** *For every finite layer,*

$$P_m(w,\eta) = \langle \Phi_m(w), \Phi_m(\eta)\rangle_{\mathcal{H}_m}.$$

Consequently P_m is positive definite.

Proof. For one summand,

$$H_{m,j}(w) := \frac{2c_{m,j}w}{w^2+\alpha_{m,j}^2}.$$

A direct computation gives

$$\frac{H_{m,j}(w) + \overline{H_{m,j}(\eta)}}{w+\overline{\eta}} = 2c_{m,j}\frac{w\overline{\eta} + \alpha_{m,j}^2}{(w^2+\alpha_{m,j}^2)(\overline{\eta}^2+\alpha_{m,j}^2)}.$$

The right side is exactly

$$\langle \phi_{m,j}(w), \phi_{m,j}(\eta)\rangle_{\mathbb{C}^2}.$$

Summing over j gives the displayed factorization in $\mathcal{H}_m$. Positive definiteness follows from the Gram form. □

9325.3 Disk Kernels and the Limiting Target

Definition 9325.10 (Disk transfer of the finite kernel)**.** *Use the centered Cayley coordinate*

$$w(z) := \frac{1+z}{2(1-z)}.$$

Define

$$f_m(z) := H_m(w(z))$$

and

$$K_m(z,\zeta) := \frac{f_m(z) + \overline{f_m(\zeta)}}{1 - z\overline{\zeta}}.$$

The feature map Ψ_m is obtained from $\Phi_m \circ w$ with the standard Cayley kernel factor. Thus K_m is again a finite Gram kernel.

Definition 9325.11 (Completed zeta Pick target)**.** *The completed zeta Pick target is*

$$f_\xi(z) := 2\frac{\xi'}{\xi}\left(\frac{1}{1-z}\right),$$

and

$$K_\xi(z,\zeta) := \frac{f_\xi(z) + \overline{f_\xi(\zeta)}}{1 - z\overline{\zeta}}.$$

Definition 9325.12 (Triadic solenoid Pick tower convergence)**.** *A cofinal finite solenoid Pick tower converges to the completed zeta Pick target when, for every finite disk window $F \subset \mathbb{D}$,*

$$K_m(z,\zeta) \to K_\xi(z,\zeta) \qquad (z,\zeta \in F)$$

with the convergence row supplied by the same source ledger. This is the hard analytic row of the tower.

Theorem 9325.13 (Finite tower convergence gives positive completed kernel)**.** *If a cofinal finite solenoid Pick tower converges to K_ξ, then K_ξ is positive definite.*

Proof. Let $z_1, \ldots, z_N \in \mathbb{D}$ and $a_1, \ldots, a_N \in \mathbb{C}$. For each m, positive definiteness of K_m gives

$$\sum_{i,j=1}^{N} a_i\overline{a_j}K_m(z_i,z_j) \geq 0.$$

Taking the displayed finite-window limit yields

$$\sum_{i,j=1}^{N} a_i\overline{a_j}K_\xi(z_i,z_j) \geq 0.$$

Thus K_ξ is positive definite. □

Theorem 9325.14 (Triadic solenoid Pick tower is conditionally RH-sufficient)**.** *If a cofinal finite solenoid Pick tower converges to the completed zeta Pick target and the standard logarithmic-derivative zero-exclusion transport is available for the same completed zeta carrier, then the BEDC RH section target is inhabited.*

Proof. By Definition 9325.13, K_ξ is positive definite. Hence

$$K_\xi(z,z) \geq 0$$

for every disk row z. Since

$$K_\xi(z,z) = \frac{2\Re f_\xi(z)}{1-|z|^2},$$

we obtain $\Re f_\xi(z) \geq 0$ on the disk. Transporting along $s = 1/(1-z)$ gives the nonnegative real-part read for ξ'/ξ on the right-half critical domain. The stated logarithmic-derivative zero-exclusion transport rules out an off-line zero there; the functional-equation mirror then rules out its reflected off-line companion. Thus the fixed-half section is obtained. □

9325.4 Moment Positivity Target

Definition 9325.15 (Moment positivity for the completed zeta carrier)**.** *Let*

$$S_\xi(x) := 2\frac{d}{dx}\log\xi\left(\frac{1}{2}+\sqrt{x}\right).$$

This convention gives

$$2wS_\xi(w^2) = 2\frac{\xi'}{\xi}\left(\frac{1}{2}+w\right)$$

on the centered branch used by Definition 9325.11. The BEDC moment positivity target for ξ is the certificate that S_ξ is a Stieltjes transform

$$S_\xi(x) = \int_0^\infty \frac{1}{x+t}\,d\nu(t), \qquad \nu \geq 0,$$

with ν constructed from the completed zeta source ledger. Equivalently, when a source-side expansion

$$S_\xi(x) = \sum_{n\geq 0}(-1)^n\mu_n x^{-n-1}$$

is displayed, the moment rows must satisfy the Stieltjes conditions

$$\det(\mu_{i+j})_{i,j=0}^N \geq 0, \qquad \det(\mu_{i+j+1})_{i,j=0}^N \geq 0$$

for every displayed finite N.

Principle 9325.16 (Moment positivity is the remaining finite-tower discharge)**.** *The finite objects of Definition 9325.1 through Definition 9325.9 are already explicit. The remaining proof load is not the abstract existence of a positive kernel; it is the source-side Stieltjes moment certificate of Definition 9325.15. Such a certificate constructs the positive measure, supplies finite atomic approximants by standard moment approximation rows, gives the convergence of Definition 9325.12, and therefore feeds the conditional RH-sufficient theorem above.*

Principle 9325.17 (Status of the triadic solenoid Pick tower)**.** *The tower turns the Source Hilbert positivity request of Definition 9289.24 into a finite sequence of concrete certificate rows: finite solenoid source, finite frequency flow, positive spectral atoms, finite Herglotz function, finite Pick kernel, and finite Hilbert factorization. The limiting identification with the completed zeta kernel remains exactly the* BEDCMomentPositivityForXi *obligation.*

Chapter 9326

Xi Hausdorff Moment Audit

chapter 9325 reduces the source-Hilbert positivity request to the moment positivity of the completed zeta carrier. The present chapter makes that request finite and auditable. Instead of asking directly for a Hilbert space factorization of the completed Pick kernel, it asks for a concrete Hausdorff moment sequence extracted from the source-side logarithmic derivative at a point where the Euler product is safely on the absolutely convergent side. The positive measure, Herglotz function, Pick kernel, and Hilbert factorization are then reconstructed from the moment certificate.

9326.1 Centered Source Moments

Definition 9326.1 (Centered completed zeta carrier)**.** *Let*

$$F(w) := \xi\left(\frac{1}{2} + w\right)$$

and let

$$G(x) := F(\sqrt{x}) = \xi\left(\frac{1}{2} + \sqrt{x}\right)$$

on a displayed branch of $\sqrt{x}$ *near* $x = 1$*. The source base point is*

$$x_0 = 1, \qquad \frac{1}{2} + \sqrt{x_0} = \frac{3}{2}.$$

This base point lies in the half-plane where the zeta Euler product is absolutely convergent.

Definition 9326.2 (Xi source Stieltjes candidate)**.** *The xi source Stieltjes candidate is the normalized logarithmic derivative*

$$S_\xi(x) := 2\frac{G'(x)}{G(x)} = 2\frac{d}{dx}\log\xi\left(\frac{1}{2} + \sqrt{x}\right).$$

The factor 2 *matches Definition 9325.15 and ensures that*

$$2wS_\xi(w^2) = 2\frac{\xi'}{\xi}\left(\frac{1}{2} + w\right)$$

on the centered branch used by the completed zeta Pick target.

Definition 9326.3 (Xi Hausdorff moment row)**.** *The xi Hausdorff moment row is the sequence*

$$a_n := \frac{(-1)^n}{n!} \frac{d^n}{dx^n} S_\xi(x)\Big|_{x=1}, \qquad n \geq 0.$$

Each a_n is a source-side coefficient because it is read from the Taylor data of S_ξ at the base point $x = 1$, corresponding to $s = 3/2$.

Principle 9326.4 (Moment row is independent of zero-location input)**.** *The sequence (a_n) is not computed from the location of zeros. It is extracted from the completed zeta carrier through the logarithmic derivative at a source-side base point. A later proof that (a_n) is a positive moment sequence may imply zero-location information, but that information is not an input to the moment row.*

9326.2 Finite Hausdorff Audit

Definition 9326.5 (Finite difference rows)**.** *For a sequence (a_n), define*

$$\Delta a_n := a_{n+1} - a_n$$

and, for $k \geq 0$,

$$\Delta^k a_n := \sum_{j=0}^{k} (-1)^{k-j} \binom{k}{j} a_{n+j}.$$

Definition 9326.6 (Xi Hausdorff moment positivity)**.** *The certificate*

$$\mathsf{XiHausdorffMomentPositivity}$$

is the family of finite inequalities

$$(-1)^k \Delta^k a_n \geq 0 \qquad (n, k \geq 0)$$

for the moment row of Definition 9326.3. Each displayed pair (n, k) is one finite audit item.

Principle 9326.7 (Hausdorff positivity is a finite audit family)**.** *The positivity target is not an uninspected infinite assertion about a Hilbert space. A failure is witnessed by a finite pair (n, k) with*

$$(-1)^k \Delta^k a_n < 0.$$

A proof supplies a stable rule producing the nonnegativity certificate for each finite pair. Thus the target is an infinite family only in the same sense as an induction or a recursive certificate family, not as an unledgered analytic object.

Theorem 9326.8 (Hausdorff positivity gives a source measure)**.** *Assume* $\mathsf{XiHausdorffMomentPositivity}$ *and the Hausdorff moment theorem for the displayed sequence. Then there is a positive measure μ on $[0, 1]$ such that*

$$a_n = \int_0^1 y^n \, d\mu(y) \qquad (n \geq 0).$$

Proof. By Definition 9326.6, the sequence (a_n) is completely monotone in the Hausdorff sense:

$$(-1)^k \Delta^k a_n \geq 0$$

for every finite pair (n, k). The Hausdorff moment theorem identifies such sequences exactly with moment sequences of positive measures on $[0, 1]$. Applying that theorem gives the displayed measure μ. □

9326.3 From Moments to Stieltjes and Pick Kernels

Definition 9326.9 (Hausdorff transform readout)**.** *For the positive measure μ of Definition 9326.8, define*

$$\widetilde{S}_\xi(x) := \int_0^1 \frac{1}{1+(x-1)y}\, d\mu(y).$$

Near $x = 1$, its Taylor expansion is

$$\widetilde{S}_\xi(x) = \sum_{n\geq 0} (-1)^n a_n (x-1)^n.$$

Definition 9326.10 (Analytic determination row)**.** *The analytic determination row for the xi Hausdorff audit states that the Taylor expansion of S_ξ at $x = 1$ is determined by the moment row (a_n) on a nonempty source neighborhood and that the equality*

$$S_\xi(x) = \widetilde{S}_\xi(x)$$

continues through the displayed zero-free analytic domain by uniqueness of analytic continuation.

Theorem 9326.11 (Hausdorff audit gives the Stieltjes target)**.** *Assume* XiHausdorffMomentPositivity*, the Hausdorff moment theorem for the moment row, and the analytic determination row of Definition 9326.10. Then S_ξ has a positive Stieltjes-type representation.*

Proof. Definition 9326.8 supplies $\mu \geq 0$ on $[0, 1]$. By Definition 9326.9,

$$\widetilde{S}_\xi(x) = \sum_{n\geq 0} (-1)^n a_n (x-1)^n$$

near $x = 1$. The definition of a_n gives the same Taylor expansion for S_ξ at $x = 1$, and the analytic determination row transports the local equality to the displayed analytic domain. Finally the change of variables

$$y = \frac{1}{1+t}$$

turns the Hausdorff transform into a Stieltjes-type transform on $[0, \infty)$, with positive pushed-forward measure. Thus the moment certificate discharges the Stieltjes target of Definition 9325.15. □

Theorem 9326.12 (Xi Hausdorff audit is conditionally RH-sufficient)**.** *Assume* XiHausdorffMomentPositivity*, the Hausdorff moment theorem for the moment row, the analytic determination row, and the standard Stieltjes-to-zero-exclusion transport for the completed zeta carrier. Then the BEDC RH section target is inhabited.*

Proof. By Definition 9326.11, the function S_ξ is represented by a positive Stieltjes-type transform. Hence the associated half-plane function

$$H_\xi(w) := 2wS_\xi(w^2)$$

has nonnegative real part on the right half-plane. The corresponding Pick kernel is therefore positive. The assumed Stieltjes-to-zero-exclusion transport is exactly the analytic discharge route recorded in Definition 9289.25: an off-line zero would produce a forbidden local real-part read near the logarithmic-derivative pole. Thus the completed non-trivial zero packets are transported to the fixed half-line section. □

9326.4 Truncated Witnesses

Definition 9326.13 (Finite Hausdorff audit window)**.** *For $N \geq 0$, the finite Hausdorff audit window is the finite list of inequalities*

$$(-1)^k \Delta^k a_n \geq 0 \qquad (0 \leq n,\ 0 \leq k,\ n+k \leq N).$$

It is a finite BEDC witness surface: all coefficients involved are among

$$a_0, \ldots, a_N.$$

Principle 9326.14 (Truncated moments produce finite positive packets)**.** *When a finite audit window is accompanied by the standard truncated Hausdorff moment construction, it yields a finite positive atomic measure*

$$\mu_N = \sum_{j=1}^{M_N} c_{N,j} \delta_{y_{N,j}}, \qquad c_{N,j} > 0, \quad 0 \leq y_{N,j} \leq 1,$$

matching the displayed moments in that window. The finite transform

$$S_N(x) := \int_0^1 \frac{1}{1+(x-1)y}\, d\mu_N(y)$$

then gives a finite Herglotz function

$$H_N(w) := 2wS_N(w^2),$$

and hence a finite Pick kernel with a finite Hilbert factorization of the form constructed in Definition 9325.9.

Principle 9326.15 (Status of the xi Hausdorff audit)**.** *The RH-facing proof load is reduced to a finite-audit family:*

$$\mathsf{XiHausdorffMomentPositivity}.$$

The finite check at (n,k) is the explicit inequality

$$(-1)^k \sum_{j=0}^{k} (-1)^{k-j} \binom{k}{j} \frac{(-1)^{n+j}}{(n+j)!} \frac{d^{n+j}}{dx^{n+j}} S_\xi(x) \bigg|_{x=1} \geq 0.$$

Together with the analytic determination row, this moment certificate constructs the measure, the Stieltjes transform, the Herglotz function, the Pick kernel, and the Hilbert factorization required by the finite tower.

Chapter 9327

Xi Triangular Moment Certificate Tower

chapter 9326 identifies XiHausdorffMomentPositivity as the finite-audit family behind the completed zeta Pick kernel. The present chapter expands that family into a triangular certificate tower. Each finite level is a concrete difference table, a positive Bernstein ledger, a finite atomic measure, a finite Herglotz function, and a Pick kernel with an explicit Hilbert factorization. Thus the phrase "positive spectral measure" is not used as a primitive existence claim; it is approached through finite certificate rows.

9327.1 Triangular Difference Ledger

Definition 9327.1 (Hausdorff difference triangle)**.** *For the xi moment row (a_n) of Definition 9326.3, the Hausdorff difference triangle is the array*

$$D_{n,k} := (-1)^k \Delta^k a_n, \qquad n, k \geq 0.$$

The entry $D_{n,k}$ is finite: it depends only on

$$a_n, a_{n+1}, \ldots, a_{n+k}.$$

Definition 9327.2 (Finite triangular moment certificate)**.** *For $N \geq 0$, a finite triangular moment certificate is the finite packet*

$$\mathcal{M}_N := \big((a_0, \ldots, a_N), (D_{n,k})_{n+k \leq N}, (\beta_{N,j})_{0 \leq j \leq N}\big),$$

where

$$D_{n,k} = (-1)^k \Delta^k a_n$$

and

$$\beta_{N,j} := \binom{N}{j} D_{j,N-j}.$$

The certificate is positive when

$$D_{n,k} \geq 0 \qquad (n + k \leq N).$$

Principle 9327.3 (Triangular audit is local and finite)**.** *Every level $\mathcal{M}_N$ is checked inside a finite triangular table. A failure of* XiHausdorffMomentPositivity *appears as a specific entry $D_{n,k} < 0$. A successful level exposes positive Bernstein weights $\beta_{N,j}$ and therefore a finite positive measure without calling on a limiting measure as an input.*

9327.2 Bernstein Measure Layer

Definition 9327.4 (Bernstein basis and moment functional)**.** *For $N \geq 0$, set*

$$B_{N,j}(y) := \binom{N}{j} y^j (1-y)^{N-j}, \qquad 0 \leq j \leq N.$$

The finite moment functional L_N is defined on monomials of degree at most N by

$$L_N(y^r) := a_r \qquad (0 \leq r \leq N)$$

and extended linearly to polynomials of degree at most N.

Theorem 9327.5 (Bernstein weights are finite differences)**.** *For $0 \leq j \leq N$,*

$$L_N(B_{N,j}) = \binom{N}{j} (-1)^{N-j} \Delta^{N-j} a_j = \beta_{N,j}.$$

Consequently a positive triangular moment certificate has $L_N(B_{N,j}) \geq 0$ for every j.

Proof. Expanding the Bernstein basis gives

$$B_{N,j}(y) = \binom{N}{j} y^j (1-y)^{N-j} = \binom{N}{j} \sum_{r=0}^{N-j} (-1)^r \binom{N-j}{r} y^{j+r}.$$

Applying L_N gives

$$L_N(B_{N,j}) = \binom{N}{j} \sum_{r=0}^{N-j} (-1)^r \binom{N-j}{r} a_{j+r}.$$

This is exactly

$$\binom{N}{j} (-1)^{N-j} \Delta^{N-j} a_j,$$

which is $\beta_{N,j}$ by Definition 9327.2. □

Definition 9327.6 (Bernstein atomic measure)**.** *The Bernstein atomic measure associated to a positive $\mathcal{M}_N$ is*

$$\mu_N := \sum_{j=0}^{N} \beta_{N,j} \delta_{j/N}.$$

It is a finite positive measure on $[0,1]$ because every $\beta_{N,j}$ is a displayed nonnegative entry of the triangular certificate.

Principle 9327.7 (Bernstein layer is the unit-positive row)**.** *The measure μ_N is the finite U_N row of the triangular certificate tower. It is not asserted by compactness or by a completed moment theorem; its atoms and weights are written directly from the finite difference triangle.*

9327.3 Finite Stieltjes and Herglotz Layer

Definition 9327.8 (Triangular finite Stieltjes readout)**.** *For a positive triangular certificate $\mathcal{M}_N$, define*

$$S_N(x) := \int_0^1 \frac{1}{1+(x-1)y}\, d\mu_N(y).$$

Equivalently,

$$S_N(x) = \sum_{j=0}^{N} \frac{\beta_{N,j}}{1+(x-1)j/N}.$$

Definition 9327.9 (Triangular finite Herglotz readout)**.** *The associated half-plane readout is*

$$H_N(w) := 2wS_N(w^2).$$

For atoms with $j > 0$, set

$$y_j := \frac{j}{N}, \qquad t_j := \frac{1-y_j}{y_j}, \qquad c_j := \frac{\beta_{N,j}}{y_j}.$$

Then the corresponding summand has the form

$$\frac{2c_j w}{w^2+t_j}.$$

The atom $j = 0$ contributes the positive linear term

$$2\beta_{N,0}w.$$

Theorem 9327.10 (Triangular Herglotz positivity)**.** *If $\mathcal{M}_N$ is positive and $\Re(w) > 0$, then*

$$\Re H_N(w) \geq 0.$$

Proof. For every atom with $j > 0$, the summand is

$$\frac{2c_j w}{w^2+t_j}$$

with $c_j \geq 0$ and $t_j \geq 0$. The computation in Definition 9325.6 gives nonnegative real part on the right half-plane. The atom $j = 0$ contributes $2\beta_{N,0}w$, whose real part is $2\beta_{N,0}\Re(w) \geq 0$. A finite sum of nonnegative real parts has nonnegative real part. □

9327.4 Finite Pick and Hilbert Layer

Definition 9327.11 (Triangular finite Pick kernel)**.** *The half-plane Pick kernel of $\mathcal{M}_N$ is*

$$P_N(w,\eta) := \frac{H_N(w) + \overline{H_N(\eta)}}{w+\overline{\eta}}.$$

The disk kernel is obtained through the centered Cayley coordinate

$$w(z) := \frac{1+z}{2(1-z)}$$

by

$$K_N(z,\zeta) := \frac{H_N(w(z)) + \overline{H_N(w(\zeta))}}{1-z\overline{\zeta}}.$$

Definition 9327.12 (Triangular Hilbert feature map)**.** *For each atom with $j > 0$, define*

$$\phi_{N,j}(w) := \sqrt{2c_j}\frac{(w, \sqrt{t_j})}{w^2 + t_j} \in \mathbb{C}^2.$$

For the atom $j = 0$, define a one-dimensional feature

$$\phi_{N,0}(w) := \sqrt{2\beta_{N,0}}.$$

Let

$$\mathcal{H}_N^{\triangle} := \mathbb{C} \oplus \bigoplus_{j=1}^{N} \mathbb{C}^2$$

and

$$\Phi_N^{\triangle}(w) := \phi_{N,0}(w) \oplus \bigoplus_{j=1}^{N} \phi_{N,j}(w).$$

Theorem 9327.13 (Triangular Pick kernel has a finite Hilbert factorization)**.** *For every positive triangular moment certificate,*

$$P_N(w, \eta) = \left\langle \Phi_N^{\triangle}(w), \Phi_N^{\triangle}(\eta) \right\rangle_{\mathcal{H}_N^{\triangle}}.$$

Consequently P_N and K_N are positive definite.

Proof. For $j > 0$, the rank-two factorization is the same calculation as Definition 9325.9 with $\alpha^2 = t_j$ and coefficient c_j. For $j = 0$, the Herglotz summand is $2\beta_{N,0}w$, and its Pick quotient is

$$\frac{2\beta_{N,0}w + 2\beta_{N,0}\overline{\eta}}{w + \overline{\eta}} = 2\beta_{N,0},$$

which is the Gram kernel of $\phi_{N,0}$. Summing the finite Gram factorizations gives the displayed factorization. Positive definiteness is immediate from the Gram form, and the disk kernel is its Cayley transport. □

9327.5 Tower Convergence Target

Definition 9327.14 (Triangular moment certificate tower)**.** *A triangular moment certificate tower is a sequence*

$$\mathcal{M}_0, \mathcal{M}_1, \mathcal{M}_2, \ldots$$

such that each $\mathcal{M}_N$ is positive and the associated transforms S_N converge locally to S_ξ on the displayed analytic domain of Definition 9326.10. The convergence row is part of the certificate; finite positivity alone does not assert it.

Theorem 9327.15 (Triangular certificate tower is conditionally RH-sufficient)**.** *If a triangular moment certificate tower exists, its convergence row identifies the limit with S_ξ, and the standard Stieltjes-to-zero-exclusion transport is available for the completed zeta carrier, then the BEDC RH section target is inhabited.*

Proof. Each level supplies a positive Pick kernel by Definition 9327.13. The convergence row gives the limiting completed zeta kernel, so the limit kernel is positive definite. The Stieltjes-to-zero-exclusion transport then applies exactly as in Definition 9326.12, forcing the completed non-trivial zero packets onto the fixed half-line section. □

Principle 9327.16 (Status of the triangular moment tower)**.** *The triangular tower is the finite constructive form of* XiHausdorffMomentPositivity*. Its level-N data are the moment prefix, the finite difference triangle, the Bernstein weights, the atomic measure, the Herglotz function, the Pick kernel, and the Hilbert feature map. A failed entry gives a finite witness; a successful cofinal tower gives the positive-kernel route required by the RH-facing certificate.*

Chapter 9328

Final Moment Obligation Core

chapter 9326 and chapter 9327 reduce the positive-kernel route to finite moment data. This chapter records the remaining proof load without repeating the reductions. The RH-facing construction has reached a point where the only unresolved mathematical content is the source-side positivity of a specific moment-difference family, or a stronger norm formula explaining that positivity.

9328.1 Moment Difference Surface

Definition 9328.1 (Final moment difference)**.** *For the xi moment row of Definition 9326.3, define*

$$M_{n,k} := (-1)^k \Delta^k a_n.$$

Equivalently,

$$M_{n,k} = \sum_{j=0}^{k} (-1)^j \binom{k}{j} a_{n+j}.$$

Using the defining derivatives of a_n, this becomes

$$M_{n,k} = (-1)^n \sum_{j=0}^{k} \binom{k}{j} \frac{1}{(n+j)!} \left. \frac{d^{n+j}}{dx^{n+j}} S_\xi(x) \right|_{x=1}.$$

Every $M_{n,k}$ is a finite source-side datum.

Definition 9328.2 (Moment norm certificate)**.** *The statement*

$$\mathsf{SourceMomentNormCertificate}$$

asserts that for every finite pair (n,k) there is a Hilbert row $\mathcal{H}_{n,k}$ and a vector $\Psi_{n,k} \in \mathcal{H}_{n,k}$ such that

$$M_{n,k} = \|\Psi_{n,k}\|^2_{\mathcal{H}_{n,k}}.$$

The Hilbert row and the vector must be constructed from the prime, Gamma, rational-boundary, and completed-zeta source ledgers. They may not be defined by using zero locations as posterior data.

Theorem 9328.3 (Norm certificates imply Hausdorff positivity)**.** *If* $\mathsf{SourceMomentNormCertificate}$ *holds, then* $\mathsf{XiHausdorffMomentPositivity}$ *holds.*

Proof. For each finite pair (n, k), the norm certificate gives

$$M_{n,k} = \|\Psi_{n,k}\|^2_{\mathcal{H}_{n,k}}.$$

Norm squares are nonnegative, so $M_{n,k} \geq 0$. Since $M_{n,k} = (-1)^k \Delta^k a_n$, this is exactly the finite inequality family of Definition 9326.6. □

9328.2 Source Decomposition Target

Definition 9328.4 (Prime–Gamma source decomposition)**.** *At the base point $x = 1$, set*

$$s(x) := \frac{1}{2} + \sqrt{x}.$$

The completed logarithmic derivative decomposes on the source side as

$$\frac{\xi'}{\xi}(s) = \frac{1}{s} + \frac{1}{s-1} - \frac{1}{2}\log\pi + \frac{1}{2}\frac{\Gamma'}{\Gamma}\left(\frac{s}{2}\right) + \frac{\zeta'}{\zeta}(s),$$

and for $\Re(s) > 1$,

$$\frac{\zeta'}{\zeta}(s) = -\sum_{m\geq 2} \frac{\Lambda(m)}{m^s}.$$

Thus every derivative appearing in $M_{n,k}$ is sourced by rational boundary terms, Gamma or polygamma terms, and prime-power von Mangoldt terms at $s = 3/2$.

Definition 9328.5 (Prime–Gamma triangular cancellation)**.** *The statement*

PrimeGammaTriadicCancellation

asserts that the decomposition of Definition 9328.4 induces rows

$$M^{\mathrm{rat}}_{n,k}, \qquad M^{\Gamma}_{n,k}, \qquad M^{\mathbb{P}}_{n,k}$$

with

$$M_{n,k} = M^{\mathrm{rat}}_{n,k} + M^{\Gamma}_{n,k} + M^{\mathbb{P}}_{n,k} \geq 0$$

for every finite pair (n, k). The assertion is not that each summand is separately nonnegative; it is that the source decomposition closes without producing a negative triangular moment row.

Principle 9328.6 (Prime–Gamma cancellation is the source-side form)**.** PrimeGammaTriadicCancellation *is the direct source-side positivity problem. It asks for a cancellation law among rational boundary, Gamma, and prime-power rows at the source-safe base point. It does not mention zero locations, and it does not use a limiting Hilbert space as an input.*

9328.3 Triadic Norm Decomposition

Definition 9328.7 (BEDC source norm formula)**.** *The statement*

BEDCSourceNormFormula

is the stronger certificate that each final moment difference has a source-built norm decomposition

$$M_{n,k} = \left\|\Psi^{\text{source}}_{n,k}\right\|^2_{\mathcal{H}_{n,k}}.$$

Equivalently, the vector may be displayed through the three BEDC-facing components

$$M_{n,k} = \|\Psi^{\mathsf{P}}_{n,k}\|^2 + \|\Psi^{\mathsf{U}}_{n,k}\|^2 + \|\Psi^{\mathsf{T}}_{n,k}\|^2,$$

where P *carries prime, Gamma, rational-boundary, and source ledger rows;* U *carries the positive inner-product row; and* T *records that* (n, k) *is a finite witness coordinate.*

Theorem 9328.8 (Source norm formula implies triangular cancellation)**.** *If* BEDCSourceNormFormula *holds and its source projection agrees with the decomposition of Definition 9328.4, then* PrimeGammaTriadicCancellat *holds.*

Proof. The source norm formula gives $M_{n,k}$ as a norm square, hence $M_{n,k} \geq 0$. Agreement with the prime–Gamma source decomposition identifies this same number with

$$M^{\text{rat}}_{n,k} + M^{\Gamma}_{n,k} + M^{\mathbb{P}}_{n,k}.$$

Therefore the displayed sum is nonnegative for every finite pair (n, k). □

Theorem 9328.9 (Final moment core is conditionally RH-sufficient)**.** *If either* BEDCSourceNormFormula *or* PrimeGammaTriadicCancellation *is established in a form that implies* XiHausdorffMomentPositivity*, and if the analytic determination and zero-exclusion transports of chapter 9326 are available, then the BEDC RH section target is inhabited.*

Proof. The source norm formula implies Hausdorff positivity by Definition 9328.3. The prime–Gamma cancellation route is assumed to imply the same finite inequality family. Once XiHausdorffMomentPositivity is available, Definition 9326.12 applies the analytic determination row and the Stieltjes-to-zero-exclusion transport to obtain the RH section target. □

9328.4 Obligation Boundary

Principle 9328.10 (Only the final moment core remains open in this route)**.** *Within the moment route, the unreduced proof load is the construction of one of the following source-side certificates:*

BEDCSourceNormFormula, PrimeGammaTriadicCancellation, XiHausdorffMomentPositivity.

The first is strongest, the second is the explicit source cancellation form, and the third is the finite Hausdorff inequality family. The positive measure, triangular finite tower, Herglotz function, Pick kernel, Hilbert factorization, and RH-facing zero exclusion are reduction surfaces once one of these source-side certificates is supplied.

Chapter 9329

Source-Positive Obligation Frontier

chapter 9328 isolates the finite moment core behind the RH route. This chapter records the remaining source-positive frontier as named proof obligations rather than as another list of equivalent RH criteria. The Li coordinate, the scale-phase split, the Hausdorff reduction, the finite Pick factorizations, and the triangular moment tower are already reduction surfaces in the preceding chapters. The unreduced content is the construction showing that the completed zeta source data generate the positive object those reductions require.

9329.1 Common Observation Coordinate

Definition 9329.1 (Source-positive observation coordinate)**.** *Fix a centered zeta coordinate and an active mode height*

$$s = \frac{1}{2} + r + it, \qquad h_a > 0.$$

The centered mode readout is

$$U_a(s) := e^{-(s-\frac{1}{2})h_a} = e^{-rh_a} e^{-ith_a}.$$

Its logarithmic orthogonal observation vector is

$$v_a(s) := (-rh_a, -th_a).$$

For a finite active packet A_m, set

$$W_m := \sum_{a \in A_m} h_a^2, \qquad E_m^{\text{scale}} := r^2 W_m.$$

The notation is the same scale-phase read used in Definition 9289.13 and Definition 9289.15; it is fixed here only to name the common projection coordinate for the source-positive frontier.

Definition 9329.2 (Triadic frontier roles)**.** *The source-positive frontier reads every unresolved RH-facing obligation through three roles:*

$$\mathsf{P} := \textit{prime, Gamma, rational-boundary, and ledger source rows},$$

$$\mathsf{U} := \textit{unit-boundary, positive-kernel, or positive-measure row},$$

and

$$\mathsf{T} := \textit{finite witness, finite tower, or analytic continuation row.}$$

The role split is a bookkeeping constraint. It does not assert positivity; it identifies which row must carry the source, which row must carry nonnegativity, and which row must make failures finitely visible or transport equality through the analytic domain.

9329.2 Legal Source and Pick Factorization

Definition 9329.3 (ZetaIsBEDCLegalObject)**.** *The obligation*

$$\mathsf{ZetaIsBEDCLegalObject}$$

asserts that every completed zeta observation relevant to a non-trivial zero is represented by a BEDC triadic generator. The P *row displays the source ledger: prime-power frequencies, Gamma normalization, functional-equation normalization, continuation rows, and the prime-register accounting behind logarithmic heights. The* U *row displays the admissible unit-boundary or positive-kernel closure; a positive real radial scale factor may not be hidden in the solenoid prime fiber. The* T *row displays the finite witness tower that connects zero packets, moment packets, and Pick packets without posterior repair.*

Principle 9329.4 (Legal zeta object refines the embedding ledger)**.** $\mathsf{ZetaIsBEDCLegalObject}$ *is the source-positive strengthening of the embedding obligations of Definition 9324.1, Definition 9290.19, and Definition 9289.20. Those obligations name the carrier and projection rows. The legal-object frontier additionally requires that the positive witness used by the RH route be generated from the same source ledger rather than attached after the zero packet has been inspected.*

Definition 9329.5 (Triangular legality rows for completed xi)**.** *A triangular legality row for a completed xi zero packet with centered coordinate*

$$\rho = \frac{1}{2} + r + it$$

is the part of a $\mathsf{ZetaIsBEDCLegalObject}$ *witness that supplies the following data. Each active mode* a *has a source-ledger height* $h_a > 0$ *coming from prime, Gamma, normalization, or continuation rows, and its centered channel is*

$$U_a(\rho) = e^{-(\rho-\frac{1}{2})h_a} = e^{-rh_a}e^{-ith_a}.$$

The solenoid gauge row is phase-valued:

$$0 \to K_S \to \Sigma_S \to \mathbb{T} \to 0, \qquad K_S \cong \prod_{p\in S} \mathbb{Z}_p,$$

so a factor in $\mathsf{Real}^{\uparrow}_{>0}$ *is not a hidden solenoid fibre. The orthogonal observation row is*

$$v_a(\rho) := (-rh_a, -th_a), \qquad |v_a(\rho)|^2 = r^2h_a^2 + t^2h_a^2.$$

For finite active packets A_m*, set*

$$W_m := \sum_{a\in A_m} h_a^2, \qquad E_m^{\mathrm{scale}}(\rho) := r^2 W_m.$$

The cofinal triangular closure row requires

$$W_m \to \infty, \qquad E_m^{\mathrm{scale}}(\rho) \le B_\rho$$

for a bound B_ρ *attached to the zero packet. The bound is a ledgered unit-positive or Pick/Hausdorff stability row; it is not a positive real scale register.*

Theorem 9329.6 (Legal triangular xi construction is conditionally RH-sufficient)**.** *Assume every completed non-trivial xi zero packet carries a* ZetaIsBEDCLegalObject *witness whose triangular legality rows are as in Definition 9329.5. Then the BEDC RH section target is inhabited.*

Proof. Let a completed non-trivial zero packet have centered coordinate

$$\rho = \frac{1}{2} + r + it.$$

The triangular legality rows give

$$E_m^{\mathrm{scale}}(\rho) = r^2 W_m, \qquad W_m \to \infty, \qquad E_m^{\mathrm{scale}}(\rho) \le B_\rho.$$

If $r \# 0$, then $r^2 > 0$, so the first two rows imply

$$E_m^{\mathrm{scale}}(\rho) \to \infty.$$

This contradicts the displayed bound row. Hence the centered radial coordinate has no apartness from zero, and the located real readback in the zero packet gives $r = 0$. Therefore

$$\mathrm{Re}(\rho) = \frac{1}{2}.$$

Since the zero packet was arbitrary, the corresponding section sends every completed non-trivial zero packet to its fixed-half witness. □

Principle 9329.7 (Legal construction is stronger than analytic description)**.** *The theorem does not assert that any formal description of ξ is enough. The construction must retain the source ledger, preserve the triangular square-norm invariant, route visible reads through $\mathbb{T}$ and the compact prime-register fibre, and supply the bounded unit-positive row that prevents E_m^{scale} from becoming an unledgered* $\mathsf{Real}^{\uparrow}_{>0}$ *coordinate. Thus the remaining analytic burden is to construct* ZetaIsBEDCLegalObject*, for example through a source-built Pick factorization or through the xi Hausdorff moment positivity route.*

Definition 9329.8 (SourcePickHilbertFactorization)**.** *For the completed zeta Pick target of Definition 9325.11, the obligation*

SourcePickHilbertFactorization

asserts the existence of a Hilbert row $\mathcal{H}$ and a feature map $\Phi : \mathbb{D} \to \mathcal{H}$ such that

$$K_\xi(z, w) = \langle \Phi(z), \Phi(w) \rangle_{\mathcal{H}}$$

for all displayed disk coordinates z, w. The carrier $\mathcal{H}$ and the map Φ must be constructed from prime, Gamma, rational-boundary, normalization, and continuation source rows. They may not be defined from the posterior zero set of ξ.

Principle 9329.9 (Pick factorization is an aggregate source balance)**.** *The Pick factorization obligation is not a demand that the prime, Gamma, and rational-boundary summands be separately positive kernels. The prime component enters through the sign of ζ'/ζ, while the Gamma and boundary rows carry archimedean and completion data. The frontier requires an aggregate Gram representation for the completed kernel, with the negative and positive source contributions balanced in one source-built inner-product row.*

Definition 9329.10 (PZGSourceCompletenessForZeta)**.** *The obligation*

PZGSourceCompletenessForZeta

asserts that every source-side Dirichlet mode used by the completed zeta carrier is read through the Prime–Zeckendorf–Goedel filtration of Definition 9291.8. In the source-safe half-plane, this means that each mode has the displayed form

$$n^{-s} = n^{-1/2} \exp\left(-(r+it)\sum_{p,k} z_{p,k}(n) F_k \log p\right)$$

for

$$s = \frac{1}{2} + r + it.$$

The pointwise identity follows from the single-mode bridge of Definition 9291.19. The obligation is the uniform source certificate: the same PZG ledger must remain attached to Euler products, logarithmic derivatives, Gamma completion, and the positive moment or Pick readouts used later in the route.

Principle 9329.11 (Analytic continuation is not source-completeness by itself)**.** *Analytic continuation preserves a meromorphic function after the local data and domain are fixed, but it does not by itself prove that the PZG source ledger, positive-kernel row, and finite witness tower have been transported. The continuation row needed here is triadic: it must retain the source ledger, preserve the positive row supplied by the Pick or Hausdorff mechanism, and expose branch and pole boundaries in finite witness data.*

Theorem 9329.12 (Source Pick factorization supplies the positive witness)**.** *If* SourcePickHilbertFactorization *holds, then the completed zeta Pick kernel is positive definite by a source-side certificate.*

Proof. For any finite disk rows $z_1, \ldots, z_N$ and coefficients $c_1, \ldots, c_N$, the factorization gives

$$\sum_{i,j=1}^{N} c_i \overline{c_j} K_\xi(z_i, z_j) = \left\| \sum_{i=1}^{N} c_i \Phi(z_i) \right\|_{\mathcal{H}}^2 \geq 0.$$

The source condition on $\mathcal{H}$ and Φ records that this positive witness belongs to the zeta source ledger rather than to a zero-location oracle. □

9329.3 Moment Positivity Frontier

Definition 9329.13 (Normalized xi moment frontier)**.** *All moment rows in this frontier use the normalization of Definition 9326.2:*

$$S_\xi(x) := 2\frac{G'(x)}{G(x)}.$$

The moment sequence is

$$a_n := \frac{(-1)^n}{n!} \frac{d^n}{dx^n} S_\xi(x)\Big|_{x=1},$$

and the finite moment-difference row is

$$M_{n,k} := (-1)^k \Delta^k a_n.$$

Thus $x = 1$, equivalently $s = 3/2$, is the source-safe base point for the moment audit.

Principle 9329.14 (PrimeGammaTriadicCancellation is the explicit source inequality)**.** PrimeGammaTriadicCance *defined in Definition 9328.5, is the explicit source-side inequality*

$$M^{\mathrm{rat}}_{n,k} + M^{\Gamma}_{n,k} + M^{\mathbb{P}}_{n,k} \geq 0 \qquad (n, k \geq 0).$$

Its P *row is the von Mangoldt, Gamma, and rational-boundary ledger of Definition 9328.4. Its* U *row is the nonnegative aggregate result. Its* T *row is the finite index* (n, k)*, because any failure is a displayed negative entry in the Hausdorff difference triangle.*

Principle 9329.15 (BEDCSourceNormFormula is the square-norm form)**.** BEDCSourceNormFormula*, defined in Definition 9328.7, is the stronger certificate that the same finite moment difference is a source-built norm square:*

$$M_{n,k} = \|\Psi^{\mathrm{source}}_{n,k}\|^2_{\mathcal{H}_{n,k}}.$$

In triadic form, $\Psi^{\mathrm{source}}_{n,k}$ *displays the source ledger row, the unit-positive inner-product row, and the finite difference witness row. This formula implies nonnegativity immediately and explains the cancellation demanded by* PrimeGammaTriadicCancellation*.*

Principle 9329.16 (XiHausdorffMomentPositivity is the finite audit form)**.** XiHausdorffMomentPositivity*, defined in Definition 9326.6, is the finite audit form of source positivity:*

$$(-1)^k \Delta^k a_n \geq 0 \qquad (n, k \geq 0).$$

It is weaker as an explanation than a source norm formula, but it is the exact Hausdorff condition needed to construct a positive measure on $[0, 1]$ *through the route of Definition 9326.8.*

9329.4 Analytic Identification and Finite Tower

Definition 9329.17 (HausdorffToXiAnalyticContinuation)**.** *Assume the Hausdorff moment row produces a positive measure* μ *on* $[0, 1]$ *and the transform*

$$\widetilde{S}_\xi(x) := \int_0^1 \frac{1}{1 + (x-1)y}\, d\mu(y)$$

as in Definition 9326.9. The obligation

HausdorffToXiAnalyticContinuation

asserts that

$$\widetilde{S}_\xi(x) = S_\xi(x)$$

on the displayed analytic domain of the completed zeta carrier. The row must expose the local Taylor agreement at $x = 1$*, the connected analytic domain used for continuation, the branch choice for* $\sqrt{x}$*, and the pole-exclusion information needed to apply uniqueness of analytic continuation without hiding an off-line zero behind a branch or pole boundary.*

Definition 9329.18 (BEDCFiniteMeasureTowerConvergence)**.** *For each positive triangular level* $N \geq 1$*, let*

$$B_{N,j}(y) := \binom{N}{j} y^j (1-y)^{N-j}$$

and form the finite Bernstein atomic measure

$$\mu_N := \sum_{j=0}^{N} L_N(B_{N,j})\delta_{j/N}$$

from the finite moment functional of Definition 9327.4. Define

$$S_N(x) := \int_0^1 \frac{1}{1+(x-1)y}\, d\mu_N(y).$$

The obligation

BEDCFiniteMeasureTowerConvergence

asserts local convergence

$$S_N \to S_\xi$$

on the same displayed analytic domain, with convergence carried by the finite tower ledger rather than by an uninspected limiting measure.

Principle 9329.19 (Tower convergence is the finite constructive form)**.** BEDCFiniteMeasureTowerConvergence *is the finite constructive form of the positive spectral measure. The* P *row is the finite moment and Bernstein ledger, the* U *row is the finite positive atomic measure and its Pick kernel, and the* T *row is local convergence of the tower. It is compatible with Definition 9327.14, whose convergence row identifies the limit with* S_ξ*.*

9329.5 Compressed Frontier Package

Definition 9329.20 (Source-positive unresolved package)**.** *The source-positive unresolved package is the finite list of named proof obligations*

ZetaIsBEDCLegalObject,
PZGSourceCompletenessForZeta,
SourcePickHilbertFactorization,
PrimeGammaTriadicCancellation,
BEDCSourceNormFormula,
XiHausdorffMomentPositivity,
HausdorffToXiAnalyticContinuation,
BEDCFiniteMeasureTowerConvergence.

The list is ordered by proof role rather than by logical independence: the legal-object row admits the completed zeta carrier, the source Pick row gives the kernel-positive target directly, the moment rows give a finite-audit route to the same positivity, and the analytic and tower rows identify the finite or moment constructions with the original completed zeta function.

Principle 9329.21 (Minimal source-positive core)**.** *Inside the moment route, the compressed mathematical core is*

PrimeGammaTriadicCancellation, BEDCSourceNormFormula, HausdorffToXiAnalyticContinuation.

The norm formula is a stronger explanatory form of the cancellation inequality; either route must supply XiHausdorffMomentPositivity*. The analytic continuation row then identifies the Hausdorff transform with the original normalized* S_ξ *rather than with a separate function sharing only Taylor coefficients at the source-safe base point.*

Theorem 9329.22 (Source-positive frontier is conditionally RH-sufficient)**.** *Assume* ZetaIsBEDCLegalObject *and the standard zero-exclusion transport for the completed zeta carrier. Assume either* SourcePickHilbertFactorizati*or the moment route consisting of* XiHausdorffMomentPositivity*, the Hausdorff moment theorem for the xi moment row, and* HausdorffToXiAnalyticContinuation*. Then the BEDC RH section target is inhabited.*

Proof. If the source Pick factorization holds, then Definition 9329.12 gives the positive completed Pick kernel from a source-side certificate. The legal-object row supplies the zero-ledger and no-hidden-radial transport needed to apply the logarithmic-derivative zero-exclusion route of Definition 9289.25.

If instead the moment route is used, Hausdorff positivity supplies a positive measure by Definition 9326.8. The analytic-continuation row identifies its transform with S_ξ on the displayed analytic domain. Then Definition 9326.12 applies the Stieltjes-to-zero-exclusion transport to obtain the RH section target. In both cases, ZetaIsBEDCLegalObject prevents the positive witness from being detached from the completed zeta source ledger. □

Principle 9329.23 (Status of the source-positive frontier)**.** *This frontier contains proof obligations only. It does not reassert the classical equivalences and reductions already recorded in the RH visions. The constructive content still to be supplied is that the prime, Gamma, rational-boundary, normalization, and continuation source data of completed zeta generate a positive moment measure or a source-built Pick factorization whose analytic continuation is the original completed zeta readout.*

Chapter 9330

Zeta BEDC Closure Strength Gate

chapter 9329 names ZetaIsBEDCLegalObject as the source-positive entry condition for the completed zeta carrier, and chapter 9331 records the radial-register package that is conditionally sufficient for the RH section target. The present chapter separates ordinary encodability from the stronger generated-closure condition needed by that package.

9330.1 Closure Strength

Definition 9330.1 (Zeta encodability row)**.** *The zeta encodability row is the statement that every Dirichlet monomial can be written through prime and PZG data:*

$$n = \prod_p p^{v_p(n)} = \prod_{p,k} (p^{F_k})^{z_{p,k}(n)}$$

and therefore

$$n^{-s} = \exp\left(-s \sum_{p,k} z_{p,k}(n) F_k \log p\right).$$

This row is a syntax and readout statement. It does not by itself supply analytic continuation, zero packets, positive kernels, limit ledgers, or closure under the circle–triangle–register invariant.

Definition 9330.2 (Zeta BEDC closure)**.** *The obligation*

$$\mathsf{ZetaBEDCClosure}$$

asserts that the completed zeta route enters BEDC as a generated closure object, not merely as an encodable formula. It consists of the following certificate rows:

$$\zeta^{\uparrow}, \quad \xi^{\uparrow}, \quad \mathsf{NTZeroType}, \quad \mathsf{ZetaZero}, \quad \mathsf{InCritStrip},$$

functional-equation transport, *analytic-continuation transport*, *explicit-formula trans*

Li coordinate readout, *zero-observation readout*, *analytic prime-shift constraint*, *prime-shift analytic compat*

Each displayed row must be admitted through a naming or operation certificate with source specification, pattern specification, classifier specification, stability certificate, and ledger policy. In particular, analytic continuation and limiting interfaces must carry the ledger rows that record branch, pole, gap, and tail data.

Definition 9330.3 (Triadic invariant preservation for zeta)**.** *Triadic invariant preservation for zeta is the assertion that every constructor used by Definition 9330.2 preserves the circle–triangle–register invariant*

$$\mathcal{I}_{\triangle} = \mathcal{I}_{\mathsf{P}} \wedge \mathcal{I}_{\mathsf{U}} \wedge \mathcal{I}_{\mathsf{T}}.$$

Here P *records prime, Gamma, rational-boundary, PZG, and source-ledger rows;* U *records unit-boundary, positive-kernel, or positive-measure rows with no hidden* $\mathsf{Real}^{\uparrow}_{>0}$ *gauge; and* T *records append-only histories, finite witnesses, analytic transport, and cofinal tower ledgers. A constructor may expose a residual only by recording it in one of these rows.*

Principle 9330.4 (Analytic prime shifts are part of zeta closure)**.** *The prime-index motion inside Definition 9330.2 must satisfy* SmoothPrimeShiftConstraint *from Definition 9296.11. Thus the PZG registers may supply discrete source uniqueness, but the completed zeta object is licensed only when those discrete shifts are compatible with holomorphic charts, compact-uniform height control, branch ledgers, Rouché no-wall-crossing, and cofinal tower coverage.*

Principle 9330.5 (Zeta continuation is prime-shift compatible)**.** *The analytic-continuation part of Definition 9330.2 is the stronger obligation* ZetaAnalyticContinuationIsPrimeShiftCompatible *from Definition 9299.4. It requires nested cell compatibility, cocycle compatibility, character-flow compatibility, normal convergence, and no radial anomaly for the continuation rows used by completed zeta.*

Definition 9330.6 (Legal zero closure object)**.** *A legal zero closure object is a completed non-trivial zero packet* ρ *admitted by Definition 9330.2 whose zero observation, Li coordinate, and closure transport are internal rows of the same generated object. Thus*

$$z_\rho := 1 - \frac{1}{\rho}$$

is not an external diagnostic attached after the zero has been selected; it is a displayed readout of the zero packet. Writing

$$z_\rho = e^{\ell + i\theta},$$

the radial row ℓ *must be either absent, ledgered as a scale row, or refused by the legal closure classifier. It cannot be hidden as unit phase, compact prime-register fibre, or ledger-free tail.*

9330.2 Conditional Consequence

Theorem 9330.7 (Strong zeta closure reduces RH to the radial obstruction package)**.** *Assume*

ZetaBEDCClosure, ZetaAnalyticContinuationIsPrimeShiftCompatible, SmoothPrimeShiftConstraint, *Defi*

and assume that every completed non-trivial zero packet is a legal zero closure object in the sense of Definition 9330.6. Then the embedding row needed by Definition 9331.25 is supplied. Consequently, together with

NoHiddenRadialRegister, CofinalTriangularTower,

and the support rows of Definition 9331.5, the BEDC RH section target is inhabited.

Proof. The closure row supplies the completed zeta carrier, completed zero packets, analytic transports, Li coordinate, and limit ledgers as one generated BEDC object. The prime-shift compatibility row supplies the nested cell, cocycle, character-flow, normal-convergence, and no-radial-anomaly

data for the analytic transports. By Definition 9299.5, the smooth prime-shift row follows as the corresponding tower-level constraint: the prime-index motion is not an arbitrary discrete address stream, but an analytic tower with chart compatibility, branch ledger, height control, and no-wall-crossing rows. The triadic preservation row prevents the constructors from changing the circle–triangle–register invariant while passing through Euler products, completion, continuation, zero readout, and positive-kernel or moment readout. The legal zero closure row supplies, for each completed non-trivial zero packet, the internal Li coordinate

$$z_\rho = 1 - \frac{1}{\rho} = e^{\ell + i\theta}.$$

Thus the required ZetaBEDCEmbedding row of Definition 9331.25 is present. Applying that theorem with NoHiddenRadialRegister, CofinalTriangularTower, and the stated support rows gives the BEDC RH section target. □

Principle 9330.8 (Encodability is not closure)**.** *The implication used in this route is not*

$$\textit{zeta is encodable} \Longrightarrow \mathsf{RH}.$$

The needed implication is the stronger closure statement

$$\mathsf{ZetaBEDCClosure} \wedge \mathsf{ZetaAnalyticContinuationIsPrimeShiftCompatible} \wedge \mathsf{SmoothPrimeShiftConstraint} \wedge \textit{Definition 9330.}$$

Only after this gate has been crossed can NoHiddenRadialRegister *and* CofinalTriangularTower *force the Li radial coordinate to vanish. The remaining analytic work is therefore not another notation for zeta, but the construction of the legal generated closure object.*

Chapter 9331

Radial Register Obstruction Frontier

chapter 9324 records the projection-facing proof obligations, and chapter 9329 records the source-positive moment and Pick frontier. The present chapter isolates the radial-register obstruction inside that package. The aim is narrow: state only the unresolved objects needed by the circle–triangle–register route, and discharge the part that is independent of zeta analysis. The discharged part is the compact-gauge obstruction: a compact phase or compact prime-register gauge cannot carry a nontrivial positive-real scale through a continuous group homomorphism.

9331.1 Unresolved Circle–Triangle–Register Package

Definition 9331.1 (TriadicGenerationInduction)**.** *The obligation*

$$\mathsf{TriadicGenerationInduction}$$

is the finite structural induction principle for the circle–triangle–register grammar. Its base rows are finite distinctions, unit phase, and append-only histories. Its constructors are unit-circle phase readout, orthogonal triangular decomposition, and finite residual registration. Its conclusion is that every certified object generated by this grammar carries the triadic invariant

$$\mathcal{I}_{\triangle} = \mathcal{I}_{\mathsf{P}} \wedge \mathcal{I}_{\mathsf{U}} \wedge \mathcal{I}_{\mathsf{T}}.$$

The grammar-specific induction theorem is Definition 9413.364, and its abstract foundation is Definition 9413.366. The open part is not the induction rule, but the coverage of zeta by the constructor grammar.

Definition 9331.2 (ZetaBEDCEmbedding)**.** *The obligation*

$$\mathsf{ZetaBEDCEmbedding}$$

asserts that the completed zeta carrier, completed zero packets, Li coordinates, Weil probes, Nyman containers, explicit-formula rows, functional-equation transport, and source-positive Pick or moment readouts enter the circle–triangle–register grammar as one certified observation object. This is the embedding form of Definition 9324.1 and the zeta constructor form of Definition 9413.373.

Definition 9331.3 (NoHiddenRadialRegister)**.** *The obligation*

$$\mathsf{NoHiddenRadialRegister}$$

asserts that a nontrivial radial factor

$$e^{\ell}, \qquad \ell \# 0,$$

cannot be represented as unit phase, compact prime-register gauge, finite Zeckendorf–Goedel residue erased without ledger, or a harmless tail of a cofinal tower. If it is recorded, the object is scale-ledgered; if it is unrecorded, the object is not legal. In neither case is it a pure unit-phase closure.

Definition 9331.4 (ContinuousDiscreteBridge)**.** *The obligation*

$$\mathsf{ContinuousDiscreteBridge}$$

asserts that the continuous zeta phase and the discrete prime register are two projections of the same source row:

$$e^{-it\log n} \quad \leftrightarrow \quad (v_p(n))_p.$$

The single-mode identity is Definition 9291.19. The open content is global: the bridge must remain lossless, cofinal, and auditable inside the completed zero-relevant packet rather than only for one Dirichlet monomial.

Definition 9331.5 (Projection and tower support obligations)**.** *The support obligations for the radial-register route are:*

$$\mathsf{TriProjectionFaithfulness},$$
$$\mathsf{DominantObservationStrand},$$
$$\mathsf{UnitBoundaryTransport},$$
$$\mathsf{CofinalTriangularTower},$$
$$\mathsf{NoOracleDiagonalSafety},$$
$$\mathsf{FiniteTowerAmplification}.$$

They state respectively that Li, Weil, and Nyman read the same radial leg; that the zero-relevant strand is source-selected; that the strand transports to a unit-boundary container without boundary crossing; that the triangular tower exhausts residuals; that no posterior oracle repairs negative directions; and that one finite positive mechanism grows cofinally across the zeta observation surface.

9331.2 Zeta Source Construction Boundary

Definition 9331.6 (ConstructorTriadicPreservation for xi)**.** *The obligation*

$$\mathsf{ConstructorTriadicPreservation}_{\xi}$$

asserts that every constructor used to build the completed zeta carrier and its positive-kernel readout is triadic-preserving. Its constructor surface includes finite sums, Dirichlet series limits, Euler products, Gamma factors, completed normalization, analytic continuation, logarithmic derivatives, Cayley transforms, Pick kernels, and limiting positive-kernel towers. Each constructor must preserve source ledger, unit-boundary or positivity, and generated witness data in the sense of Definition 9413.365.

Definition 9331.7 (ZetaSourceConstruction)**.** *The obligation*

$$\mathsf{ZetaSourceConstruction}$$

asserts that

$$\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$$

is generated from source-side rows rather than from zero-location data. The prime-power and von Mangoldt rows supply the P *component; the Gamma, power of* π*, and completed boundary rows supply the archimedean* U *component; and the continuation from the source-safe half-plane supplies the* T *component. The open part is not the displayed formula, but the certificate that analytic continuation and completion preserve the source-side positivity needed by the Pick or moment route.*

Theorem 9331.8 (Direct sums preserve source Pick positivity)**.** *Let* K_X *and* K_Y *be positive kernels with source-built Hilbert factorizations*

$$K_X(z,w) = \langle \Phi_X(z), \Phi_X(w)\rangle_{\mathcal{H}_X}, \qquad K_Y(z,w) = \langle \Phi_Y(z), \Phi_Y(w)\rangle_{\mathcal{H}_Y}.$$

Then

$$K_X(z,w) + K_Y(z,w)$$

has a source-built Hilbert factorization on $\mathcal{H}_X \oplus \mathcal{H}_Y$*.*

Proof. Define

$$\Phi(z) := \Phi_X(z) \oplus \Phi_Y(z).$$

Then

$$\langle \Phi(z), \Phi(w)\rangle_{\mathcal{H}_X\oplus\mathcal{H}_Y} = \langle \Phi_X(z), \Phi_X(w)\rangle_{\mathcal{H}_X} + \langle \Phi_Y(z), \Phi_Y(w)\rangle_{\mathcal{H}_Y} = K_X(z,w) + K_Y(z,w).$$

The feature map is source-built from the two source-built feature maps by the displayed direct-sum constructor. □

Theorem 9331.9 (Finite-window limits preserve positive kernels)**.** *Let* (K_m) *be positive kernels on a domain* D *and suppose*

$$K_m(z,w) \to K(z,w)$$

for every displayed finite pair $z, w \in D$*. Then* K *is positive definite.*

Proof. Let $z_1, \ldots, z_N \in D$ and $c_1, \ldots, c_N \in \mathbb{C}$ be displayed. For every m,

$$\sum_{i,j=1}^{N} c_i\overline{c_j}K_m(z_i, z_j) \geq 0$$

because K_m is positive definite. Taking the finite sum through the pointwise limit gives

$$\sum_{i,j=1}^{N} c_i\overline{c_j}K(z_i, z_j) \geq 0.$$

Since the finite window was arbitrary, K is positive definite. □

Principle 9331.10 (Analytic continuation is the remaining constructor risk)**.** *The direct-sum and finite-window limit constructors above are triadic-preserving once their source rows are displayed. The remaining constructor risk in* $\mathsf{ConstructorTriadicPreservation}_\xi$ *is the combined Euler-product, Gamma-completion, and analytic-continuation step: it must preserve source-side Pick, Herglotz, or Hausdorff positivity, not merely equality of meromorphic functions.*

9331.3 Single-Mode Source Bridge

Definition 9331.11 (Prime exponent ledger for a zeta monomial)**.** *For a positive integer n, the prime exponent ledger is the finite support function*

$$\upsilon(n) := (v_p(n))_p, \qquad n = \prod_p p^{v_p(n)}.$$

Its logarithmic height is

$$h_n := \log n = \sum_p v_p(n) \log p.$$

Theorem 9331.12 (A zeta monomial has a prime-ledger phase readout)**.** *For every displayed positive integer n and real phase time t,*

$$n^{-it} = e^{-it \log n} = \exp\left(-it \sum_p v_p(n) \log p\right).$$

Proof. The first equality is the definition of the exponential logarithmic readout for the positive real n. The second equality substitutes the prime exponent ledger identity

$$\log n = \sum_p v_p(n) \log p$$

from Definition 9331.11. Since the ledger has finite support, the displayed sum is finite. □

Principle 9331.13 (Status of the single-mode bridge)**.** *Definition 9331.12 closes only the single-mode bridge. It proves that one Dirichlet monomial has continuous unit-phase readout and discrete prime-register provenance. It does not prove the global* ContinuousDiscreteBridge *obligation for completed zeta zero packets, where functional-equation transport, analytic continuation, explicit-formula rows, and cofinal tower coverage must share the same source certificate.*

9331.4 Invariant Separation

Definition 9331.14 (Expressible but not generated)**.** *An object is* expressible but not generated *relative to a BEDC grammar when its external notation is well formed, but no derivation from the declared initial packets and constructors reaches a certificate for that object. The distinction is semantic for this chapter: a complex coordinate, a formal zero packet, or a radial parameter may be written in ambient notation without being admitted by the circle–triangle–register construction grammar.*

Definition 9331.15 (Hidden scale energy)**.** *For a proposed pure phase closure packet, let*

$$\ell_1, \ldots, \ell_N$$

be the displayed radial scale legs not recorded as scale-ledgered rows. Its hidden scale energy is

$$\mathcal{E}_{\text{scale}} := \sum_{i=1}^{N} \ell_i^2.$$

For an iterated Li observation, the corresponding finite observation energy at level n is

$$\mathcal{E}_{\text{scale}}(n) := \sum_{i=1}^{N} (e^{n\ell_i} - 1)^2.$$

A pure phase closure is scale-clean when

$$\mathcal{E}_{\text{scale}} = 0.$$

Principle 9331.16 (Scale energy is not cancelled by mirror signs)**.** *The obstruction is quadratic rather than additive. Opposite radial parameters may have zero algebraic sum,*

$$\ell + (-\ell) = 0,$$

but their hidden scale energy is

$$\ell^2 + (-\ell)^2 = 2\ell^2.$$

Thus a radial leg cannot be erased by pairing it with an opposite radial leg inside a pure phase closure. It must either be absent, or be recorded as explicit scale-ledger data.

Theorem 9331.17 (Scale-clean invariant for generated pure closures)**.** *Every pure closure generated by the circle–triangle–register grammar and satisfying the no-hidden-scale ledger rule has*

$$\mathcal{E}_{\text{scale}} = 0.$$

Proof. Proceed by structural induction on the generating certificate. The initial distinction split has only append-only history and orthogonal residual rows. Any residual used by the packet is recorded in the ledger, so it is not an unrecorded radial scale leg. A circle constructor adds a unit phase $e^{i\theta}$ and hence has radial coordinate $\log |e^{i\theta}| = 0$. A triangle-readout constructor decomposes a readout into an existing projection and an orthogonal residual; if that residual is used, the register rule records it, and if it is not recorded the packet is not legal. The register constructor converts a displayed residual into ledger data and therefore does not create hidden scale. Hence no generated pure closure contains an unrecorded nonzero radial leg. The hidden scale energy is a sum of squares over an empty or zero family, so it is 0. □

Theorem 9331.18 (Off-line Li coordinates are not generated pure closures)**.** *Let a completed zero candidate have Li coordinate*

$$z_\rho = 1 - \frac{1}{\rho} = e^{\ell + i\theta}.$$

If $\ell \# 0$, then the candidate cannot be a generated pure circle–triangle–register closure satisfying the no-hidden-scale ledger rule.

Proof. For any displayed positive observation level n, the Li defect decomposition of Definition 9290.17 contains the radial square

$$(e^{n\ell} - 1)^2.$$

When $\ell \# 0$, this is a nonzero scale leg for some displayed observation. If it is recorded, the packet is scale-ledgered and not a pure phase closure by Definition 9331.23. If it is not recorded, it contributes positive hidden scale energy, contradicting Definition 9331.17. Hence the candidate is expressible in ambient notation but not generated as a legal pure closure by the stated grammar. □

9331.5 Compact Gauge Obstruction

Definition 9331.19 (Compact legal gauge)**.** *A legal gauge row K is* compact *when it is a compact topological group and all gauge readouts used by a pure phase closure are continuous group homomorphisms from K to the displayed target group. Unit phase containers and finite-prime solenoid fibres are read as compact legal gauges at the scope where their compactness row is displayed.*

Theorem 9331.20 (Compact gauges have no nontrivial radial character)**.** *Let K be a compact legal gauge and let*

$$\phi : K \to \mathbb{R}_{>0}$$

be a continuous group homomorphism, with $\mathbb{R}_{>0}$ under multiplication. Then

$$\phi(K) = \{1\}.$$

Proof. The image $H := \phi(K)$ is compact because K is compact and ϕ is continuous. It is a subgroup of $\mathbb{R}_{>0}$ because ϕ is a group homomorphism. Apply the logarithm isomorphism

$$\log : \mathbb{R}_{>0} \to \mathbb{R}.$$

Then $\log H$ is a compact subgroup of the additive group $\mathbb{R}$. If $x \in \log H$ and $x\#0$, then all integer multiples

$$nx \qquad (n \in \mathbb{Z})$$

lie in $\log H$, because $\log H$ is a subgroup. This set is unbounded in $\mathbb{R}$, contradicting compactness. Hence every element of $\log H$ is 0, so $\log H = \{0\}$ and therefore $H = \{1\}$. □

Corollary 9331.21 (Compact phase and prime gauges cannot hide scale)**.** *If the legal hidden row of a pure zeta phase closure is compact, then no nontrivial radial factor e^{ℓ} with $\ell\#0$ can be supplied by that hidden row.*

Proof. A hidden compact gauge would supply the radial factor through a continuous character

$$\phi : K \to \mathbb{R}_{>0}.$$

By Definition 9331.20, the image of ϕ is $\{1\}$. Thus every radial factor obtained from the compact gauge is trivial. □

9331.6 Ledgered Scale Is Not Pure Closure

Definition 9331.22 (Scale-ledgered closure)**.** *A zeta observation packet is* scale-ledgered *when its ledger contains a nontrivial radial row*

$$\ell\#0$$

or the corresponding positive factor e^{ℓ}. A scale-ledgered packet may be a legal object with an explicit residual, but it is not a pure unit-phase closure.

Theorem 9331.23 (Recorded radial scale changes the closure type)**.** *If a zeta observation packet records a radial row $\ell\#0$, then it is not a pure unit-phase closure.*

Proof. By Definition 9331.22, recording $\ell\#0$ makes the packet scale-ledgered. A pure unit-phase closure has only unit phase, orthogonal unit readout, and legal compact or finite ledgers as hidden rows; it has no nontrivial positive-real radial row. Therefore a packet with recorded radial scale has changed closure type. □

Principle 9331.24 (Two ways a radial factor is refused)**.** *The radial obstruction has two independent parts. If the radial factor is sent through compact phase or compact prime gauge, it is trivial by Definition 9331.20. If it is recorded as ledger data, it is no longer pure phase closure by Definition 9331.23. The remaining open content of* NoHiddenRadialRegister *is the global classification that every legal zeta gauge is either compact in this sense or ledger-explicit in this sense.*

9331.7 Conditional Core

Theorem 9331.25 (Radial obstruction package is conditionally RH-sufficient)**.** *Assume*

ZetaBEDCEmbedding, NoHiddenRadialRegister, CofinalTriangularTower,

together with the support rows of Definition 9331.5. Then the BEDC RH section target is inhabited.

Proof. The embedding row supplies, for each completed non-trivial zero packet ρ, a circle–triangle–register observation with Li coordinate

$$z_\rho = 1 - \frac{1}{\rho} = e^{\ell + i\theta}.$$

If $\ell \# 0$, the radial leg is nontrivial. The no-hidden-radial-register row says that this leg is neither unit phase nor a legal hidden prime-register gauge and cannot disappear as unledgered finite data. The projection faithfulness support row exposes the same radial leg through the Li, Weil, and Nyman readouts; the cofinal triangular tower prevents it from being postponed to the infinite tail; diagonal safety prevents posterior repair by a zero-dependent oracle. Thus a legal pure zeta closure cannot have $\ell \# 0$. The located readback gives $\ell = 0$. By Definition 9290.16,

$$\left|1 - \frac{1}{\rho}\right| = 1 \Longleftrightarrow \Re(\rho) = \frac{1}{2}.$$

Since the zero packet was arbitrary, the RH section target is inhabited. □

Principle 9331.26 (Status of the radial obstruction frontier)**.** *The compact-gauge obstruction and the single-mode prime-ledger bridge are closed local rows. They do not close the zeta embedding, projection faithfulness, or cofinal tower obligations. The remaining core is the global theorem that every zero-relevant zeta gauge is compact or ledger-explicit, and that the finite triangular tower covers the completed zero ledger without an oracle-dependent repair step.*

Chapter 9332

Bulk–Boundary Prime-Shadow Interface for RH

chapter 9254 identifies the RH statement as a section over the zeta-zero source carrier, while chapter 9246 isolates the carrier-level incompatibility still required by the prime-window route. The present chapter records a typed interface between these two readings. It treats prime defects as boundary-visible shadows of a single constrained body and states the exact hypotheses under which that interface yields the BEDC-RH witness target. The chapter supplies only a conditional assembly schema; the analytic content remains the displayed incompatibility row.

9332.1 Bulk and Boundary Data

Definition 9332.1 (Omega boundary readout diagram)**.** *An Omega boundary readout diagram is a tuple*

$$\mathcal{D}_\Omega := (I, (R_i, \sim_i, C_i, \alpha_i, \rho_{ji}, \Lambda_i)_{i\in I})$$

where I is a directed preorder, R_i is the carrier of the i-th readout layer, $\sim_i$ is its classifier, C_i is its legality predicate, $\alpha_i : R_i \to R_i$ is its self-similar operation, Λ_i is its ledger, and $\rho_{ji} : R_j \to R_i$ is the readback map whenever $j \geq i$. The readback maps satisfy

$$\rho_{ii} = \mathrm{id}_{R_i}, \qquad \rho_{ki} = \rho_{ji} \circ \rho_{kj} \quad (k \geq j \geq i),$$

and preserve classifiers:

$$x \sim_j y \to \rho_{ji}(x) \sim_i \rho_{ji}(y).$$

The self-similar operations are compatible when

$$\rho_{ji}(\alpha_j(x)) \sim_i \alpha_i(\rho_{ji}(x))$$

for all $j \geq i$ and $x : R_j$.

Definition 9332.2 (Boundary limit with ledger)**.** *The ledgered boundary limit of $\mathcal{D}_\Omega$ is*

$$\partial_\infty \mathcal{D}_\Omega := \sum_{(r_i)\in\prod_{i\in I} R_i} \left(\prod_{i\in I} C_i(r_i)\right) \times \left(\prod_{j\geq i} \rho_{ji}(r_j) \sim_i r_i\right) \times \Lambda_\partial.$$

The component Λ_∂ records the readback rows, compression sources, and legality witnesses consumed by the limit carrier.

Definition 9332.3 (Bulk-boundary exactness)**.** *Let T_Ω be a constrained bulk carrier with projections*

$$\pi_i : T_\Omega \to R_i.$$

The comparison map

$$\kappa : T_\Omega \to \partial_\infty \mathcal{D}_\Omega$$

sends x to the compatible family $((\pi_i(x))_{i\in I}, \Lambda_x)$. Bulk-boundary exactness is the conjunction

$$\mathsf{BulkBoundaryExact}_\Omega(T_\Omega) := \mathsf{Full}_\kappa \times \mathsf{Faithful}_\kappa \times \mathsf{LedgerExact}_\kappa.$$

Here Full_κ says every compatible boundary family is represented by a bulk row, $\mathsf{Faithful}_\kappa$ says equality of all boundary projections identifies bulk rows, and $\mathsf{LedgerExact}_\kappa$ says information compressed by the projection is recoverable from the boundary ledger.

Theorem 9332.4 (Exactness excludes ghost bulk distinctions)**.** *If $\mathsf{BulkBoundaryExact}_\Omega(T_\Omega)$ holds, then there are no bulk rows $x, y : T_\Omega$ such that*

$$\prod_{i\in I}(\pi_i(x) \sim_i \pi_i(y))$$

holds while x and y remain distinct in the bulk classifier.

Proof. The displayed product is exactly the premise consumed by $\mathsf{Faithful}_\kappa$. Hence $x \sim_\Omega y$, contradicting any claimed bulk distinction. The ledger-exact component ensures that the argument is not merely pointwise: any compressed distinction would have to appear in the boundary ledger and therefore in one of the compared rows. □

9332.2 Prime Sieve and Shadows

Definition 9332.5 (Prime invariant packet)**.** *For a readout layer R_i, a prime invariant packet on a row $r : R_i$ is the displayed product*

$$\mathsf{PrimeInv}_i(r) := \mathsf{Irred}_i(r) \times \mathsf{PrimeLike}_i(r) \times \mathsf{Valuation}_i(r) \times \mathsf{Factorization}_i(r) \times \mathsf{EulerLocal}_i(r).$$

In the arithmetic layer this packet is read through the $\mathsf{Prime}^\uparrow$ certificate rows: prime classifier, trial division, factorization composition, Euclid-style divisibility, unboundedness, and Euler-local response.

Definition 9332.6 (Prime sieve)**.** *For a target layer R_i, the prime sieve is the class of arrows $f : X \to R_i$ whose image carries prime invariant packets:*

$$f \in \mathsf{PrimeSieve}_i \quad :\Longleftrightarrow \quad \prod_{x:X} \mathsf{PrimeInv}_i(f(x)).$$

Theorem 9332.7 (Prime sieve is closed under precomposition)**.** *If $f : X \to R_i$ belongs to $\mathsf{PrimeSieve}_i$ and $g : Y \to X$ is any arrow, then $f \circ g : Y \to R_i$ belongs to $\mathsf{PrimeSieve}_i$.*

Proof. For each $y : Y$, the row $(f \circ g)(y)$ is $f(g(y))$. Since $g(y) : X$ and f belongs to the prime sieve, $\mathsf{PrimeInv}_i(f(g(y)))$ holds. This is the required product over Y. □

Definition 9332.8 (Prime shadows and defects)**.** *For $x : T_\Omega$, the prime shadow at layer i is*

$$\mathsf{PrimeShadow}_i(x) := \mathsf{PrimeInv}_i(\pi_i(x)).$$

Assume the layer carries a defect-magnitude readout

$$|\mathsf{PrimeShadow}_i(x)|_i : M_i.$$

The layer defect predicate is

$$\mathsf{PrimeDefect}_i(x) := (|\mathsf{PrimeShadow}_i(x)|_i \# 0),$$

and the bulk prime-defect predicate is

$$\mathsf{PrimeDefect}_\Omega(x) := \sum_{i \in I} \mathsf{PrimeDefect}_i(x).$$

Prime normality is the absence of such a displayed defect:

$$\mathsf{PrimeNormal}_\Omega(x) := \neg \mathsf{PrimeDefect}_\Omega(x).$$

Definition 9332.9 (Prime-shadow faithfulness)**.** *Prime-shadow faithfulness is the statement*

$$\mathsf{PrimeShadowFaithful}_\Omega := \prod_{x:T_\Omega} \left(\mathsf{PrimeInv}_\Omega(x) \# 0 \to \sum_{i \in I} \mathsf{PrimeDefect}_i(x) \right).$$

It says that a nonzero bulk prime invariant cannot be invisible to all boundary readout layers.

Theorem 9332.10 (Ledgered prime expansion gives shadow detection)**.** *Assume* $\mathsf{BulkBoundaryExact}_\Omega(T_\Omega)$*. If the bulk prime invariant ledger of x expands through the boundary ledger, then a nonzero bulk prime invariant in x yields* $\mathsf{PrimeDefect}_i(x)$ *for some $i \in I$.*

Proof. By $\mathsf{LedgerExact}_\kappa$, every bulk prime-invariant witness compressed by κ is recorded in the boundary ledger. If the witness is nonzero, the boundary ledger expansion places that nonzero witness in one coordinate row. That coordinate is precisely a layer i with $|\mathsf{PrimeShadow}_i(x)|_i \# 0$, hence $\mathsf{PrimeDefect}_i(x)$. □

9332.3 Zero Atoms and Defect Incompatibility

Definition 9332.11 (Omega zero atom)**.** *Let*

$$\pi_\zeta : T_\Omega \to R_\zeta$$

be the projection to the zeta-zero readout layer. The Omega zero atom and non-trivial Omega zero atom predicates are

$$\mathsf{ZeroAtom}_\Omega(x) := \mathsf{ZetaZero}(\pi_\zeta(x)),$$

and

$$\mathsf{NTZeroAtom}_\Omega(x) := \mathsf{ZeroAtom}_\Omega(x) \times \mathsf{InCritStrip}(\pi_\zeta(x)).$$

This is the Ω-indexed reading of the source carrier $\mathcal{Z}_\zeta$ from Definition 9254.1.

Definition 9332.12 (Prime-defect zero incompatibility)**.** *The direct incompatibility form is*

$$\mathsf{PrimeDefectZeroIncompatibility}_\Omega := \prod_{x:T_\Omega} (\mathsf{NTZeroAtom}_\Omega(x) \times \mathsf{PrimeDefect}_\Omega(x) \to \bot)\,.$$

The constructive apartness form is

$$\mathsf{PrimeDefectApartZero}_\Omega := \prod_{x:T_\Omega} (\mathsf{InCritStrip}(\pi_\zeta(x)) \times \mathsf{PrimeDefect}_\Omega(x) \to \mathsf{Apart}_0(\zeta(\pi_\zeta(x))))\,.$$

Theorem 9332.13 (Apart-zero form gives defect-zero incompatibility)**.** *Assume* $\mathsf{PrimeDefectApartZero}_\Omega$ *and zero-ledger soundness, namely*

$$\mathsf{ZeroAtom}_\Omega(x) \to \zeta(\pi_\zeta(x)) = 0.$$

Then $\mathsf{PrimeDefectZeroIncompatibility}_\Omega$ *holds.*

Proof. Let $x : T_\Omega$ carry both $\mathsf{NTZeroAtom}_\Omega(x)$ and $\mathsf{PrimeDefect}_\Omega(x)$. The non-trivial zero atom supplies $\mathsf{InCritStrip}(\pi_\zeta(x))$ and $\mathsf{ZeroAtom}_\Omega(x)$. The apart-zero form gives

$$\mathsf{Apart}_0(\zeta(\pi_\zeta(x))).$$

Zero-ledger soundness gives $\zeta(\pi_\zeta(x)) = 0$. These two rows are incompatible, yielding $\bot$. □

9332.4 Conditional RH Assembly

Definition 9332.14 (Omega RH interface)**.** *The Omega-indexed RH target is*

$$\mathsf{RH}_\Omega := \prod_{x:T_\Omega} (\mathsf{NTZeroAtom}_\Omega(x) \to \mathsf{OnCritLine}(\pi_\zeta(x)))\,.$$

It is transported to the BEDC-RH predicate when every legal non-trivial zeta-zero packet is represented by a row of T_Ω *through* π_ζ *and* $\mathsf{OnCritLine}$ *is stable under the zeta-layer classifier.*

Theorem 9332.15 (Prime-shadow sufficient interface for RH)**.** *Assume the following data:*

$$\mathsf{BulkBoundaryExact}_\Omega(T_\Omega), \qquad \mathsf{PrimeShadowFaithful}_\Omega,$$
$$\mathsf{PrimeDefectApartZero}_\Omega, \qquad \textit{zero-ledger soundness},$$
$$\prod_{x:T_\Omega} (\neg\mathsf{PrimeDefect}_\Omega(x) \to \mathsf{PrimeNormal}_\Omega(x)),$$
$$\prod_{x:T_\Omega} (\mathsf{NTZeroAtom}_\Omega(x) \times \mathsf{PrimeNormal}_\Omega(x) \to \mathsf{OnCritLine}(\pi_\zeta(x))),$$

and representation of every legal non-trivial zeta-zero packet in T_Ω*. Then the BEDC-RH predicate of Definition 9239.7 holds.*

Proof. By Definition 9332.13, the apart-zero form and zero-ledger soundness give $\mathsf{PrimeDefectZeroIncompatibility}_\Omega$. Fix $x : T_\Omega$ with $\mathsf{NTZeroAtom}_\Omega(x)$. If $\mathsf{PrimeDefect}_\Omega(x)$ held, incompatibility would yield $\bot$. Hence $\neg\mathsf{PrimeDefect}_\Omega(x)$, and the located classifier row gives $\mathsf{PrimeNormal}_\Omega(x)$. The prime-normal-to-critical-line row then yields $\mathsf{OnCritLine}(\pi_\zeta(x))$, so RH_Ω holds. Representation of legal non-trivial zeta-zero packets through π_ζ transports this statement to the BEDC-RH predicate. □

Principle 9332.16 (Status of the interface)**.** *The sufficient interface above rephrases the RH route as prime-shadow rigidity over a ledgered bulk-boundary diagram. It does not discharge Definition 9246.13; rather, it identifies that incompatibility as the analytic carrier row that prevents a non-trivial zero atom from carrying a positive prime defect.*

Concretized in §8791: Finite prime-shadow boundary interface for the RH bulk-boundary vision.

Chapter 9333

RH Proof Obligation Package

chapter 9253 isolates the type-theoretic zero fiber, and chapter 9332 isolates the prime-shadow rigidity interface. The present chapter records the proof obligation package obtained by composing those two interfaces. It is not a proof of RH. It states which rows are definitional, which rows are already structural consequences, and which rows carry the remaining analytic content.

9333.1 Constructive Target

Definition 9333.1 (RH witness function)**.** *The BEDC-RH witness function is the dependent function*

$$\Phi : \mathsf{NTZeroType} \to \mathsf{FixedHalfZeroType}$$

whose projection back to NTZeroType *is classifier-equal to the identity. Equivalently, for every source row s with*

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s),$$

it returns a displayed $\mathsf{OnCritLine}(s)$ *witness. This is the constructive target of Definition 9239.7 and the section form of Definition 9253.7.*

Concretized in §9046: The typed fixed-half zero witness packages the witness-function route without proving RH.

Definition 9333.2 (Quantitative off-line barrier)**.** *A quantitative off-line barrier is a function*

$$\beta : \mathsf{Nat}^{\uparrow} \times \mathsf{Nat}^{\uparrow} \to \mathsf{Rat}^{\uparrow}_{>0}$$

such that for every critical-strip row s,

$$|\Re(s) - 1/2| > 2^{-n} \wedge |\Im(s)| \leq T \to |\zeta(s)| \geq \beta(n, T).$$

It is the positive-apartness strengthening on a displayed compact height window. A height-uniform function of n alone is a separate global analytic barrier assumption and is not part of the ordinary fixed-half witness.

Principle 9333.3 (Refutation data must be typed)**.** *A contradiction route contributes to the BEDC-RH witness target only when it is typed as a same-source conflict between a zero ledger and an apart-zero ledger. A classical refutation without the transport rows needed to build Φ does not inhabit Definition 9333.1.*

9333.2 Structural Rows

Definition 9333.4 (Zero-fiber rows)**.** *The zero-fiber part of the package consists of the following rows:*

$$\mathsf{ZetaZeroType} \simeq \mathrm{Fib}_0(\zeta), \qquad \mathsf{NTZeroType} \simeq \sum_s \big(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)\big),$$

and the section equivalence

$$\mathsf{RH} \Longleftrightarrow \mathsf{NTZeroType} \to \mathsf{FixedHalfZeroType}.$$

These are structural descriptions of the target, not analytic exclusions.

Definition 9333.5 (Zero-generator rows)**.** *The zero-generator part of the package consists of the factorization row*

$$G : A \to \mathsf{ZetaDom}^{\uparrow}, \quad \theta_G(a) : \sum_{z:\mathsf{Complex}^{\uparrow}} \big(\mathsf{ZetaVal}(G(a), z) \times z \sim_{\mathsf{Complex}^{\uparrow}} e_{\mathsf{Complex}^{\uparrow}}\big) \quad \Longrightarrow \quad \overline{G} : A \to \mathsf{ZetaZeroType},$$

and the canonical-presentation row asserting that two canonical presentations of the same zero type are equivalent licensed presentations. Hence incompatible canonical generators cannot be presentations of one zero type.

Definition 9333.6 (Omega representation row)**.** *The Ω representation row is the assertion that every legal non-trivial zeta-zero packet is represented by some row of the Omega non-trivial zero carrier*

$$T_\Omega^{nt0} := \sum_{x:T_\Omega} \left(\mathsf{ZetaZero}(\pi_\zeta(x)) \times \mathsf{InCritStrip}(\pi_\zeta(x))\right).$$

This row is the transport bridge from the zero-type statement to the bulk-boundary tower statement.

9333.3 Rigidity Rows

Definition 9333.7 (Prime normal defect)**.** *The prime normal defect predicate is the tower-visible defect*

$$\mathsf{PrimeNormalDefect}_\Omega(x) := \sum_{i \in I} \mathsf{PrimeDefect}_i(x),$$

where each $\mathsf{PrimeDefect}_i(x)$ *is a nonzero prime-shadow readout at boundary layer i. Its negation is*

$$\mathsf{NoPrimeNormalDefect}_\Omega(x) := \neg\mathsf{PrimeNormalDefect}_\Omega(x).$$

This notation packages the same defect surface as Definition 9332.8; it emphasizes the normal direction read by finite prime-window and bulk-boundary shadows.

Definition 9333.8 (Zero atom prime-normal rigidity)**.** *Zero atom prime-normal rigidity is the statement*

$$\mathsf{ZeroAtomNoPrimeNormalDefect}_\Omega := \prod_{x:T_\Omega} \left(\mathsf{NTZeroAtom}_\Omega(x) \to \mathsf{NoPrimeNormalDefect}_\Omega(x)\right).$$

It says that a non-trivial zero atom may carry phase data, but cannot carry a nonzero prime-normal defect.

Definition 9333.9 (Prime-normal critical-line row)**.** *The prime-normal critical-line row is*

$$\mathsf{PrimeNormalImpliesCriticalLine}_\Omega := \prod_{x:T_\Omega} (\mathsf{NTZeroAtom}_\Omega(x) \times \mathsf{NoPrimeNormalDefect}_\Omega(x) \to \mathsf{OnCritLine}(\pi_\zeta(x)))\,.$$

This is the fixed-half interpretation of the absence of prime-normal defect.

Definition 9333.10 (Apart-zero defect row)**.** *The apart-zero defect row is*

$$\mathsf{PrimeDefectApartZero}_\Omega := \prod_{x:T_\Omega} (\mathsf{InCritStrip}(\pi_\zeta(x)) \times \mathsf{PrimeNormalDefect}_\Omega(x) \to \mathsf{Apart}_0(\zeta(\pi_\zeta(x))))\,.$$

Together with zero-ledger soundness, it turns prime-normal defect into a same-source zero and apart-zero conflict.

Theorem 9333.11 (Apart-zero defect gives zero atom prime-normal rigidity)**.** *Assume* $\mathsf{PrimeDefectApartZero}_\Omega$ *and zero-ledger soundness, namely*

$$\mathsf{ZeroAtom}_\Omega(x) \to \zeta(\pi_\zeta(x)) = 0.$$

Then $\mathsf{ZeroAtomNoPrimeNormalDefect}_\Omega$ *holds.*

Proof. Let $x : T_\Omega$ carry $\mathsf{NTZeroAtom}_\Omega(x)$. Suppose, for contradiction, that $\mathsf{PrimeNormalDefect}_\Omega(x)$ holds. The non-trivial zero atom supplies both $\mathsf{InCritStrip}(\pi_\zeta(x))$ and $\mathsf{ZeroAtom}_\Omega(x)$. The apart-zero defect row gives

$$\mathsf{Apart}_0(\zeta(\pi_\zeta(x))).$$

Zero-ledger soundness gives $\zeta(\pi_\zeta(x)) = 0$. This is the same-source conflict of Definition 9253.17. Hence the assumed prime-normal defect is impossible. □

Theorem 9333.12 (Proof obligation package implies RH)**.** *Assume the following rows:*

$$\mathsf{PrimeDefectApartZero}_\Omega, \qquad \textit{zero-ledger soundness}, \qquad \mathsf{PrimeNormalImpliesCriticalLine}_\Omega,$$

and representation of every legal non-trivial zeta-zero packet in T_Ω^{nt0}*. Then the BEDC-RH predicate holds.*

Proof. By Definition 9333.11, the apart-zero defect row and zero-ledger soundness give ZeroAtomNoPrimeNormalDef
For any represented non-trivial zero row $x : T_\Omega^{nt0}$, this yields $\mathsf{NoPrimeNormalDefect}_\Omega(x)$. Applying Definition 9333.9 gives $\mathsf{OnCritLine}(\pi_\zeta(x))$. Representation transports this critical-line witness to every $u : \mathsf{NTZeroType}$, and Definition 9253.7 gives the BEDC-RH predicate. □

Principle 9333.13 (Remaining mathematical content)**.** *After the zero-fiber, generator-factorization, and representation rows are in place, the remaining mathematical content is concentrated in two rigidity rows:*

$$\mathsf{PrimeDefectApartZero}_\Omega, \qquad \mathsf{PrimeNormalImpliesCriticalLine}_\Omega.$$

The first says that a positive prime-normal defect forces apartness from the zero value on the same source row. The second says that absence of such defect is read in the complex projection as the fixed-half condition.

9333.4 Proof Route Ordering

Definition 9333.14 (RH route state)**.** *An RH route state is a packet*

$$\mathsf{RHRouteState} := (\mathsf{AnalyticBase}, \mathsf{ZeroType}, T_\Omega, \mathsf{BulkBoundaryExact}, \mathsf{PrimeSieve}, \mathsf{ZeroRigidity}, \mathsf{CriticalLineReadout}, \mathsf{Wit}$$

The components are interpreted as follows. AnalyticBase *records the closed arithmetic, real, complex, holomorphic, Dirichlet, and zeta interfaces consumed by Definition 9239.7.* ZeroType *is the zero-fiber package of Definition 9333.4.* T_Ω *is the compatible tower body.* BulkBoundaryExact *is the fullness, faithfulness, and ledger-exactness row of Definition 9332.3.* PrimeSieve *is the prime-invariant sieve of Definition 9332.6.* ZeroRigidity *abbreviates Definition 9333.8.* CriticalLineReadout *abbreviates Definition 9333.9. Finally,* WitnessExport *records extraction of* Φ *and the associated modulus and barrier witnesses.*

Principle 9333.15 (Route dependency order)**.** *The route state is ordered by dependency. The analytic base licenses zeta-value and zero predicates. The zero-type package turns those predicates into the source carrier* NTZeroType*. The* Ω *body and bulk-boundary exactness provide a tower representation whose boundary shadows and ledgers are visible. The prime sieve defines the defect surface. The zero-rigidity row rules out prime-normal defect on zero atoms. The critical-line readout converts absence of prime-normal defect into* OnCritLine*. Only after those rows are present can* WitnessExport *produce the BEDC-RH witness function.*

Theorem 9333.16 (Route state closes the witness target)**.** *If an RH route state carries inhabited rows for*

$$\mathsf{ZeroRigidity}, \qquad \mathsf{CriticalLineReadout}, \qquad \mathsf{WitnessExport},$$

and the representation row of Definition 9333.6, then it supplies the witness function

$$\Phi : \mathsf{NTZeroType} \to \mathsf{FixedHalfZeroType}.$$

Proof. Let $u : \mathsf{NTZeroType}$. The representation row supplies $x : T_\Omega^{nt0}$ whose zeta projection is classified with the source of u. The zero-rigidity row yields $\mathsf{NoPrimeNormalDefect}_\Omega(x)$. The critical-line readout row then yields $\mathsf{OnCritLine}(\pi_\zeta(x))$. Transporting this witness along the source classifier gives $\mathsf{OnCritLine}(\pi_s(u))$. Pairing u with that witness gives an element of $\mathsf{FixedHalfZeroType}$ over u, which is $\Phi(u)$. □

9333.5 Witness Export

Definition 9333.17 (Witness export packet)**.** *The witness export packet is*

$$\mathsf{WitnessExport} := (\Phi, \mu, \beta_{\mathrm{loc}}, \mathsf{CriticalLineRestriction}).$$

Here Φ *is the fixed-half section of Definition 9333.1. For a zero-on-strip row* s*, the modulus*

$$\mu_s : \mathsf{Nat}^\uparrow \to \mathsf{Nat}^\uparrow$$

extracts rational approximants witnessing $\Re(s) \sim 1/2$*. The barrier*

$$\beta_{\mathrm{loc}} : \mathsf{Nat}^\uparrow \times \mathsf{Nat}^\uparrow \to \mathsf{Rat}^\uparrow_{>0}$$

is the height-local off-line apartness function of Definition 9333.2. The remaining field is the restriction equivalence between non-trivial zero packets and critical-line height rows described in section 9239.4. The Riemann-von Mangoldt count and the trivial-zero classifier are support ledgers for the full zeta formalization; they are not fields exported by the RH section.

Theorem 9333.18 (Fixed-half section exports the modulus witness)**.** *An inhabitant of*

$$\Phi : \mathsf{NTZeroType} \to \mathsf{FixedHalfZeroType}$$

exports, for each $u : \mathsf{NTZeroType}$*, a modulus row*

$$\mu_{\pi_s(u)} : \mathsf{Nat}^{\uparrow} \to \mathsf{Nat}^{\uparrow}$$

of the kind stated in Definition 9239.13.

Proof. The value $\Phi(u)$ contains the same zero packet u and a witness of $\mathsf{OnCritLine}(\pi_s(u))$. By Definition 9239.13, the constructive content of that $\mathsf{OnCritLine}$ witness is a modulus selecting rational approximants whose distance from $1/2$ is bounded by the requested dyadic tolerance. □

Principle 9333.19 (Barrier export is analytic content)**.** *The function* β_{loc} *is not obtained from the section form alone. It is exported only from the apart-zero defect row when that row is strengthened to a quantitative lower-bound statement on a displayed height window:*

$$|\Re(s) - 1/2| > 2^{-n} \wedge |\Im(s)| \leq T \to |\zeta(s)| \geq \beta(n, T).$$

Thus Φ *records fixed-half membership, while* β_{loc} *records the compact-window lower-bound form of off-line exclusion. A global height-uniform barrier remains a distinct route assumption.*

Principle 9333.20 (Witness export boundary)**.** *The route ordering and witness export packet do not reduce the analytic difficulty of* RH*. They specify the shape of a closed BEDC proof: first a same-source zero/apart-zero exclusion via* $\mathsf{PrimeDefectApartZero}_{\Omega}$*, then a fixed-half readout via* $\mathsf{PrimeNormalImpliesCriticalLine}_{\Omega}$*, and only then the export of* Φ*,* μ*, height-local barrier data when supplied by the analytic route, and critical-line restriction witnesses.*

Chapter 9334

Non-Fixed Orbit Targets for RH

chapter 9254 identifies the RH statement as a section into a fixed half fiber over the zero source. The present chapter isolates the corresponding orbit formulation. It records the tower-internal target that a constructive proof would have to inhabit, and separates that target from weaker refutational orbit exclusions. It does not prove RH.

9334.1 Candidate Carrier and Orbit Predicates

Definition 9334.1 (Critical-strip candidate carrier)**.** *The candidate carrier below the zero source is*

$$\mathcal{C}_\zeta := \sum_s \mathsf{InCritStrip}(s).$$

Write

$$Z_\zeta(c) := \mathsf{ZetaZero}(c)$$

for the zero predicate on this carrier. The mirror readout is the involution

$$J_\zeta : \mathcal{C}_\zeta \to \mathcal{C}_\zeta, \qquad J_\zeta(s) := 1 - \overline{s},$$

with the displayed equation

$$J_\zeta(J_\zeta(c)) = c.$$

The source carrier $\mathcal{Z}_\zeta$ of Definition 9254.1 may equivalently be read as $\sum_{c:\mathcal{C}_\zeta} Z_\zeta(c)$.

Definition 9334.2 (Mirror orbit predicates)**.** *For $c : \mathcal{C}_\zeta$ define the fixed and non-fixed predicates*

$$\mathsf{Fix}_J(c) := (J_\zeta(c) = c), \qquad \mathsf{NonFix}_J(c) := \neg(J_\zeta(c) = c).$$

If

$$c = 1/2 + \delta(c) + i\tau(c),$$

the apart non-fixed predicate is the positive separation certificate

$$\mathsf{ApartNonFix}_J(c) := \sum_{\varepsilon:\mathbb{Q}_{>0}} (|\delta(c)| \geq \varepsilon).$$

The orbit-zero predicate is

$$\mathsf{OrbitZero}_J(c) := Z_\zeta(c) + Z_\zeta(J_\zeta(c)).$$

9334.2 Fixed Section and Orbit Exclusions

Definition 9334.3 (Zero fixed section and orbit exclusions)**.** *The source fixed-section target is*

$$\mathsf{ZeroFix}_\zeta := \prod_{c:\mathcal{C}_\zeta} (Z_\zeta(c) \to J_\zeta(c) = c).$$

The weak non-fixed orbit exclusion is

$$\mathsf{NoZeroOnNonFixedOrbit} := \prod_{c:\mathcal{C}_\zeta} (\mathsf{NonFix}_J(c) \to \neg\mathsf{OrbitZero}_J(c)).$$

The apart orbit exclusion is

$$\mathsf{NoZeroOnApartOrbit} := \prod_{c:\mathcal{C}_\zeta} (\mathsf{ApartNonFix}_J(c) \to \mathsf{Apart}_0(\zeta(c))),$$

where $\mathsf{Apart}_0(\zeta(c))$ *is a positive lower-bound certificate separating* $\zeta(c)$ *from the zero row.*

Theorem 9334.4 (Source fixed section is the RH target)**.** *The source fixed-section target* $\mathsf{ZeroFix}_\zeta$ *is equivalent to the section form* $\mathsf{Sec}_{\mathsf{RH}}$*. This is a scoped readout of the same fixed-half section through the mirror-orbit layer.*

Proof. By Definition 9334.1, an element of $\mathcal{Z}_\zeta$ is a candidate row $c : \mathcal{C}_\zeta$ together with a zero witness $Z_\zeta(c)$. By Definition 9414.163, the mirror fixed equation $J_\zeta(c) = c$ is equivalent to $\Re(c) = 1/2$. The latter is the real half predicate used in Definition 9254.2. Thus a function $Z_\zeta(c) \to J_\zeta(c) = c$ is exactly a section into the fixed real half fiber, and the constructions in Definition 9254.4 give the equivalence. □

Theorem 9334.5 (Fixed section excludes weak non-fixed orbit zeros)**.** *There is a canonical implication*

$$\mathsf{ZeroFix}_\zeta \to \mathsf{NoZeroOnNonFixedOrbit}.$$

Proof. Assume $\mathsf{ZeroFix}_\zeta$ and fix $c : \mathcal{C}_\zeta$ with $n : \mathsf{NonFix}_J(c)$. If the left summand of $\mathsf{OrbitZero}_J(c)$ holds, then $Z_\zeta(c)$ and the fixed section give $J_\zeta(c) = c$, contradicting n. If the right summand holds, apply the fixed section to $J_\zeta(c)$. This gives $J_\zeta(J_\zeta(c)) = J_\zeta(c)$. Since J_ζ is an involution, this identifies c with $J_\zeta(c)$, again contradicting n. Hence $\mathsf{OrbitZero}_J(c)$ is impossible. □

Proposition 9334.6 (Weak orbit exclusion only double-negates fixedness)**.** *There is a canonical map*

$$\mathsf{NoZeroOnNonFixedOrbit} \to \prod_{c:\mathcal{C}_\zeta} (Z_\zeta(c) \to \neg\neg(J_\zeta(c) = c)).$$

Proof. Let $N : \mathsf{NoZeroOnNonFixedOrbit}$ and let $z : Z_\zeta(c)$. To prove $\neg\neg(J_\zeta(c) = c)$, assume $n : \neg(J_\zeta(c) = c)$. The zero witness z gives the left summand of $\mathsf{OrbitZero}_J(c)$. Applying $N(c)(n)$ contradicts that orbit-zero witness. Thus the fixed equation is double-negated. Producing $J_\zeta(c) = c$ itself would require an additional stability, located equality, or decidability principle. □

9334.3 Constructive Apart Route

Theorem 9334.7 (Apart orbit exclusion yields the fixed section under located readout)**.** *Assume the bias readout $\delta : \mathcal{C}_\zeta \to \mathbb{R}$ is located in the sense that, for every rational $q > 0$, a proof of $\neg(|\delta(c)| \geq q)$ gives $|\delta(c)| < q$. Assume also that $\mathsf{Apart}_0(\zeta(c))$ contradicts $Z_\zeta(c)$. Then* $\mathsf{NoZeroOnApartOrbit}$ *supplies* $\mathsf{ZeroFix}_\zeta$*.*

Proof. Fix $c : \mathcal{C}_\zeta$ and $z : Z_\zeta(c)$. It suffices to show $\delta(c) = 0$, since the mirror fixed equation is equivalent to $\delta(c) = 0$ by Definition 9414.163. Let $q : \mathbb{Q}_{>0}$. If $|\delta(c)| \geq q$, then $(q, |\delta(c)| \geq q)$ is an element of $\mathsf{ApartNonFix}_J(c)$. Applying $\mathsf{NoZeroOnApartOrbit}$ yields $\mathsf{Apart}_0(\zeta(c))$, contradicting z. Hence $\neg(|\delta(c)| \geq q)$, and locatedness gives $|\delta(c)| < q$. Since this holds for every positive rational q, the located real readout identifies $\delta(c)$ with zero. Therefore $J_\zeta(c) = c$, giving the fixed section. □

Principle 9334.8 (Constructive orbit boundary)**.** *The tower-internal source target is* $\mathsf{ZeroFix}_\zeta$*. The apart orbit exclusion is a constructive route to that target only when paired with located equality transport for the bias coordinate. The weak non-fixed orbit exclusion is a refutation schema and does not by itself inhabit the BEDC witness type of Definition 9239.8.*

Concretized in §8874: Finite mirror-orbit target packet records the critical-strip candidate, mirror involution, orbit-zero row, fixedness boundary, apartness witness, and weak-exclusion obstruction as NameCert rows.

Chapter 9335

Counterexample Program Safety Flow for RH

chapter 9252 rewrites the critical line as the zero-bias surface of the prime information channels. The present chapter records the adjacent computational normal form. It does not supply a proof of RH. It rewrites the same conjecture as a safety claim for a recognized program run: no accepted run of the counterexample-search flow emits a CounterRH event.

9335.1 Elementary arithmetic interface

Definition 9335.1 (Lagarias bound interface)**.** *The Lagarias bound interface is the displayed arithmetic predicate* $\mathsf{LagBound}(n)$ *on positive natural-number packets:*

$$\mathsf{LagBound}(n) :\Longleftrightarrow \sigma(n) \leq H_n + \exp(H_n)\log(H_n),$$

where

$$\sigma(n) = \sum_{d|n} d, \qquad H_n = \sum_{k=1}^{n} \frac{1}{k}.$$

Write the right-hand side as

$$\mathsf{LagRHS}(n) = H_n + \exp(H_n)\log(H_n).$$

The interface also carries the external transport row

$$\mathsf{RH} \Longleftrightarrow \forall n \geq 1,\ \mathsf{LagBound}(n).$$

Inside the present vision chapter this row is consumed as an equivalence interface, not as an internal BEDC proof of the analytic theorem.

Definition 9335.2 (Lagarias bad packet)**.** *For a positive natural-number packet* n*, define*

$$\mathsf{LagBad}(n) :\Longleftrightarrow \neg\mathsf{LagBound}(n).$$

Equivalently, at the arithmetic display level,

$$\mathsf{LagBad}(n) :\Longleftrightarrow \sigma(n) > \mathsf{LagRHS}(n).$$

Proposition 9335.3 (Bad packets are RH counter packets)**.** *Under the Lagarias bound interface,*

$$\mathsf{RH} \iff \neg\exists n \geq 1,\ \mathsf{LagBad}(n).$$

Proof. The interface gives

$$\mathsf{RH} \iff \forall n \geq 1,\ \mathsf{LagBound}(n).$$

By Definition 9335.2, the negation of the right-hand side is precisely the existence of a positive index with $\mathsf{LagBad}(n)$. Thus RH is equivalent to the absence of Lagarias bad packets. □

Definition 9335.4 (Lagarias interval certificate)**.** *A Lagarias interval certificate*

$$\mathsf{IntervalCert}(n, q, a, b)$$

is a finite rational packet with $a, b \in \mathbb{Q}$ such that

$$a \leq \mathsf{LagRHS}(n) \leq b \qquad \textit{and} \qquad b - a < 2^{-q}.$$

The interval row is the finite comparison surface for the real expression $\exp(H_n)\log(H_n)$; it is not an exact real-number oracle.

Definition 9335.5 (Certified counter packet)**.** *A certified counter packet $\mathsf{CounterLag}(n, q)$ is the existence of rational endpoints a, b such that*

$$\mathsf{IntervalCert}(n, q, a, b) \qquad \textit{and} \qquad b < \sigma(n).$$

It is the finite event saying that the upper interval bound for $\mathsf{LagRHS}(n)$ already lies below the exact divisor sum.

Proposition 9335.6 (Certified counters are sound)**.** *For every positive index n and precision row q,*

$$\mathsf{CounterLag}(n, q) \Longrightarrow \mathsf{LagBad}(n).$$

Proof. Choose rational endpoints a, b witnessing $\mathsf{CounterLag}(n, q)$. Then

$$\mathsf{LagRHS}(n) \leq b < \sigma(n),$$

so $\sigma(n) > \mathsf{LagRHS}(n)$. This is exactly $\mathsf{LagBad}(n)$ by Definition 9335.2. □

9335.2 Program and prime-register carrier

Definition 9335.7 (Counterexample enumerator)**.** *The counterexample enumerator P_{Lag} is the program-flow schema whose state contains a positive index n, a precision parameter q, divisor-sum data, harmonic-number data, a comparison row, and an output row. Its scheduler fairly enumerates pairs (n, q) with $n \geq 1$. At the pair (n, q) it computes the exact rows $\sigma(n)$ and H_n, computes the precision-q interval row for $\exp(H_n)\log(H_n)$, and emits only when that finite row certifies $\mathsf{CounterLag}(n, q)$. When such a packet is accepted, the output row is*

$$\mathsf{CounterRH}(n, q).$$

Proposition 9335.8 (Enumerator output criterion)**.** *The program P_{Lag} emits a $\mathsf{CounterRH}$ event exactly when some positive index satisfies LagBad:*

$$P_{\mathsf{Lag}} \Downarrow \mathsf{CounterRH} \iff \exists n \geq 1,\ \mathsf{LagBad}(n).$$

Proof. If P_{Lag} emits $\mathsf{CounterRH}(n, q)$, the emission row is guarded by the accepted certified counter packet $\mathsf{CounterLag}(n, q)$. By Definition 9335.6, this implies $\mathsf{LagBad}(n)$. Conversely, if $\mathsf{LagBad}(n)$ holds, the strict comparison has a positive gap. Exact arithmetic supplies $\sigma(n)$ and H_n, while interval narrowing for $\exp(H_n)\log(H_n)$ eventually separates the two sides. Hence some precision q gives a certified counter packet. The fair scheduler eventually reaches the pair (n, q) and accepts that packet, so it emits $\mathsf{CounterRH}(n, q)$. □

Definition 9335.9 (Prime-register Godel state)**.** *A prime-register Godel state is a natural-number packet*

$$N = \prod_i p_i^{r_i},$$

where p_i is the i-th displayed prime row and r_i is the value of the i-th register. The register readback and encoding rows satisfy

$$\mathsf{Encode}(\mathsf{Decode}(N))\mathsf{hsame}N.$$

For the RH counterexample program the register list includes the current index, precision budget, divisor-sum accumulators, harmonic numerator and denominator accumulators, comparison state, program counter, and counter-output flag.

Definition 9335.10 (FRACTRAN counterexample program)**.** *A FRACTRAN counterexample program F_{RH} is a finite ordered list of positive rational instructions*

$$f_0, \ldots, f_{m-1}.$$

At state N, the accepted instruction is the least displayed index i such that Nf_i is a natural number, and the next state is

$$N \mapsto Nf_i.$$

The program F_{RH} is the prime-register compilation of P_{Lag}: the listed rational instructions implement the enumerator registers, the certified counter-packet registers, and the counter-output flag.

Proposition 9335.11 (Prime-register preservation of counter output)**.** *The FRACTRAN program F_{RH} reaches a state with positive counter-output flag exactly when P_{Lag} emits* $\mathsf{CounterRH}$*:*

$$F_{\mathsf{RH}} \Downarrow \mathsf{halt}_{\mathsf{RH}} \iff P_{\mathsf{Lag}} \Downarrow \mathsf{CounterRH}.$$

Proof. The compilation is register preserving. The prime exponent of each register prime stores the corresponding program register of P_{Lag}, and each rational instruction performs the guarded increment, decrement, and branch operations of the enumerator. The counter-output flag is set only by the instruction block reached after an accepted certified counter packet, and every accepted certified counter packet routes to that block. Hence the FRACTRAN halt-prime state and the $\mathsf{CounterRH}$ output row are the same event read through different register coordinates. □

9335.3 GroundCompiler run recognition

Definition 9335.12 (RH FRACTRAN event)**.** *An RH FRACTRAN event is a finite tuple*

$$E_k = (N_k, i_k, f_{i_k}, N_{k+1}, C_k),$$

where N_k and N_{k+1} are prime-register Godel states, f_{i_k} is the accepted FRACTRAN instruction, and C_k is a step-certificate row proving

$$N_{k+1}\mathsf{hsame}N_k f_{i_k},$$

with i_k the least displayed instruction index for which $N_k f_{i_k}$ is a natural-number packet.

Definition 9335.13 (Recognized RH run)**.** *A recognized RH run is an EventFlow*

$$S = E_0 \mid E_1 \mid E_2 \mid \cdots$$

accepted by a GroundCompiler recognizer $\mathsf{RecognizedRHRun}(F_{\mathsf{RH}}, S)$*. The recognizer checks the legal EventFlow channel row, the FRACTRAN transition row of each event, the least-instruction row, the prime-exponent register ledger, the initial state row for* P_{Lag}*, and the output decoding row.*

Definition 9335.14 (Counter output)**.** *For a recognized RH run* S*, the predicate* $\mathsf{Emits}(S, \mathsf{CounterRH}(n, q))$ *means that some event in* S *decodes the counter-output flag with payload* (n, q)*. The no-counter predicate is*

$$\mathsf{NoCounterOutput}(S) :\Longleftrightarrow \neg\exists n, q,\ n \geq 1 \wedge \mathsf{Emits}(S, \mathsf{CounterRH}(n, q)).$$

Definition 9335.15 (Information RH program flow)**.** *The information RH program flow is the compiler-facing packet*

$$\mathsf{InfoRHProgramFlow}^{\uparrow} = (G, F, L, E, R, I, N),$$

where

$$G : \textit{prime-register Godel state rows}, \quad F : F_{\mathsf{RH}}\ \textit{FRACTRAN program rows},$$
$$L : \mathsf{LagBound}, \mathsf{LagRHS}, \mathsf{IntervalCert}, \mathsf{CounterLag}\ \textit{rows},$$
$$E : \textit{GroundCompiler EventFlow rows}, \quad R : \mathsf{CounterRH}(n, q)\ \textit{recognizer rows},$$
$$I : \mathsf{NoCounterOutput}\ \textit{and safety-invariant rows}, \quad N : \mathsf{NameCert}\ \textit{local naming row.}$$

The packet names the counterexample-search run surface; it does not certify that the surface is counter-free.

Theorem 9335.16 (Program safety normal form of RH)**.** *Under the Lagarias bound interface and the register-preserving compilation of* P_{Lag} *into* F_{RH}*, the Riemann Hypothesis is equivalent to the absence of recognized counter output:*

$$\mathsf{RH} \Longleftrightarrow \neg\exists S, n, q,\ \mathsf{RecognizedRHRun}(F_{\mathsf{RH}}, S) \wedge \mathsf{Emits}(S, \mathsf{CounterRH}(n, q)).$$

Proof. By Definition 9335.3, RH is equivalent to the absence of a positive n satisfying $\mathsf{LagBad}(n)$. By Definition 9335.8, such an n exists exactly when P_{Lag} emits $\mathsf{CounterRH}$. By Definition 9335.11, this is exactly the event that F_{RH} reaches the counter-output flag. Finally, Definition 9335.13 makes the GroundCompiler recognizer accept precisely the initial-state FRACTRAN run with its step certificates and prime-exponent ledger. Thus a recognized counter event exists exactly when the Lagarias bad packet exists, which is exactly the negation of RH under the interface. □

Corollary 9335.17 (Specific halting instance)**.** *The halt-prime reachability claim for* F_{RH} *is a single program-instance claim:*

$$F_{\mathsf{RH}} \Downarrow \mathsf{halt}_{\mathsf{RH}} \Longleftrightarrow \neg\mathsf{RH}.$$

It is not a uniform classifier for arbitrary program halting.

Proof. Combine Definition 9335.11 with Definition 9335.8 and Definition 9335.3. The resulting statement concerns the fixed program F_{RH} and the fixed counter-output row defined above. No classifier ranging over arbitrary program codes is introduced. □

9335.4 Refutation layer

Definition 9335.18 (Counter refutation transformer)**.** *A counter refutation transformer for the RH program flow is a displayed function*

$$\mathsf{RefuteCounter} : \prod_{n,q} \mathsf{CounterLag}(n,q) \to \bot.$$

Equivalently, it is a proof that no certificate accepted by the counter-output gate can pass the Lagarias comparison rows.

Proposition 9335.19 (Halting assumption exposes a counter packet)**.** *Assuming that P_{Lag} halts does not by itself produce a contradiction. It produces a certified counter packet:*

$$P_{\mathsf{Lag}} \Downarrow \mathsf{CounterRH} \Longrightarrow \exists n, q,\ \mathsf{CounterLag}(n,q).$$

Consequently,

$$P_{\mathsf{Lag}} \Downarrow \mathsf{CounterRH} \Longrightarrow \exists n \geq 1,\ \mathsf{LagBad}(n).$$

Proof. By the definition of P_{Lag}, the only output row is $\mathsf{CounterRH}(n,q)$, and that output is guarded by an accepted $\mathsf{CounterLag}(n,q)$ packet. The second implication follows from Definition 9335.6. □

Theorem 9335.20 (Halting refutation normal form)**.** *Under the Lagarias bound interface, the following are equivalent:*

$$\mathsf{RH},$$

$$\neg(P_{\mathsf{Lag}} \Downarrow \mathsf{CounterRH}),$$

and

$$\prod_{n,q} \mathsf{CounterLag}(n,q) \to \bot.$$

Proof. By Definition 9335.3, RH is equivalent to the absence of any $\mathsf{LagBad}(n)$. By Definition 9335.8, the existence of such an n is equivalent to P_{Lag} emitting a counter event. Hence RH is equivalent to $\neg(P_{\mathsf{Lag}} \Downarrow \mathsf{CounterRH})$.

The program emits a counter event exactly when some finite $\mathsf{CounterLag}(n,q)$ packet is accepted. Therefore the negation of halting is the absence of all such packets, which is the displayed product of refutations

$$\prod_{n,q} \mathsf{CounterLag}(n,q) \to \bot.$$

□

Remark 9335.21 (Role of contradiction)**.** *The contradiction step in a proof by contradiction is not supplied by the halting assumption alone. The halting assumption supplies* $\mathsf{CounterLag}(n,q)$ *for some finite pair (n,q). A contradiction is obtained only after a separate no-counter invariant supplies* $\mathsf{CounterLag}(n,q) \to \bot$*. This invariant is not a free compiler fact; by Definition 9335.20, it is the RH proof content in the Lagarias coordinates.*

9335.5 Safety fixed point

Definition 9335.22 (RH safety class)**.** *The RH safety class is*

$$\mathsf{Safe}_{\mathsf{RH}} = \{S : \mathsf{NoCounterOutput}(S)\}.$$

For a recognized finite prefix S, write $T_{\mathsf{RH}}(S) = S \mid E_{\mathsf{next}}$ when the next RH FRACTRAN event is accepted by the recognizer.

Proposition 9335.23 (Safety invariance is no-counter output)**.** *For the recognized run of F_{RH} from the initial counterexample-search state, the following are equivalent:*

$$\forall \text{ recognized prefixes } S, \quad S \in \mathsf{Safe}_{\mathsf{RH}},$$

and

$$\mathsf{NoCounterOutput}(S^{\infty}_{\mathsf{RH}}).$$

Proof. If every recognized prefix is safe, no event in the infinite recognized run can decode a $\mathsf{CounterRH}$ payload, because any such event appears in some finite prefix. Conversely, if the infinite recognized run has no counter-output event, every finite prefix inherits the same absence. □

Corollary 9335.24 (RH as a safety fixed point)**.** *Under the interfaces of Definition 9335.16,*

$$\mathsf{RH} \iff \forall \text{ recognized prefixes } S, \quad T_{\mathsf{RH}}(S) \in \mathsf{Safe}_{\mathsf{RH}} \text{ whenever } S \in \mathsf{Safe}_{\mathsf{RH}}.$$

Equivalently, the recognized counterexample-search EventFlow remains inside the greatest safety class

$$\nu X.\ \{S : \mathsf{next}(S) \text{ is not a } \mathsf{CounterRH} \text{ event and every prefix lies in } X\}.$$

Proof. The transition form is the prefix reading of Definition 9335.23. Combining that proposition with Definition 9335.16 gives the RH equivalence. The greatest-fixed-class display is the coinductive packaging of the same prefix condition: a run remains inside the class exactly when no recognized step exits through the counter-output row. □

Remark 9335.25 (Residual bridge target)**.** *A stronger structural route would not merely refute $\mathsf{CounterLag}(n, q)$ directly. It would route an accepted $\mathsf{CounterRH}(n, q)$ event into an off-mirror residual packet and then show that the residual dynamics force the residual to vanish. In schematic form the missing bridge is*

$$\mathsf{CounterRH}(n, q) \to \mathsf{OffMirrorZero} \to \mathsf{NonzeroSkewResidual}.$$

If a later Zeckendorf or finite-window projection tower supplied a return rule $R(\Delta) = -\frac{1}{2}\Delta$ together with a zero-event safety rule $R(\Delta) = \Delta$, then the residual would satisfy $\Delta = 0$, contradicting the nonzero residual row. The present chapter records this as a bridge target only; it does not claim a certified map from Lagarias counter packets to that residual surface.

Theorem 9335.26 (Information halting normal form)**.** *Under the displayed interfaces of this chapter, the following claims are equivalent:*

$$\mathsf{RH},$$

$$\forall n \geq 1,\ \mathsf{LagBound}(n),$$

$$\neg(P_{\mathsf{Lag}} \Downarrow \mathsf{CounterRH}),$$

$$\neg(F_{\mathsf{RH}} \Downarrow \mathsf{halt}_{\mathsf{RH}}),$$

$$\neg\exists S, n, q,\ \mathsf{RecognizedRHRun}(F_{\mathsf{RH}}, S) \wedge \mathsf{Emits}(S, \mathsf{CounterRH}(n, q)),$$

and

$$\mathsf{InfoRHProgramFlow}^{\uparrow} \textit{ preserves } \mathsf{NoCounterOutput}.$$

Proof. The first two claims are the Lagarias bound interface of Definition 9335.1. The second and third are equivalent by Definition 9335.8. The third and fourth are equivalent by Definition 9335.11. The fourth and fifth are equivalent by the recognized-run relation of Definition 9335.13 and the counter-output predicate of Definition 9335.14. The fifth and sixth are the safety field of the packet in Definition 9335.15. Therefore all six are the same no-counter safety claim read through arithmetic, program, prime-register, EventFlow, and packet coordinates. □

Remark 9335.27 (Halting boundary)**.** *The packet* $\mathsf{InfoRHProgramFlow}^{\uparrow}$ *is a precise counterexample-search object, not a proof of counterexample absence. Producing the program, the FRACTRAN carrier, and the EventFlow recognizer only exposes the safety invariant. Proving that the recognized run never emits* $\mathsf{CounterRH}$ *is, by Definition 9335.16, the RH proof obligation itself. Thus the construction sits below the boundary of chapter 9336: it records a fixed program run and a no-counter safety claim, while a classifier deciding such claims for arbitrary routes would cross the halting boundary described in chapter 9369.*

Concretized in §829: GroundCompiler event-flow audit packets supply the channel, event, certificate-gate, transport, provenance, and local naming rows used by the recognized RH run surface.

Concretized in §1048: GroundCompiler recognizer-flow packets supply the generated recognizer discipline for accepting only ledgered FRACTRAN step events and output rows.

Concretized in §1094: Flow-level compile-decode packets supply the event-boundary readback needed before the counter-output recognizer is applied.

Concretized in §64: Prime packets supply the factorization rows that make prime-exponent register states readable as finite arithmetic ledgers.

Concretized in §556: Generator fixed-point packets supply the fixed-output boundary separating a displayed no-counter safety invariant from an unrestricted route-deciding oracle.

Chapter 9336

RH Route Closure and the Halting Boundary

The RH capstone of chapter 9239 states the Riemann Hypothesis as a BEDC Π-statement and fixes its constructive proof content: a proof is a total function Φ sending every critical-strip zeta-zero witness to an $\mathsf{OnCritLine}$ witness. The present chapter records the adjacent boundary. It separates the fixed proposition RH from proof search, from condition-chain closure, and from a proposed decision procedure for all theorem routes. This separation is necessary because the halting obstruction of chapter 9368 acts on families of Cont-chains, not directly on the truth value of one fixed conjecture.

9336.1 Three strata around RH

Definition 9336.1 (RH condition)**.** *An* RH condition *is a pair* (K, τ) *where* K *is a displayed condition, classifier, spectral statement, positivity statement, zero-set statement, operator statement, or other BEDC proposition, and* $\tau : K \to \mathsf{RH}$ *is a certified transport. If a witness* $k : K$ *is also supplied, then* $\tau(k)$ *is a proof of* RH*.*

Definition 9336.2 (Finite RH condition)**.** *An RH condition* (K, τ) *is* finite *when* K *has a finite* $\mathsf{NameCert}$ *or proof packet,* K *has a witness* $k : K$*, the transport* $\tau : K \to \mathsf{RH}$ *is checked, the dependency ledger is complete, the proof passes axiom-purity, and no hidden selector, quotient identification, proposition-extensional collapse, external proof source, or unclosed* GAP *is consumed.*

Theorem 9336.3 (Finite RH condition closes RH)**.** *If* (K, τ) *is a finite RH condition and* $k : K$ *is its displayed witness, then* RH *is closed on that route.*

Proof. The transport component of the condition is a function $\tau : K \to \mathsf{RH}$. Applying it to $k : K$ gives $\tau(k) : \mathsf{RH}$. Finiteness adds the BEDC side conditions: the witness, the transport, the dependency ledger, and the purity audit all live inside the displayed fragment. Thus the result is an internal proof route, not a meta-level assertion that such a route exists. □

Definition 9336.4 (RH condition chain)**.** *An* RH condition chain *is a sequence* $K_0, K_1, K_2, \ldots$ *with* $K_0 = \mathsf{RH}$ *and displayed transports*

$$K_n \to K_{n+1}, \qquad K_{n+1} \to K_n$$

at each stage where equivalence is claimed. It closes at level N *when a witness* $w_N : K_N$ *is supplied and the reverse transports carry* w_N *back to* K_0*.*

Theorem 9336.5 (Equivalence chains transport obligations)**.** *An infinite chain*

$$\mathsf{RH} \Longleftrightarrow K_1 \Longleftrightarrow K_2 \Longleftrightarrow \cdots$$

does not by itself prove RH*. It proves* RH *only when some displayed stage has a witness that can be transported back to* K_0*.*

Proof. Each equivalence supplies transport between neighbouring obligations. A transport moves an existing witness; it does not create one. If no stage K_N has a witness $w_N : K_N$, there is no term for the reverse transport chain to consume. The chain then changes the coordinate system of the remaining GAP without discharging it. □

9336.2 Grounding rank

Definition 9336.6 (Rule-presented condition)**.** *An infinite RH condition is* rule-presented *when it is supplied by a displayed generator, recognizer, continuation system, classifier, or packet family rather than by a bare external totality claim. It is* closed-rule-presented *when the generator itself has a finite* NameCert*, a totality witness, a correctness witness, and a dependency ledger.*

Definition 9336.7 (Grounding rank)**.** *The grounding rank of an RH condition is defined by the following clauses. The rank is* 0 *when the condition itself has a finite certificate and finite witness packet. The rank is* $n + 1$ *when the condition is generated by a rule whose grounding rank is* n*. If no finite rank is available, the rank is* ω*.*

Theorem 9336.8 (Finite grounding rank gives a finite route)**.** *If an RH condition has grounding rank* $N < \omega$*, and every transport from the finite top of the rule tower back to* RH *has a finite certificate, then the condition determines a finite BEDC proof route to* RH*.*

Proof. Unfold the finite rank. At the top level there is a finite certificate and witness packet. The certified rules below it successively generate the next lower condition, and the certified transports carry the resulting witness down the tower until it reaches $K_0 = \mathsf{RH}$. Only finitely many rules and transports are consumed, so the route remains a finite BEDC object even if the condition it presents has infinite extension. □

Theorem 9336.9 (Infinite rule towers are sockets)**.** *If an RH route has grounding rank* ω*, then that route is not an internal proof of* RH*. It is a* GAP *socket whose far end is named by the apophatic boundary* T*.*

Proof. Rank ω means that every displayed rule still requires a higher rule. No finite layer supplies the top certificate that BEDC needs in order to consume the route as proof data. Treating the entire tower as one object only moves the demand: the tower-object itself now requires a generator, certificate, totality witness, correctness witness, and ledger. In their absence the demand is recorded as a GAP socket. By the far-end discipline of chapter 9401, the far end of such a socket is named only apophatically:

$$\mathrm{FarEnd}(\mathrm{socket}) \equiv_{\mathrm{apo}} \mathsf{T}.$$

□

9336.3 Closure deciders and halting

Definition 9336.10 (Global theorem-route closure decider)**.** *A* global theorem-route closure decider *is a BEDC classifier D that, for every theorem target A and every proof-search route R, decides whether R eventually outputs a closed proof of A.*

Theorem 9336.11 (No global theorem-route closure decider)**.** *There is no global theorem-route closure decider in BEDC.*

Proof. Assume such a classifier D is available. Given an arbitrary certificate $\mathsf{NameCert}_P$ and history h, construct a route $R_{\mathsf{NameCert}_P,h}$ that replays the Cont_P-chain from h and outputs a fixed proof of a trivial target precisely when that chain terminates. Then D applied to that target and route decides whether the Cont_P-chain from h terminates. This is a halting predicate in the sense of Definition 9368.2. By Definition 9368.7 and Definition 9368.4, such a predicate closes the open meta loop at the certificate stratum. The fixed-point obstruction recorded in chapter 9368 forbids that closure. Hence D cannot exist. □

Definition 9336.12 (RH-route closure decider)**.** *An* RH-route closure decider *is a classifier that decides, for each route in a specified class of RH condition chains, rule towers, or proof-output programs, whether that route eventually yields a proof of* RH.

Theorem 9336.13 (Expressive RH-route deciders are Type VII sockets)**.** *If an RH-route closure decider ranges over a class of routes expressive enough to encode arbitrary* Cont*-chain termination problems, then its request is a Type VII socket rather than an internal BEDC classifier.*

Proof. By the expressiveness assumption, each halting instance $(\mathsf{NameCert}_P, h)$ can be represented as closure of an RH-directed route. The proposed decider would therefore decide arbitrary Cont_P-chain termination. This is the same certificate-stratum halting predicate ruled out in Definition 9336.11. Under the socket taxonomy, requests for total truth predicates, runtime validators, self-certifying checkers, and halting-level self-reference closure are Type VII sockets. Thus the proposed decider is not a closed classifier; it is a named self-reference boundary. □

Theorem 9336.14 (Fixed RH is not made independent by halting)**.** *The nonexistence of a global closure decider does not imply*

$$\mathsf{BEDC} \nvdash \mathsf{RH} \qquad \textit{and} \qquad \mathsf{BEDC} \nvdash \neg\mathsf{RH}.$$

Proof. The halting obstruction concerns uniform classification over arbitrary certificate-history pairs or arbitrary theorem routes. The displayed formula RH of Definition 9239.7 is one fixed Π-statement. A fixed statement may be provable, refutable by a constructive counterexample, or independent of a chosen fragment. The third outcome requires an RH-specific meta-theorem about that fragment. It is not obtained merely from the absence of a uniform route-closure classifier. □

9336.4 Audit bases

Theorem 9336.15 (MetaCIC and GroundCompiler are distinct audit bases)**.** *The RH route boundary is read through two cooperating audit bases:* $\mathsf{MetaCIC}$ *and* $\mathsf{GroundCompiler}$*. The former audits the closed-CIC meta-theory surface; the latter audits event flows, source channels, generated recognizers, certificate gates, and non-claim rows. Neither base collapses into the other.*

Proof. chapter 9385 records the closed-CIC critical path: typing surfaces, substitution, reduction geometry, normalisation, confluence fragments, decidable checking, and the blocked subject-reduction lift. The ground-compiler chapters record a different surface: event-flow representation, source-channel separation, recognizer generation, certificate-gate passage, and no-hidden-input discipline. An RH proof route must pass the relevant proof-theoretic checks and the relevant compiler-facing visibility checks, but a pass on one surface is not a pass on the other. This is why a local parser boundary, such as the channel termination of chapter 9369, cannot become a certificate-level halting classifier, and why a MetaCIC decidable checker cannot become a global theorem-route closure decider. □

9336.5 Finite human expression maximality

Definition 9336.16 (Finite communicable expression)**.** *A* finite communicable mathematical expression *is any finite written or programmable mathematical artifact that can be exchanged, inspected, and audited: a definition, theorem, proof, counterexample, conjecture, axiomatic extension, equivalence, proof route, algorithm, condition chain, rule tower, meta-theorem, numerical certificate, spectral condition, operator condition, or zeta-specific analytic packet.*

Definition 9336.17 (BEDC encoding premise for finite expression)**.** *The* finite-expression encoding premise *says that every finite communicable mathematical expression relevant to* RH *can be read in BEDC as one of the following surfaces: a statement row, proof row, program row, condition route,* NameCert *packet,* Pkg *packet,* GAP *row, socket row, cannot-claim row, or meta-theorem row. The premise is an encoding premise, not a truth-completeness premise.*

Definition 9336.18 (Non-oracular expression)**.** *A finite expression is* non-oracular *when it does not consume an unmarked global truth predicate, global halting oracle, global proof-search oracle, global RH-route decider, hidden* Classical.choice*, hidden* Quot.sound*, hidden* propext*, unledgered external supply, or unmarked meta-closure. If such a supply is requested, the expression remains non-oracular only by exposing the request as a* GAP *socket whose far end is named apophatically.*

Definition 9336.19 (RH decision datum)**.** *An* RH decision datum *is one of four artifacts:*

1. *a proof datum* $\Phi : \mathsf{RH}$ *in the sense of Definition 9239.8;*
2. *a constructive counterexample packet* $s_0, \mathsf{ZetaZero}(s_0), \mathsf{InCritStrip}(s_0), \neg\mathsf{OnCritLine}(s_0)$*;*
3. *an RH-specific meta-theorem* $F \not\vdash \mathsf{RH}$ *and* $F \not\vdash \neg\mathsf{RH}$ *for the chosen fragment* F*;*
4. *a finite route-closure certificate, consisting of a displayed route stage witness and certified transports back to* RH*.*

Definition 9336.20 (RH boundary statement)**.** *The* RH boundary statement *is the conjunction of the following claims:* RH *is the* Π*-statement of Definition 9239.7; a proof must supply the total witness function of Definition 9239.8; a disproof must supply a constructive counterexample packet; independence must be an RH-specific meta-theorem about the chosen fragment; an RH condition proves* RH *only through a witness and certified transport; an equivalence chain without a witnessed stage transports obligations rather than producing proof; an infinite rule tower without finite grounding rank is a* GAP *socket; a global route-closure classifier is a halting oracle; and an unclosed RH decision request has only the apophatic far-end reading*

$$\mathrm{FarEnd}(\mathrm{socket}_{\mathsf{RH}}) \equiv_{\mathrm{apo}} \mathsf{T}.$$

Definition 9336.21 (Strict RH-decision strengthening)**.** *A finite expression strictly strengthens the RH boundary statement at the decision layer when it claims more than boundary placement: for example, that* RH *is proved, refuted, or independent; that a concrete RH route closes or cannot close; that all relevant routes are decidable; or that an infinite condition can be consumed as proof resource without finite grounding.*

Theorem 9336.22 (Finite non-oracular RH boundary maximality)**.** *Assume the finite-expression encoding premise of Definition 9336.17. Assume also that no RH proof datum, constructive RH counterexample packet, RH-specific independence theorem, or finite RH route-closure certificate is supplied, and that global halting or proof-search oracles are not admitted. Then any finite communicable non-oracular expression that strictly strengthens the RH boundary statement at the decision layer supplies an RH decision datum.*

Proof. Let E be a finite communicable non-oracular expression, and suppose that it strictly strengthens the RH boundary statement at the decision layer. By the encoding premise, E has a BEDC reading as a statement, proof, program, route, certificate, gap, socket, cannot-claim row, or meta-theorem row.

If E proves RH, then by the constructive form of Definition 9239.8 it supplies a total function Φ from critical-strip zeta-zero witnesses to $\mathsf{OnCritLine}$ witnesses. This is a proof datum.

If E refutes RH constructively, then by the RH formulation it must display a complex history s_0 together with witnesses $\mathsf{ZetaZero}(s_0)$, $\mathsf{InCritStrip}(s_0)$, and $\neg\mathsf{OnCritLine}(s_0)$. This is a counterexample datum.

If E claims independence of RH over a fragment F, then it must supply the fragment-specific meta-theorem $F \nvdash \mathsf{RH}$ and $F \nvdash \neg\mathsf{RH}$. This is an independence datum. By Definition 9336.14, it cannot be inferred merely from the halting boundary.

If E closes a concrete RH route, then it must display a route stage witness and certified transports back to RH, as in Definition 9336.4. This is a finite route-closure certificate, and by Definition 9336.3 it yields the corresponding proof route.

If E only provides another equivalent condition or an infinite chain of equivalent conditions, then Definition 9336.5 applies: without a witnessed stage, it transports the GAP rather than closing it. Such an expression is not a strict decision-layer strengthening.

If E claims that an infinite rule tower can be consumed without finite grounding, then Definition 9336.9 applies: the unavailable finite top certificate is recorded as a GAP socket whose far end is named by T. Again there is no strict decision-layer strengthening unless a finite grounding and closure certificate is supplied.

If E supplies a global route-closure decider, then Definition 9336.11 turns it into a halting predicate and hence an open-meta-loop closure. That violates non-oracularity unless the request is exposed as a socket. A socketed request is a boundary placement, not a decision datum.

These cases exhaust the ways a finite encoded expression can claim more at the RH decision layer. Therefore every non-oracular strict strengthening supplies an RH decision datum. □

Corollary 9336.23 (The apophatic far end does not decide RH)**.** *The boundary reading*

$$\mathrm{FarEnd}(\mathrm{socket}_{\mathsf{RH}}) \equiv_{\mathrm{apo}} \mathsf{T}$$

does not supply Φ, a counterexample, an independence theorem, or a route-closure certificate.

Proof. The symbol T names the far end of an uninternalized supply socket; it is not a kernel object, proof term, zeta value, decision classifier, or global oracle. Thus it records where the request leaves the closed fragment, not what the answer to RH is. □

Corollary 9336.24 (Local RH work remains admissible)**.** *Finite non-oracular work may introduce additional RH equivalences, condition chains, finite exclusions of route classes, zeta-continuation packets, zero-counting witnesses, critical-strip barriers, Hilbert–Polya style packets, Li-criterion generators, or RH-specific independence interfaces. Such work changes the RH decision layer exactly when it produces an RH decision datum.*

Proof. Each listed artifact is a finite communicable expression and so has a BEDC reading under the encoding premise. If it remains local, conditional, or socketed, it refines the boundary without deciding RH. If it strictly strengthens the decision layer, the maximality theorem forces it to supply one of the four RH decision data. □

Corollary 9336.25 (RH boundary summary)**.** *BEDC can state* RH *as a fixed constructive* Π*-statement, can recognize finite RH conditions as proof routes, and can reject infinite rule towers without finite grounding as* GAP/T *sockets. It can also reject global route-closure deciders by the halting boundary. Under the finite-expression encoding premise, this boundary is maximal among finite communicable non-oracular expressions at the RH decision layer: any strict strengthening supplies a proof datum, counterexample datum, fragment-specific independence datum, or finite route-closure certificate.*

Proof. The first claim is Definition 9239.7 and Definition 9239.8. The second is Definition 9336.3. The third is Definition 9336.9. The fourth is Definition 9336.11. The maximality claim is Definition 9336.22. □

Concretized in §5564: The RH-route halting boundary is realized as finite route, grounding-rank, decider-refusal, and NameCert rows.

Concretized in §6933: Finite zero-inspection windows realize the RH route boundary as bounded zeta-zero, critical-strip, transport, provenance, and NameCert rows.

Chapter 9337

Route Closure and Fixed RH Separation

chapter 9336 rejects total closure classifiers for theorem routes by the halting boundary. The present chapter fixes the logical separation needed for the RH stack: route closure is a family-level classification problem, while RH is one fixed constructive Π-statement. A diagonal obstruction against the former is not, by itself, a meta-theorem about the independence of the latter.

9337.1 Route Layer and Statement Layer

Definition 9337.1 (Fixed RH proposition)**.** *The fixed RH proposition is the proposition of Definition 9239.7:*

$$\mathsf{RH} := \prod_s \big(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)\big) \to \mathsf{OnCritLine}(s).$$

It is a single constructive statement. It is not the carrier of all proof searches, condition chains, route programs, or theorem generators.

Definition 9337.2 (Route closure family)**.** *For a theorem target A and a route R, write*

$$\mathsf{Closes}(R, A)$$

for the assertion that R eventually outputs a closed proof datum for A. The route closure family is the two-variable predicate $(R, A) \mapsto \mathsf{Closes}(R, A)$.

Definition 9337.3 (Fragment independence)**.** *For a named fragment F, define*

$$\mathsf{Indep}_F(\mathsf{RH}) := (F \nvdash \mathsf{RH}) \times (F \nvdash \neg\mathsf{RH}).$$

This is a statement about the proof predicate of F and the fixed formula RH.

9337.2 Route Closure Undecidability

Theorem 9337.4 (No total route closure classifier)**.** *There is no BEDC classifier D satisfying*

$$D(A, R) = 1 \quad \Longleftrightarrow \quad \mathsf{Closes}(R, A)$$

for every theorem target A and every route R.

Proof. This is the route-family form of Definition 9336.11. If such a classifier existed, then for any certificate $\mathsf{NameCert}_P$ and history h one could form the route $R_{\mathsf{NameCert}_P,h}$ that replays the Cont_P-chain from h and emits a proof of a fixed trivial target exactly when the chain terminates. Applying D to that target and route would decide termination of arbitrary Cont_P-chains, giving the certificate-stratum halting predicate ruled out by Definition 9368.7 and Definition 9368.4. □

Theorem 9337.5 (Expressive RH route families are not decidable)**.** *Let $\mathcal{R}_{\mathsf{RH}}$ be a class of RH-directed routes. If every* Cont*-chain termination instance can be encoded as a route $R_{\mathsf{NameCert}_P,h} \in \mathcal{R}_{\mathsf{RH}}$ such that*

$$\mathsf{Halts}(\mathsf{NameCert}_P, h) \iff \mathsf{Closes}(R_{\mathsf{NameCert}_P,h}, \mathsf{RH}),$$

then no total classifier decides closure of all routes in $\mathcal{R}_{\mathsf{RH}}$.

Proof. A total classifier for closure of all routes in $\mathcal{R}_{\mathsf{RH}}$ would decide the right-hand side of the displayed equivalence. By the assumed encoding, it would decide arbitrary Cont-chain termination. This contradicts the halting boundary used in Definition 9336.11. Thus the requested classifier is a Type VII socket in the sense of Definition 9336.13, not an internal BEDC classifier. □

Theorem 9337.6 (Diagonal route classifier obstruction)**.** *If a route carrier is expressive enough to encode its own route interpreter and conditional branching, then it cannot carry an internal total classifier for its own closure predicate.*

Proof. Assume that such a classifier D exists. Construct a diagonal route Δ which, on input a route code r, queries $D(\bot, r)$ and then behaves oppositely at the target $\bot$: if the classifier says that r closes $\bot$, the diagonal route refuses to close $\bot$; if the classifier says that r does not close $\bot$, it closes $\bot$. Applying the construction to the code of Δ gives

$$D(\bot, \ulcorner\Delta\urcorner) = 1 \iff D(\bot, \ulcorner\Delta\urcorner) = 0,$$

which is impossible. Hence no such internal total classifier exists. □

9337.3 Fixed RH Independence Requires a Separate Meta-Theorem

Theorem 9337.7 (Route undecidability does not imply RH independence)**.** *The assertion*

$$\neg\exists D,\ D \text{ decides route closure}$$

does not imply

$$\mathsf{Indep}_F(\mathsf{RH})$$

for a named fragment F.

Proof. The first assertion is about the absence of a total classifier for a two-variable family of routes and targets. The second assertion is about the proof predicate of one fragment applied to one fixed formula. A system may lack a total route closure classifier while still proving, refuting, or leaving open a particular fixed proposition. For instance, a trivial fixed proposition such as $0 = 0$ can be proved in ordinary proof fragments even though global proof-route closure remains undecidable. Therefore the family-level halting obstruction does not entail a fragment-specific independence theorem for RH. □

Theorem 9337.8 (Fixed propositions do not carry halting families)**.** *There is no nonconstant many-one reduction of the halting family to the single proposition* RH *of the form*

$$\mathsf{Halts}(e, x) \iff \mathsf{RH}$$

for all program-input pairs (e, x)*.*

Proof. The right-hand side is independent of (e, x). If the displayed equivalence held for all (e, x), then $\mathsf{Halts}(e, x)$ would have the same truth value for all program-input pairs. The halting predicate is not constant. Thus the halting family can be encoded into a family of RH-directed routes, but not into the truth value of the single fixed proposition RH by such a reduction. □

Definition 9337.9 (RH-specific diagonal bridge)**.** *An RH-specific diagonal bridge for a fragment* F *is data consisting of the proof predicate of* F*, the code of* RH*, a transformation from any* F*-proof of* RH *to a contradiction, a transformation from any* F*-proof of* $\neg\mathsf{RH}$ *to a contradiction, and correctness proofs for both transformations.*

Theorem 9337.10 (Independence requires an RH-specific bridge)**.** *To prove* $\mathsf{Indep}_F(\mathsf{RH})$ *by diagonal means, it is necessary to supply an RH-specific diagonal bridge for* F*. A route closure undecidability theorem alone does not supply such a bridge.*

Proof. By Definition 9337.3, independence consists of two fragment-specific non-provability claims. A diagonal proof of those claims must transform any alleged F-proof of RH and any alleged F-proof of $\neg\mathsf{RH}$ into contradictions. That information is exactly the RH-specific diagonal bridge. The route closure theorem gives a contradiction only from a total classifier over a route family; it does not inspect the proof predicate of F at the fixed code of RH or of $\neg\mathsf{RH}$. □

9337.4 Finite Counterexample Constraint

Theorem 9337.11 (Finite counterexample constraint)**.** *Let a statement* A *be presented as*

$$\forall n > N,\ P(n),$$

where $P(n)$ *is a decidable arithmetic predicate, and let* F *be a fragment that verifies concrete computations of* P*. If* A *is false in the standard reading and a counterexample index* $n_0 > N$ *is displayed, then* F *proves* $\neg A$ *from the finite computation certificate for* $\neg P(n_0)$*.*

Proof. The displayed counterexample index reduces the negation of A to the finite computation $\neg P(n_0)$. Since P is decidable and the fragment verifies concrete computations of P, the finite certificate is accepted inside F. Therefore F proves $\neg P(n_0)$ and hence $\neg\forall n > N,\ P(n)$. □

Corollary 9337.12 (Arithmetic counterexample searches do not prove independence)**.** *Finite arithmetic counterexample interfaces such as chapter 9335 can supply constructive refutation data when a certified bad packet is emitted, and can supply safety targets when no accepted run emits such a packet. They do not by themselves supply* $\mathsf{Indep}_F(\mathsf{RH})$*.*

Proof. A certified bad packet is a finite counterexample datum, not an independence theorem. Absence of an emitted packet is a safety target for a recognized program run, not a proof that neither RH nor $\neg\mathsf{RH}$ is provable in a fragment. By Definition 9337.10, independence requires an RH-specific meta-theorem about the proof predicate of the chosen fragment. □

Corollary 9337.13 (Separation summary)**.** *The BEDC RH stack proves the following boundary separation: route closure classification is blocked by halting and diagonalization; sufficiently expressive RH route families inherit that blockage; the fixed proposition* RH *is not thereby proved independent of any fragment. A claim of RH independence must be carried by an RH-specific meta-theorem.*

Proof. The first claim is Definition 9337.4; the second is Definition 9337.5; the third is Definition 9337.7. The final sentence is Definition 9337.10. □

Concretized in §8824: The route/fixed-statement separation is realized as finite route-layer, statement-layer, refusal, transport, replay, provenance, and local NameCert data.

Chapter 9338

Dyadic Truncation Laguerre–Pólya Route Refutation

The completed zeta function admits the de Bruijn–Newman Fourier representation

$$\xi(z) = \int_0^\infty \Phi(u)\cos(zu)\,du,$$

with Φ the standard super-exponentially decaying kernel. This suggests a tempting finite-cutoff route to the Riemann Hypothesis: dyadically truncate the integral, show that every truncation lies in the Laguerre–Pólya class, and pass to the limit by Hurwitz's theorem. The present chapter records that this route does not close, because its central premise is false for sharp cutoffs. It does not prove or disprove the Riemann Hypothesis; it isolates, with a finite reproducible counterexample, why the route cannot be completed.

Definition 9338.1 (Sharp dyadic truncation)**.** *For a cutoff $a_K > 0$ write the sharp dyadic truncation*

$$\xi_K(z) := \int_0^{a_K} \Phi(u)\cos(zu)\,du,$$

and let κ_K denote the number of non-real zeros of ξ_K in the upper half plane. Since every Laguerre–Pólya entire function has only real zeros, any certificate $\kappa_K > 0$ refutes the all-K Laguerre–Pólya premise for this sharp-cutoff family.

Principle 9338.2 (The conditional Hurwitz bridge)**.** *Since $\xi_K \to \xi$ uniformly on compact sets and the Laguerre–Pólya class is closed under locally uniform limits, the implication*

$$(\forall K,\ \kappa_K = 0) \ \Rightarrow\ \xi \in \mathrm{LP} \ \Rightarrow\ \mathsf{RH}$$

is valid. The implication is sound, and that is precisely why it carries no content on its own: all of the difficulty is shifted into its premise.

Principle 9338.3 (The premise is false: a finite counterexample)**.** *The premise $\forall K,\ \kappa_K = 0$ fails. The reproducible experiment* `papers/bedc/experiments/dyadic_truncation_lp_refutation.py` *exhibits non-real zeros of small-cutoff truncations ξ_K, each certified by an argument-principle winding count together with a Newton residual check, so that $\kappa_K > 0$ for those cutoffs. The all-K Laguerre–Pólya premise therefore cannot hold, and the route above cannot be discharged.*

Principle 9338.4 (Forced bifurcation mechanism)**.** *The failure is structural rather than incidental. Write the boundary-corrected truncation as a homotopy $F_t = Q_K + tP_K$ running from a Robin characteristic function Q_K, whose zeros are all real and simple, to the truncation at $t = 1$. For large cutoffs the first Robin zeros cluster near the origin and move under the homotopy with opposite-sign velocities, so they are forced to collide before the endpoint, producing a real double zero from which a non-real pair is born. Hence the no-bifurcation sub-route is impossible: real-rootedness of the limit cannot be secured merely by keeping every truncation inside the Laguerre–Pólya class, and any salvage would require a separate birth-and-death cancellation argument across the homotopy.*

Principle 9338.5 (Scope and provenance of the refutation)**.** *The obstruction is that a sharp domain cutoff lacks the Laguerre–Pólya preservation enjoyed by the smooth de Bruijn–Newman heat deformation $e^{tu^2}\Phi$. The same failure mode is classical: the proven failure of the Turán partial-sum route, the Szegő-curve behaviour of the partial sums of the exponential whose zeros stay complex even though the limit is zero-free, and the insensitivity of Jensen-polynomial hyperbolicity to off-line zeros. The route is recorded here as not-claimed. It makes no positive or negative statement about the Riemann Hypothesis itself; it removes one tempting but unsound bridge so that effort is not spent re-deriving it.*

Concretized in §9025: Sharp dyadic truncation refutation windows realize the Laguerre–Polya route obstruction as finite cutoff, zero-count, refusal, transport, replay, provenance, and NameCert rows.

Chapter 9339

A Constructive Winding-Certificate Layer for the Argument-Principle Route

The argument-principle route at finite height separates into two obligations. The topological and combinatorial half defines a winding number for rational boundary polygons and proves that this number is well defined under the certificate operations used by a finite verifier. The analytic half proves that such a polygon faithfully tracks $\zeta(\partial R)$ and that the constructive argument-principle theorem identifies the resulting winding with the number of zeros inside R. Only the topological half is closed here.

The present layer therefore does not prove the Riemann Hypothesis, does not locate every zeta zero, and does not supply the analytic bridge from $\zeta(\partial R)$ to a rational polygon. It records the completed mathlib-free, 0-axiom, propext-free Lean certificate layer in the namespace BEDC.Derived.RHRoute.RationalPolygonWinding and its sibling modules. The layer works with finite rational vertices and the signed crossing count of the positive real ray. Its 'Up' versions use the BEDC integer carrier so that the algebra remains inside the same constructive kernel fragment.

Definition 9339.1 (Rational-polygon winding certificate layer)**.** *A rational-polygon winding certificate consists of a finite cyclic list of rational complex vertices, the oriented edge list obtained from that cycle, and the signed sum of edge crossings of the positive real ray. The ordinary integer count is written as* computedWinding*, while the BEDC-integer count is written as* computedWindingUp*. A certificate generator may perturb rational vertices within certified crossing margins, refine an edge by inserting an intermediate rational point, rotate the starting vertex, reverse edge orientations, and split a rectangular boundary into adjacent boxes.*

Principle 9339.2 (Perturbation stability)**.** *If every edge of a rational polygon carries a margin certificate keeping it away from the crossing discriminants, then any edgewise rational perturbation preserving those margins has the same computed winding. This is the stability fact used when a finite evaluator replaces a boundary trace by nearby rational vertices without changing the topological certificate.*

Lean4 ✓ `BEDC.Derived.RHRoute.RationalPolygonWindingStability.computedWinding stable of edgewiseMarginPr`

Principle 9339.3 (Collinear edge subdivision)**.** *Inserting a rational point strictly between the endpoints of a segment splits the segment into two collinear directed segments without changing the total crossing contribution of that edge. This is the local algebraic fact behind boundary refinement.*

Lean4 ✓ `BEDC.Derived.RHRoute.RationalPolygonEdgeSubdivision.edgeCrossing collinear split`

Principle 9339.4 (Surface-level subdivision invariance)**.** *At the summed BEDC-integer level, replacing one edge in an oriented edge list by its two collinear subedges preserves the total crossing sum. Thus adaptive refinement changes the mesh of the polygon, not its winding certificate.*

Lean4 ✓ `BEDC.Derived.RHRoute.RationalPolygonEdgeSubdivision.sumEdgeCrossingsUp subdivide one`

Principle 9339.5 (Cyclic rotation invariance)**.** *The chosen starting vertex of a nonempty cyclic vertex list is not part of the certificate content. Rotating the list by one step preserves the BEDC-integer winding count.*

Lean4 ✓ `BEDC.Derived.RHRoute.RationalPolygonWinding.computedWindingUp cyclic rotate one`

Principle 9339.6 (Orientation reversal cancellation)**.** *Traversing the same rational edge in the two opposite directions contributes opposite signed crossings, so the two directed copies have net contribution* 0 *in the BEDC integer carrier.*

Lean4 ✓ `BEDC.Derived.RHRoute.RationalPolygonWinding.edgeCrossingUp reverse cancel`

Principle 9339.7 (Box-split additivity)**.** *When a rectangular boundary is split into adjacent boxes, the shared interior edge is traversed once in each direction and cancels. The resulting crossing sum is additive across the split, giving the combinatorial skeleton for recursive box certificates.*

Lean4 ✓ `BEDC.Derived.RHRoute.RationalPolygonWinding.sumEdgeCrossingsUp box split`

Together these checked facts say the following precise thing: for rational boundary polygons, the winding number is a finite combinatorial object that is well defined, stable under certified perturbation, invariant under edge subdivision and cyclic rotation, antisymmetric under orientation reversal, and additive under box splitting. These are the structural properties needed by the topological side of an argument-principle certificate, and they are all kernel-verified in the 0-axiom BEDC fragment. They are not a zero-counting theorem for ζ.

Principle 9339.8 (Open analytic bridges)**.** *Two analytic obligations remain open. First, the route needs a located interval evaluator for ζ on ∂R. The intended evaluator passes through the eta series*

$$\eta(s) = \sum_{n\geq 1} (-1)^{n-1} n^{-s}, \qquad \zeta(s) = \frac{\eta(s)}{1-2^{1-s}},$$

with

$$n^{-s} = \exp(-s\ln n), \qquad n^{-it} = \cos(t\ln n) - i\sin(t\ln n).$$

The critical point is the tail: a naive Leibniz estimate does not directly apply because the phase n^{-it} rotates in the complex plane. A strict Euler–Boole alternating-summation bound is the concrete 0-axiom shape needed for the critical strip, including derivative bounds for interval-Newton or Krawczyk certificates.

Second, the route needs the constructive argument-principle theorem itself: a discrete Rouché or faithful-approximation theorem proving that a rational polygon whose certified tube contains $\zeta(\partial R)$ has the same winding as the true boundary trace and therefore counts zeros inside R. These are multi-week constructive-analysis obligations, not completed certificate payload.

A usable Euler–Boole obligation can be stated without hiding the analytic work. For a box

$$B = \{s = \sigma + it : \sigma_- \le \sigma \le \sigma_+,\ t_- \le t \le t_+\}, \qquad 0 < \sigma_- < \sigma_+ < 1,$$

set $X = N + 1$ and $f_s(x) = x^{-s}$. With Euler polynomials defined by

$$\frac{2e^{xz}}{e^z + 1} = \sum_{\nu \ge 0} E_\nu(x) \frac{z^\nu}{\nu!},$$

Euler–Boole summation gives endpoint terms plus a remainder

$$R_N(s) = (-1)^N \left[\frac{1}{2} \sum_{\nu=0}^{2L-1} \frac{E_\nu(0)}{\nu!} f_s^{(\nu)}(X) + \mathcal{E}_L(s) \right],$$

where

$$f_s^{(\nu)}(X) = (-1)^\nu (s)_\nu X^{-s-\nu}, \qquad E_{2j}(0) = 0 \quad (j \ge 1).$$

A constructive interval evaluator must turn this into a uniform complex-box bound for $\mathcal{E}_L(B)$ and for $\partial_s \mathcal{E}_L(B)$, then propagate those enclosures through $\zeta(s) = \eta(s)/(1 - 2^{1-s})$. This is the analytic bottleneck shared by the winding and local-zero routes.

Principle 9339.9 (Located-zero complement)**.** *The local alternative is to locate a single zero by a Krawczyk or interval-Newton certificate. Near the first nontrivial zero, $c \approx 1/2 + 14.1347i$, one chooses a high-precision approximate inverse $a \approx 1/\zeta'(c)$ and studies the Newton-like map*

$$N(z) = z - a\,\zeta(z).$$

For a closed complex box B around c, the constructive target has the form

$$N(B) \subseteq B, \qquad \sup_{z \in B} |1 - a\zeta'(z)| < 1.$$

This traps a unique zero in B. It is a local located-zero certificate, not a global statement about all zeros. It is complementary to the rational-polygon winding layer because both legs need the same located-ζ interval evaluator and the same Euler–Boole complex tail control.

This should also be read against the route separation in chapter 9338. The sharp dyadic Laguerre–Pólya premise fails as a global preservation strategy. The present chapter does not try to revive that premise. It keeps the finite topological certificate layer and points the analytic work toward located ζ evaluation, Krawczyk-style local boxes, and a constructive argument-principle bridge.

Closure status for NameCert$_{\text{ConstructiveWindingCertificate}^\uparrow}$.

Constructive story: A ConstructiveWindingCertificate$^\uparrow$ packet is generated from finite rational boundary vertices, oriented rational edges, signed positive-ray crossing rows, perturbation-margin rows, subdivision rows, cyclic-rotation rows, reversed-edge cancellation rows, and box-split rows, with all exported structure witnessed by the listed Lean targets.

Theory closure: TheoryGate(NameCert$_{\text{ConstructiveWindingCertificate}^\uparrow}$, scopedClosed)

Scope closed: Rational-boundary-polygon winding number's combinatorial certificate layer, including well-definedness, stability, subdivision and cyclic-rotation invariance, orientation cancellation, and box additivity; excluding located-zeta evaluation and the analytic argument-principle theorem

Formal verification: FormalStatus(NameCert$_{\text{ConstructiveWindingCertificate}^\uparrow}$, theoremChecked)

Lean target: `BEDC.Derived.RHRoute.RationalPolygonWinding.sumEdgeCrossingsUp\_box\_split`

Bridge status: none

Not claimed: Not closed: the located-zeta interval evaluator and the constructive argument-principle theorem identifying winding with zero count

Upgrade path: Add located complex exp/ln/trig continuity evaluators plus discrete Rouché or faithful-approximation error control

Origin: ai

Chapter 9340

Contour Integration as an Operation on $\mathsf{Holomorphic}^{\uparrow}$

This chapter licenses contour integration $\int_\gamma f\,dz$ along a piecewise-rational-linear contour γ inside the holomorphic domain of f. Unlike the naming-certificate chapters that pin down a closed object (a number system, an algebraic carrier, a topological structure), this chapter licenses an *operation*: a constructive procedure that turns a (contour, holomorphic-function) pair into a complex-history value. The chapter sits above $\mathsf{Holomorphic}^{\uparrow}$ (chapter 68) and $\mathsf{CFun}^{\uparrow}$ (chapter 59). Following the Bishop-style discipline of the rest of the paper, the carrier of contours is restricted to piecewise-linear paths over $\mathsf{Rat}^{\uparrow}$ endpoints with explicit Riemann-sum modulus, and the integral is the unique complex-history value approached by these sums up to an effective rate of convergence. The chapter ends with an *operation certificate* — an analogue of the naming certificate adapted to operations, with input/output classifier-aware predicate plus operation laws (linearity, concatenation, reversal, reparameterization) in place of the standard 5-field NameCert tuple.

9340.1 Piecewise-linear contour carrier

Definition 9340.1 (Piecewise-linear contour)**.** *A piecewise-linear contour γ is a finite list $[z_0, z_1, \ldots, z_k]$ of complex-history endpoints with $k \geq 1$, each z_i classified by $\mathsf{Complex}^{\uparrow}$. The closed inductive predicate $\mathsf{PLContour}(\gamma)$ is generated by:*

1. $\mathsf{PLContour}([z_0, z_1])$ *for any pair of complex histories (the singleton segment);*
2. *if* $\mathsf{PLContour}([z_0, \ldots, z_k])$ *and z_{k+1} is a complex history, then* $\mathsf{PLContour}([z_0, \ldots, z_k, z_{k+1}])$ *(extension by one further segment).*

The single-segment BEDC carrier records two complex-history endpoints z_0, z_1 and the continuation witness $\mathsf{Cont}(z_0, z_1, \gamma)$. The total length is the sum of the segment lengths $|z_{i+1} - z_i|$, each computed via the metric carrier of $\mathsf{Complex}^{\uparrow}$ (chapter 39).

Lean4 (definition) `BEDC.Derived.ContourIntegralUp.PLContourSegment`

Lemma 9340.2 (Piecewise-linear contour well-formedness)**.** *For every BEDC single-segment* $\mathsf{PLContourSegment}(\gamma$ *there are complex-history endpoints z_0, z_1 with $\mathsf{Cont}(z_0, z_1, \gamma)$, and the contour history γ is unary.*

Proof. Destructure the segment witness. The endpoint carrier fields give z_0 and z_1 as complex histories. Each complex history is unary, and the continuation witness closes unary histories under Cont, so γ is unary. □

Lean4 ✓ `BEDC.Derived.ContourIntegralUp.PLContourSegment unary result`

Lemma 9340.3 (Piecewise-linear segment hsame-transport)**.** *If* $\mathsf{PLContourSegment}(\gamma)$ *and* $\mathsf{hsame}(\gamma, \gamma')$*, then* $\mathsf{PLContourSegment}(\gamma')$*, and* γ' *is unary.*

Proof. Keep the same endpoints z_0, z_1 and transport the continuation result from γ to γ' along $\mathsf{hsame}(\gamma, \gamma')$. Unary closure for γ' follows from the same endpoint carriers and the transported continuation. □

Concretized in §583: Contour-integral sockets are realized as finite BHist operation packets for contour rows, holomorphic input rows, Riemann-sum modulus rows, ComplexUp output rows, and non-escape ledger obligations.

Lean4 ✓ `BEDC.Derived.ContourIntegralUp.PLContourSegment hsame transport`

Lemma 9340.4 (Concatenation of piecewise-linear contours)**.** *If* $\mathsf{PLContour}([z_0, \ldots, z_j])$ *and* $\mathsf{PLContour}([w_0, \ldots, w$ *and* $\mathsf{hsame}(z_j, w_0)$*, then* $\mathsf{PLContour}([z_0, \ldots, z_j, w_1, \ldots, w_k])$ *and the total length of the concatenation equals the sum of the two component lengths.*

Lean4 ✓ `BEDC.Derived.ContourIntegralUp.PLContour concat closed`

Proof. By induction on the second contour, using the extension constructor of $\mathsf{PLContour}$ at each step. Length additivity follows by direct computation. □

9340.2 Riemann sum approximation

Definition 9340.5 (Subdivided Riemann sum)**.** *For a function* f *classified by* $\mathsf{CFun}^{\uparrow}$ *on a domain containing* γ*, a piecewise-linear contour* $\gamma = [z_0, \ldots, z_k]$*, a unary subdivision count* n*, and an explicit choice of sampling points* $S_n = \{\xi_{i,j}\}$ *on each subsegment, the Riemann sum* $\mathsf{RiemannSum}(f, \gamma, n, S_n)$ *is the complex-history value*

$$\sum_{i=0}^{k-1} \sum_{j=0}^{n-1} f(\xi_{i,j}) \cdot \frac{z_{i+1} - z_i}{n}.$$

The closed inductive carrier indexes both the segment and the subdivision step.

Lemma 9340.6 (Riemann sum is a well-defined complex history)**.** *For every* $\mathsf{PLContour}(\gamma)$*, continuous* f *on a domain containing* γ*, unary* n*, and sampling choice* S_n*, the value* $\mathsf{RiemannSum}(f, \gamma, n, S_n)$ *is classified by* $\mathsf{Complex}^{\uparrow}$*.*

Proof. By induction on the length of the contour list. The base case is a single sum of n products of complex histories, each well-defined by the multiplicative closure of $\mathsf{Complex}^{\uparrow}$ (chapter 39). The step adds one further segment's contribution to a previously well-defined complex history; closure under finite sums of $\mathsf{Complex}^{\uparrow}$ preserves the classification. □

9340.3 The contour integral

Definition 9340.7 (Contour integral predicate)**.** *For a function* f *classified by* $\mathsf{Holomorphic}^{\uparrow}$ *on a neighbourhood containing* γ*, a piecewise-linear contour* γ*, and a complex history* I*, the predicate* $\mathsf{ContInt}(f, \gamma, I)$ *holds when there is an explicit modulus function* $N : \mathsf{Unary} \to \mathsf{Unary}$ *such that for every unary precision* k *and every* n *with* $\mathsf{NatGT}(n, N(k))$ *and every sampling choice* S_n*,*

$$\left|\mathsf{RiemannSum}(f, \gamma, n, S_n) - I\right| \leq 2^{-k}.$$

Lemma 9340.8 (Existence of the contour integral on holomorphic inputs)**.** *For every* $\mathsf{PLContour}(\gamma)$ *and every* f *classified by* $\mathsf{Holomorphic}^{\uparrow}$ *on an open neighbourhood of (the image of)* γ*, there exists a complex history* I *with* $\mathsf{ContInt}(f, \gamma, I)$*.*

Sketch. The holomorphicity classifier of f on the neighbourhood provides an explicit local modulus of continuity. Combining this with the bounded total length of γ (Definition 9340.2) yields a uniform Cauchy modulus on the Riemann-sum sequence indexed by n; its limit I is constructed as a complex history by the Cauchy completeness of $\mathsf{Complex}^{\uparrow}$ (chapter 39). □

Theorem 9340.9 (Uniqueness of the contour integral up to hsame)**.** *If* $\mathsf{ContInt}(f, \gamma, I_1)$ *and* $\mathsf{ContInt}(f, \gamma, I_2)$*, then* $\mathsf{hsame}(I_1, I_2)$*.*

Proof. For each unary k, the Riemann sum at precision $\max(N_1(k+1), N_2(k+1))$ is within $2^{-(k+1)}$ of both I_1 and I_2, so $|I_1 - I_2| \leq 2^{-k}$ for every k. Hence $|I_1 - I_2|$ is the zero history, and $\mathsf{hsame}(I_1, I_2)$ follows from the metric reflection of $\mathsf{Complex}^{\uparrow}$. □

9340.4 Operation laws

Lemma 9340.10 (Linearity in the integrand)**.** *If* $\mathsf{ContInt}(f, \gamma, I_f)$ *and* $\mathsf{ContInt}(g, \gamma, I_g)$ *and* a, b *are complex histories, then* $\mathsf{ContInt}(af + bg, \gamma, aI_f + bI_g)$*.*

Proof. Riemann sums are linear in the integrand, and the bound on $|aI_f + bI_g - \mathsf{RiemannSum}(af + bg, \gamma, n, S_n)|$ follows by the triangle inequality from the bounds on the two component Riemann sums. □

Lemma 9340.11 (Concatenation in the contour)**.** *If* γ *is the concatenation of* γ_1 *and* γ_2 *(with shared endpoint via Definition 9340.4) and* $\mathsf{ContInt}(f, \gamma_1, I_1)$ *and* $\mathsf{ContInt}(f, \gamma_2, I_2)$*, then* $\mathsf{ContInt}(f, \gamma, I_1 + I_2)$*.*

Proof. A Riemann sum on the concatenated contour is the sum of the Riemann sums on the two component contours; pass to the joint modulus $\max(N_1(k+1), N_2(k+1))$. □

Lemma 9340.12 (Reversal negates the integral)**.** *Let* $\gamma^- = [z_k, z_{k-1}, \ldots, z_0]$ *be the reverse of* $\gamma = [z_0, \ldots, z_k]$*. If* $\mathsf{ContInt}(f, \gamma, I)$*, then* $\mathsf{ContInt}(f, \gamma^-, -I)$*.*

Proof. Each Riemann-sum segment $f(\xi_{i,j}) \cdot (z_{i+1} - z_i)/n$ flips sign under reversal because $z_{i+1} - z_i$ is replaced by $z_i - z_{i+1}$. The modulus is unchanged. □

Lemma 9340.13 (Reparameterization invariance for piecewise-linear reparameterizations)**.** *If* γ' *is obtained from* γ *by inserting one additional intermediate endpoint along an existing segment (a piecewise-linear refinement), then* $\mathsf{ContInt}(f, \gamma, I)$ *iff* $\mathsf{ContInt}(f, \gamma', I)$*.*

Proof. Refinement decomposes a single segment's Riemann contribution into a sum over the two refined sub-segments; this leaves both the limit I and the modulus unchanged up to an additive constant in k. □

9340.5 Cauchy's theorem and the integral formula

Theorem 9340.14 (Cauchy's theorem on triangulated regions)**.** *If γ is a closed piecewise-linear contour bounding a triangle inside the holomorphic domain of f, then* $\mathsf{ContInt}(f, \gamma, 0)$*, where* 0 *denotes the zero complex history.*

Sketch. The standard Goursat-style nested-triangle subdivision argument: bisect the triangle into four congruent sub-triangles, observe that the sum of the four sub-integrals equals the original integral (cancellations along shared edges by Definition 9340.12), pick the largest sub-integral and iterate. Holomorphicity provides the bound that the integral over the n-th nested triangle decays like $4^{-n} \cdot (\text{perimeter})^2$, forcing the limit to be zero. □

Lemma 9340.15 (Cauchy on triangulated polygons)**.** *For any closed piecewise-linear γ bounding a region triangulated by finitely many triangles inside the holomorphic domain of f,* $\mathsf{ContInt}(f, \gamma, 0)$*.*

Proof. Apply Definition 9340.14 to each triangle in the triangulation. The sum of the triangle integrals equals the integral over the boundary of the polygon by Definition 9340.11 and Definition 9340.12; the interior edges cancel pairwise. □

Theorem 9340.16 (Cauchy integral formula, constructive form)**.** *Let z_0 be a complex history, r a positive rational history, and γ a closed piecewise-linear contour approximating the circle of radius r about z_0 inside the open disk* $\mathsf{OpenDisk}(z_0, r)$*. For f classified by* $\mathsf{Holomorphic}^{\uparrow}$ *on the disk,*

$$\mathsf{ContInt}(\lambda z.f(z)/(z - z_0), \gamma, 2\pi i \cdot f(z_0))$$

holds, with explicit modulus computed from the rational approximation of π provided by $\mathsf{Real}^{\uparrow}$ *(chapter 38).*

Sketch. By Cauchy's theorem on triangulated regions, the integral over γ equals the integral over a small piecewise-linear circle approximation around z_0 (the difference contour bounds a triangulated annulus). On the small approximation, the integrand is approximately $f(z_0)/(z - z_0)$, whose contour integral is $2\pi i \cdot f(z_0)$ by direct computation on the rational endpoints. The explicit modulus combines the holomorphicity modulus with the rational-π approximation modulus. □

9340.6 Operation laws and ledger

Definition 9340.17 (Contour-integral input specification)**.** *The input specification of the contour-integral operation is the pair (f, γ) where f is classified by* $\mathsf{Holomorphic}^{\uparrow}$ *on an open neighbourhood and γ is classified by* $\mathsf{PLContour}$ *inside that neighbourhood.*

Definition 9340.18 (Contour-integral output specification)**.** *The output specification is a single complex history I classified by* $\mathsf{Complex}^{\uparrow}$*, uniquely determined up to* hsame *by Definition 9340.9.*

Definition 9340.19 (Contour-integral classifier)**.** *The classifier of the operation is* hsame *on the output complex history. Two outputs are classified together iff they are* hsame*-equal.*

Definition 9340.20 (Contour-integral operation laws)**.** *The operation laws of the contour-integral operation collect:*

1. *linearity in the integrand (Definition 9340.10);*
2. *concatenation in the contour (Definition 9340.11);*

3. *reversal of the contour negates the integral (Definition 9340.12);*
4. *invariance under piecewise-linear reparameterization (Definition 9340.13).*

Definition 9340.21 (Contour-integral ledger policy)**.** *The ledger policy records:*

1. *Cauchy closure: closed contours bounding triangulated regions inside the holomorphic domain produce zero (Definition 9340.14, Definition 9340.15);*
2. *Cauchy integral formula composition (Definition 9340.16): point evaluation factors through a rational-approximated circle integral.*

Theorem 9340.22 (Concrete contour-integral operation certificate)**.** *The data* (ContIntInputSpec, ContIntOutputSp *of Definition 9340.17–Definition 9340.21 forms an operation certificate over* Hist *for contour integration on* $\mathsf{Holomorphic}^{\uparrow}$*. The operation is total on its input specification (Definition 9340.8), uniquely determined up to* hsame *(Definition 9340.9), and closed under the four operation laws.*

Sketch. Totality is Definition 9340.8. Uniqueness is Definition 9340.9. The operation laws are Definition 9340.10, Definition 9340.11, Definition 9340.12, and Definition 9340.13. The ledger policy fields are Definition 9340.14, Definition 9340.15, and Definition 9340.16. The certificate uses no Classical.choice, no Quot.sound, and no propext, so the operation's Lean targets fall under the project's axiom-purity gate. □

Theorem 9340.23 (Semantic contour-integral operation certificate)**.** *The concrete operation certificate of Definition 9340.22 satisfies the semantic operation-certificate schema: the input and output specifications are* Hist*-predicates, the classifier is a restriction of* hsame*, and every operation law is given by an explicit constructive proof. The operation is functorial in its input pair under* hsame*: if* $\mathsf{hsame}(f, f')$ *(in the sense of pointwise classifier on the holomorphic carrier) and* $\mathsf{hsame}(\gamma, \gamma')$ *(in the sense of endpoint-wise classifier on* PLContour*), then the resulting integrals are* hsame*-equal.*

Sketch. Direct verification of the schema fields using the constructions of this chapter and the hsame-respect of the underlying $\mathsf{Holomorphic}^{\uparrow}$ and $\mathsf{Complex}^{\uparrow}$ classifiers. □

Lemma 9340.24 (Affine concatenation closure for contour integrals)**.** *Let* $\gamma = \gamma_1 * \gamma_2$ *be the concatenation of* γ_1 *and* γ_2*, with the shared endpoint condition supplied by Definition 9340.4. Suppose that*

$$\mathsf{ContInt}(f, \gamma_1, I_1^f), \quad \mathsf{ContInt}(f, \gamma_2, I_2^f), \quad \mathsf{ContInt}(g, \gamma_1, I_1^g), \quad \mathsf{ContInt}(g, \gamma_2, I_2^g)$$

hold. If a *and* b *are complex histories, then*

$$\mathsf{ContInt}(af + bg, \gamma, a(I_1^f + I_2^f) + b(I_1^g + I_2^g)).$$

Proof. Apply Definition 9340.11 to the two f-integrals along γ_1 and γ_2. This gives

$$\mathsf{ContInt}(f, \gamma, I_1^f + I_2^f).$$

Apply the same concatenation law to the two g-integrals, giving

$$\mathsf{ContInt}(g, \gamma, I_1^g + I_2^g).$$

Now apply linearity in the integrand, Definition 9340.10, to these two contour integrals on the same contour γ with scalar histories a and b. The resulting certified value is exactly $a(I_1^f + I_2^f) + b(I_1^g + I_2^g)$, which is the required contour integral for $af + bg$ along γ. □

Concretized in §521: Contour-integral operation packets realize piecewise-linear contour rows, Riemann-sum ledgers, uniqueness boundary, and operation-law public export as a finite NameCert surface.

Concretized in §587: Contour integration is realized as finite contour, subdivision, Riemann-sum, output, transport, continuation, package, and NameCert rows.

Concretized in §704: Contour affine-concatenation packets realize the shared-endpoint concatenation and affine-linearity operation law as finite BHist, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1019: Contour reversal ledgers realize the piecewise-linear contour reversal law as a finite BHist NameCert packet with contour, reversed-contour, integral-output, transport, route, provenance, and local naming rows.

Concretized in §7037: Contour reparameterization ledgers realize the contour-integral operation law as finite PL-contour, holomorphic-input, Riemann-sum modulus, ComplexUp output, transport, replay, provenance, and NameCert rows.

Concretized in §3978: The residue handoff is realized as a finite contour-operation consumer packet over PLContour, HolomorphicUp, ContourIntegralOperationUp, ResidueUp, and non-escape rows.

Chapter 9341

Analytic Continuation as an Operation on $\mathsf{Holomorphic}^{\uparrow}$

This chapter licenses analytic continuation as the operation $\mathsf{AnaCont}^{\uparrow}$ that, given a holomorphic f on a domain D_1 and an overlapping holomorphic g on D_2 with $f = g$ on a non-trivial overlap region U, produces the unique holomorphic extension h on $D_1 \cup D_2$. The chapter is an OPERATION chapter rather than a pure namecert: the structure is input/output classifier-aware predicate plus operation laws (functoriality, composition, hsame-respect) instead of the standard 5-field NameCert. Builds on $\mathsf{Holomorphic}^{\uparrow}$ (chapter 68) and the constructive identity theorem of that chapter. Branch obstruction (the constructive face of monodromy / multi-valued continuation around branch points) is flagged as a SCHEMA-ONLY HORIZON: the chapter exposes the constructive interface but admits that closed witnesses for general branch behaviour do not in general live inside the framework. The construction is fully constructive on the parts that close; uses no Classical.choice, no Quot.sound, and no propext, so the operation's Lean targets fall under the project's axiom-purity gate.

Concretized in §569: Analytic continuation is realized as a finite BHist operation-socket NameCert packet over holomorphic source rows, overlap witnesses, continuation outputs, and branch-obstruction non-escape.

Concretized in §577: Analytic continuation operations are realized as classifier-stable BEDC operation packets over holomorphic inputs, overlap evidence, and continuation ledgers.

Concretized in §694: Branch-obstruction packets realize branch-sensitive continuation requests as finite BHist ledger rows whose nonlocal reads do not export branch selectors, quotient germs, monodromy theorems, or new holomorphic outputs.

Concretized in §1060: Schwarz reflection routes realize boundary-symmetric analytic continuation as finite HolomorphicUp, ComplexDiffUp, hsame, Cont, Pkg, and NameCert rows.

Concretized in §312: Monodromy packets realize the continuation-around-a-loop boundary as finite loop, base endpoint, local-system or fibre, returned-row, transport, provenance, and NameCert rows.

9341.1 Domain compatibility

Definition 9341.1 (Domain compatibility)**.** *For two open domains D_1, D_2 of $\mathsf{Complex}^{\uparrow}$, the predicate $\mathsf{DomCompat}(D_1, D_2, U)$ is satisfied by an explicit overlap region U which contains an*

$\mathsf{OpenDisk}(z_c, r_c)$ *inside* $D_1 \cap D_2$ *together with a quantitative density bound at a center point* z_c *(i.e. a sequence of points* $(z_n)_n$ *clustering at* z_c *inside* U *with* $|z_n - z_c| \leq 2^{-n}$*). The density witness is required for the constructive identity theorem (chapter 68) to apply.*

Lemma 9341.2 (Domain compatibility witness)**.** *The predicate* $\mathsf{DomCompat}$ *is decidable when* D_1, D_2 *are concrete unions of open disks with rational centers and radii.*

Proof. For unions of open disks, intersection is decidable from radii comparisons; the inner disk witness is obtained explicitly. □

9341.2 The continuation predicate

Definition 9341.3 (Analytic continuation predicate)**.** *For* f *holomorphic on* D_1*,* g *holomorphic on* D_2*, with* $\mathsf{DomCompat}(D_1, D_2, U)$*, the predicate* $\mathsf{AnaCont}(f, D_1, g, D_2, h)$ *holds when* h *is a holomorphic function on* $D_1 \cup D_2$ *such that:*

1. h *restricted to* D_1 *equals* f *under* hsame *pointwise;*
2. h *restricted to* D_2 *equals* g *under* hsame *pointwise;*
3. f *and* g *agree on the overlap region* U *under* hsame *pointwise (a precondition for existence).*

Theorem 9341.4 (Continuation is unique)**.** *If* $\mathsf{AnaCont}(f, D_1, g, D_2, h)$ *and* $\mathsf{AnaCont}(f, D_1, g, D_2, h')$ *both hold, then* $h = h'$ *under* hsame *pointwise on* $D_1 \cup D_2$*.*

Sketch. Constructive identity theorem (chapter 68) applied at the cluster sequence in U: both h and h' agree with f and g on dense subsets, hence on the union. □

9341.3 Chain continuation

Theorem 9341.5 (Chain continuation)**.** *If* $\mathsf{AnaCont}(f_1, D_1, f_2, D_2, h_{12})$ *and* $\mathsf{AnaCont}(h_{12}, D_1 \cup D_2, f_3, D_3, h_{123})$ *hold (with* $\mathsf{DomCompat}(D_1 \cup D_2, D_3, U_{23})$*), then composing the two continuations gives a single* $\mathsf{AnaCont}$ *witness on* $D_1 \cup D_2 \cup D_3$ *with explicit modulus inheritance.*

Sketch. Direct composition of holomorphic restrictions; uniqueness from Definition 9341.4 applied at each step. □

9341.4 Branch obstruction (schema-only horizon)

Definition 9341.6 (Branch obstruction)**.** *When the chain continuation closes a loop around a topological obstruction (e.g. continuing* $\sqrt{z}$ *along a circle around the origin), the resulting two extensions through different paths can disagree. The branch obstruction predicate* $\mathsf{BranchObstruction}$ *records this disagreement as a SCHEMA-ONLY structure: it codifies the constructive interface (input: two chain continuations; output: a quantitative non-agreement witness) without producing closed witnesses for general topological branches inside the BEDC framework.*

Remark 9341.7 (Schema-only nature of branch obstruction)**.** *The branch obstruction interface is intentionally a SCHEMA-ONLY HORIZON: BEDC can express the obstruction predicate, can produce concrete witnesses on specific examples (*$\sqrt{z}$*,* $\log z$ *around 0), but cannot in general decide whether a given chain configuration produces obstruction witnesses. This is consistent with the BEDC project's general schema-only horizon protocol — the chapter exposes the interface so future framework extensions can codify the closed witnesses, while the current chapter holds the schema open.*

9341.5 Concrete continuations

Theorem 9341.8 (Schwartz reflection)**.** *If f is holomorphic on the upper half-plane $\{z : \Im(z) > 0\}$ and continuous on the closure including a real boundary segment, with real values on the real boundary, then the function $\tilde{f}(z) = \overline{f(\bar{z})}$ defines a holomorphic continuation across the real boundary into the lower half-plane. The continuation is given as an explicit function with explicit modulus.*

Sketch. Direct verification using the Cauchy-Riemann equations (chapter 67) and the symmetry of the boundary trace. □

9341.6 Operation laws

Lemma 9341.9 (Functoriality)**.** AnaCont *respects* hsame *on inputs: if* hsame *on f, f' and on g, g' (pointwise on the respective domains), then* $\mathsf{AnaCont}(f, D_1, g, D_2, h)$ *implies* $\mathsf{AnaCont}(f', D_1, g', D_2, h)$ *for the same h up to* hsame *pointwise.*

Proof. Direct transport of equality witnesses under hsame. □

9341.7 The operation certificate

Definition 9341.10 (Analytic continuation operation certificate)**.** *The operation certificate consists of: (i) input spec — pairs (f, D_1) and (g, D_2) with overlap witness* $\mathsf{DomCompat}(D_1, D_2, U)$*; (ii) output spec — holomorphic h on $D_1 \cup D_2$ restricting compatibly; (iii) classifier —* hsame *pointwise on the union; (iv) operation laws — functoriality, chain composition, schwartz reflection as a concrete instance, and branch obstruction as the schema-only horizon; (v) ledger policy — uniqueness and existence under domain compatibility.*

Theorem 9341.11 (Concrete $\mathsf{AnaCont}^{\uparrow}$ operation certificate)**.** *The data above forms an operation certificate on* $\mathsf{Holomorphic}^{\uparrow}$ *for the analytic-continuation interface* $\mathsf{AnaCont}^{\uparrow}$*.*

Sketch. Each operation law is verified by direct construction in the preceding sections; the schema-only branch obstruction is exposed as a horizon, not closed. The certificate uses no Classical.choice, no Quot.sound, and no propext, so the operation's Lean targets fall under the project's axiom-purity gate. □

Theorem 9341.12 (Semantic $\mathsf{AnaCont}^{\uparrow}$ operation certificate)**.** *The concrete certificate of Definition 9341.11 satisfies the semantic operation-certificate schema obtained by adapting* NameCert *(chapter 9) to operation inputs/outputs.*

Sketch. Direct verification of the schema fields using the constructions of this chapter and the hsame-respect of the underlying $\mathsf{Holomorphic}^{\uparrow}$ classifier. □

Lemma 9341.13 (Domain compatibility is symmetric)**.** *If* $\mathsf{DomCompat}(D_1, D_2, U)$ *holds, then* $\mathsf{DomCompat}(D_2, D_1, U)$ *holds for the same overlap region U.*

Proof. Unpack Definition 9341.1. The displayed witness consists of an open disk $\mathsf{OpenDisk}(z_c, r_c)$ contained in $D_1 \cap D_2$ and a quantitative sequence in U clustering at z_c with the stated unary bound. The same center, radius, open-disk witness, overlap region, sequence, and density estimates witness compatibility in the reversed order. Only the containment record changes: membership in $D_1 \cap D_2$ is transported to membership in $D_2 \cap D_1$ by commutativity of intersection. □

Theorem 9341.14 (Analytic continuation symmetry)**.** *For any overlap region U,*

$$\mathsf{DomCompat}(D_1, D_2, U) \wedge \mathsf{AnaCont}(f, D_1, g, D_2, h) \Longrightarrow \mathsf{DomCompat}(D_2, D_1, U) \wedge \mathsf{AnaCont}(g, D_2, f, D_1, h).$$

Proof. The first conclusion is Definition 9341.13. For the continuation conclusion, unfold Definition 9341.3. The holomorphic carrier for h is unchanged because $D_1 \cup D_2$ and $D_2 \cup D_1$ are the same domain by commutativity of union. The restriction of h to D_2 is the second restriction clause of the given continuation witness, and becomes the first restriction clause after the swap. The restriction of h to D_1 is the first restriction clause of the given witness, and becomes the second restriction clause after the swap. On the common overlap U, the given pointwise agreement of f with g transports to pointwise agreement of g with f by symmetry of the classifier hsame. These are exactly the three clauses required for $\mathsf{AnaCont}(g, D_2, f, D_1, h)$ under the reversed compatibility witness. □

Theorem 9341.15 (Analytic continuation triple-chain associativity)**.** *Let D_1, D_2, D_3 be open domains of $\mathsf{Complex}^{\uparrow}$. Suppose*

$$\mathsf{AnaCont}(f_1, D_1, f_2, D_2, h_{12}) \wedge \mathsf{AnaCont}(f_2, D_2, f_3, D_3, h_{23}) \wedge \mathsf{AnaCont}(h_{12}, D_1 \cup D_2, f_3, D_3, h_{(12)3}).$$

Then there is a holomorphic carrier $h_{1(23)}$ such that

$$\mathsf{AnaCont}(f_1, D_1, h_{23}, D_2 \cup D_3, h_{1(23)})$$

and

$$\mathsf{hsame}(h_{(12)3}, h_{1(23)})$$

pointwise on $D_1 \cup D_2 \cup D_3$.

Proof. Unpack the three continuation witnesses using Definition 9341.3. The first witness says that h_{12} restricts to f_1 on D_1 and to f_2 on D_2. The second says that h_{23} restricts to f_2 on D_2 and to f_3 on D_3. The third says that $h_{(12)3}$ restricts to h_{12} on $D_1 \cup D_2$ and to f_3 on D_3.

The domain-compatibility witness for D_1 with $D_2 \cup D_3$ is obtained from the first overlap witness. Its open disk, center, radius, and cluster sequence are unchanged; the containment clause is transported from $U_{12} \subseteq D_1 \cap D_2$ to $U_{12} \subseteq D_1 \cap (D_2 \cup D_3)$ by the canonical inclusion $D_2 \subseteq D_2 \cup D_3$. This is exactly the data required by Definition 9341.1, equivalently by the topological form in Definition 77.31.

Apply Definition 9341.5 to the first two links, with the union parenthesized as $D_1 \cup (D_2 \cup D_3)$. This gives a holomorphic carrier $h_{1(23)}$ whose restrictions are f_1 on D_1 and h_{23} on $D_2 \cup D_3$, hence

$$\mathsf{AnaCont}(f_1, D_1, h_{23}, D_2 \cup D_3, h_{1(23)}).$$

It remains to identify this carrier with the left-grouped carrier. The same restriction clauses show that $h_{(12)3}$ is also a continuation of f_1 against h_{23} over D_1 and $D_2 \cup D_3$. On D_1, $h_{(12)3}$ restricts to h_{12} and h_{12} restricts to f_1. On D_2, both $h_{(12)3}$ and h_{23} restrict to f_2: the former through h_{12}, the latter by the second continuation witness. On D_3, both restrict to f_3. Transitivity and symmetry of the classifier hsame combine these pointwise restriction witnesses. The overlap agreement is the inherited D_1-D_2 agreement, transported along $D_2 \subseteq D_2 \cup D_3$.

Thus $h_{(12)3}$ and $h_{1(23)}$ are two witnesses for the same predicate

$$\mathsf{AnaCont}(f_1, D_1, h_{23}, D_2 \cup D_3, -).$$

By uniqueness of analytic continuation, Definition 9341.4, they are classified by hsame pointwise on $D_1 \cup (D_2 \cup D_3)$. Transporting along associativity of union identifies this domain with $D_1 \cup D_2 \cup D_3$. □

Theorem 9341.16 (Analytic continuation identity law)**.** *Let D be an open domain of* $\mathsf{Complex}^{\uparrow}$*, let f be holomorphic on D, and let U be an overlap region with* $\mathsf{DomCompat}(D, D, U)$*. Suppose the compatibility witness is non-trivial in the sense of Definition 9341.1: its displayed open disk and quantitative cluster sequence lie inside the overlap region contained in $D \cap D$. Then*

$$\mathsf{AnaCont}(f, D, f, D, f)$$

holds. Moreover, for every h,

$$\mathsf{AnaCont}(f, D, f, D, h) \Longrightarrow \forall z,\ z \in D \Longrightarrow \mathsf{hsame}(h(z), f(z)).$$

Equivalently, h and f are pointwise hsame *on $D \cup D$, transported along the canonical idempotence equivalence $D \cup D = D$.*

Proof. Unpack Definition 9341.3. The output domain for the pair (D, D) is $D \cup D$. This domain is constructively equivalent to D: membership in D maps into $D \cup D$ by the left inclusion, and membership in $D \cup D$ returns membership in D by case analysis on the two identical summands. Thus the given holomorphic carrier of f on D also presents f as a holomorphic carrier on $D \cup D$.

The first restriction clause is the restriction of f from $D \cup D$ to the first copy of D, which is pointwise hsame to f by reflexivity of the classifier. The second restriction clause is identical for the second copy of D. The overlap clause asks that the two input functions, both equal to f, agree on U; this is again pointwise reflexivity of hsame. The non-trivial disk and cluster data in the compatibility witness supply exactly the admissible overlap record required by Definition 9341.1. These three clauses give $\mathsf{AnaCont}(f, D, f, D, f)$.

Now assume $\mathsf{AnaCont}(f, D, f, D, h)$. Comparing this witness with the identity witness just constructed, Definition 9341.4 gives pointwise $\mathsf{hsame}(h, f)$ on $D \cup D$. Transporting this classifier through the same idempotence equivalence $D \cup D = D$ yields, for every $z \in D$, the pointwise comparison $\mathsf{hsame}(h(z), f(z))$. □

Concretized in §577: Analytic continuation is realized as a finite operation certificate over holomorphic source rows, overlap witnesses, and branch-obstruction ledgers.

Chapter 9342

The ζ Continuation Application: Extending $\mathsf{ZetaBasic}^{\uparrow}$ to $\mathsf{Complex}^{\uparrow} \setminus \{1\}$

This chapter is an APPLICATION of $\mathsf{AnaCont}^{\uparrow}$ (chapter 9341) to the basic ζ function $\mathsf{ZetaBasic}^{\uparrow}$ (chapter 71). It produces $\mathsf{ZetaCont}^{\uparrow}$: the unique meromorphic extension of ζ from $\Re(s) > 1$ to $\mathsf{Complex}^{\uparrow} \setminus \{1\}$ with a simple pole of explicit residue 1 at $s = 1$. The chapter proceeds in two stages: (i) use the Dirichlet eta quotient on the open locus where $1 - 2^{1-s} \neq 0$, fill the non-pole eta-quotient zeroes by removable continuation, and keep $s = 1$ as the pole; then (ii) extend ζ to $\mathsf{Complex}^{\uparrow} \setminus \{1\}$ through the meromorphic completed-function identity. Both stages are concrete applications of analytic continuation. The chapter uses the constructive Gamma function Γ on $\mathsf{Complex}^{\uparrow} \setminus \{0, -1, -2, \ldots\}$ as a black-box meromorphic factor — the constructive Gamma is itself a SCHEMA-ONLY HORIZON awaiting a future BEDC chapter; the present chapter exposes the interface but does not close all underlying witnesses. The construction uses no Classical.choice, no Quot.sound, and no propext, so the application's Lean targets fall under the project's axiom-purity gate.

9342.1 The Dirichlet eta function

Definition 9342.1 (Dirichlet eta function)**.** *The Dirichlet eta function is the alternating Dirichlet series $\eta(s) = \sum_{n=1}^{\infty}(-1)^{n-1}n^{-s}$, with coefficients $a_n = (-1)^{n-1}$ (decidable on parity of unary index).*

Theorem 9342.2 (Eta well-defined on $\Re(s) > 0$)**.** *The Dirichlet eta function converges in $\mathsf{CplxSer}^{\uparrow}$ (chapter 69) for every s with $\Re(s) > 0$, with explicit modulus given by an alternating-series majorant. The function $s \mapsto \eta(s)$ is holomorphic on $\Re(s) > 0$ (chapter 68).*

Sketch. The alternating-sign structure gives Cauchy-criterion convergence on the half-plane $\Re(s) > 0$; explicit modulus from successive-difference bounds. Holomorphicity from term-wise differentiation with uniform modulus on compact sub-half-planes. □

Theorem 9342.3 (Eta-zeta relation)**.** *For every s with $\Re(s) > 1$, the relation*

$$\zeta(s) = \frac{\eta(s)}{1 - 2^{1-s}}$$

holds, where the right-hand side is computed using complex division ($\mathsf{Complex}^{\uparrow}$, chapter 39). The denominator is non-zero on $\Re(s) > 1$. On the larger half-plane $\Re(s) > 0$, its zero locus is the

discrete line

$$s = 1 + \frac{2\pi i k}{\log 2}, \qquad k \in \mathbb{Z}.$$

Sketch. The relation $\eta(s) = (1-2^{1-s})\zeta(s)$ follows from the rearrangement $\zeta(s) - 2\cdot 2^{-s}\zeta(s) = \eta(s)$, valid by absolute convergence. Solve for ζ. □

9342.2 ζ on the half-plane $\Re(s) > 0$ via eta

Theorem 9342.4 (ζ on $\Re(s) > 0$)**.** *On the open set*

$$U_\eta = \{s : \Re(s) > 0 \text{ and } 1 - 2^{1-s} \neq 0\},$$

the eta quotient $\eta(s)/(1-2^{1-s})$ gives the holomorphic continuation of ζ from $\Re(s) > 1$. At each point

$$s = 1 + \frac{2\pi i k}{\log 2}, \qquad k \in \mathbb{Z},\ k \neq 0,$$

the quotient has a removable $0/0$ singularity and the value is defined by the unique holomorphic continuation across a small punctured neighbourhood. The point $s = 1$ is not filled by this row; it is the pole recorded in Definition 9342.5. The extension is unique by the constructive identity theorem (chapter 68); the underlying analytic-continuation witness is supplied by $\mathsf{AnaCont}^{\uparrow}$ *applied to overlapping disk neighbourhoods inside both half-planes.*

Sketch. Apply $\mathsf{AnaCont}$ (chapter 9341) to the holomorphic restrictions of (i) ζ on $\Re(s) > 1$ and (ii) $\eta(s)/(1-2^{1-s})$ on U_η. The eta-relation provides the overlap-region agreement. At the non-pole denominator zeroes, the two sides agree on punctured neighbourhoods and the singularity is removable by the continuation row; at $s = 1$ the pole ledger is used instead. □

9342.3 The pole at $s = 1$

Theorem 9342.5 (Simple pole at $s = 1$ with residue 1)**.** *ζ has a simple pole at $s = 1$ with residue exactly* $\mathsf{E1(e)}$ *(the unit complex history). Concretely, the limit $\lim_{s\to 1}(s-1)\zeta(s) = 1$ holds with explicit modulus given by the harmonic-series log-divergence rate.*

Sketch. The harmonic divergence $\sum_{n=1}^{N} 1/n \sim \log N$ gives $(s-1)\zeta(s) \to 1$ as $s \to 1^+$ with explicit unary-history modulus on the difference. Apply the eta-relation continuation to extend this to a simple-pole witness on a neighbourhood of $s = 1$. □

9342.4 The functional equation

Theorem 9342.6 (Riemann functional equation)**.** *The functional equation is recorded first as a meromorphic identity for the completed zeta carrier. Writing*

$$\Lambda(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s),$$

the identity is

$$\Lambda(s) = \Lambda(1-s)$$

as meromorphic functions after the pole ledger is attached. Equivalently, the classical factorized expression

$$\zeta(s) = 2^s \pi^{s-1} \sin(\pi s/2)\Gamma(1-s)\zeta(1-s)$$

is read as an identity in the meromorphic function field before any pointwise value is claimed. The displayed factors are:

1. $2^s = \exp(s \log 2)$ *on the constructive complex* $\exp$ *and constructive real* $\log 2$ *(*$\mathsf{Real}^\uparrow$*, chapter 38);*
2. π^{s-1} *defined similarly with constructive real* $\log \pi$*;*
3. $\sin(\pi s/2)$ *defined via the constructive complex sine power series (radius of convergence infinity);*
4. $\Gamma(1-s)$ *is the constructive complex Gamma function on* $\mathsf{Complex}^\uparrow \setminus \{0, -1, -2, \ldots\}$ *— exposed here as a SCHEMA-ONLY interface awaiting a future BEDC* $\mathsf{Gamma}^\uparrow$ *chapter.*

At positive integers where $\Gamma(1-s)$ *has a pole and* $\sin(\pi s/2)$ *may cancel it, the pointwise value is admitted only after a separate removable-cancellation row has been checked. Thus this theorem is not a pointwise assertion at every displayed complex history.*

Sketch. The functional equation is established by the classical contour-integral identity reorganization, made constructive on the BEDC contour-integral framework (chapter 9340). The Gamma factor's constructive Lean target is held open as a schema-only horizon; the rest of the derivation (the trigonometric/exponential factors and the contour reorganization) is fully constructive on the data of this chapter. □

Remark 9342.7 (Constructive Gamma as schema-only horizon)**.** *The constructive complex Gamma function* Γ *on* $\mathsf{Complex}^\uparrow \setminus \{0, -1, -2, \ldots\}$ *is intentionally exposed here as a schema-only horizon: this chapter uses* Γ *as a black-box meromorphic factor in the functional equation, identifies the input/output classifier interface (input: complex history outside the negative integers; output: complex-history value with explicit modulus), but does not produce the closed Lean witness. A future BEDC chapter* $\mathsf{Gamma}^\uparrow$ *is the natural home for closing the schema.*

9342.5 ζ on $\mathsf{Complex}^\uparrow \setminus \{1\}$

Theorem 9342.8 (Full continuation)**.** *The function* ζ *extends holomorphically to* $\mathsf{Complex}^\uparrow \setminus \{1\}$ *by applying the functional equation to reflect from* $\Re(s) > 0$ *into* $\Re(s) < 1$ *through the line* $\Re(s) = 1/2$*. The extension is unique by the identity theorem.*

Sketch. Apply $\mathsf{AnaCont}$ (chapter 9341) twice: first to extend ζ from $\Re(s) > 1$ to $\Re(s) > 0$ (via eta), then to extend from $\Re(s) > 0$ to $\Re(s) < 1$ (via functional equation reflection). The two extensions agree on the strip $0 < \Re(s) < 1$, giving a single continuation on $\mathsf{Complex}^\uparrow \setminus \{1\}$. □

9342.6 Trivial zeros from the functional equation

Theorem 9342.9 (Trivial zeros witness)**.** *For every unary* $n \geq \mathsf{E1}(\mathsf{e})$*,* $\zeta(-2n) = 0$ *constructively, with witness coming from* $\sin(\pi s/2) = 0$ *at even* $s \leq -2$ *in the functional equation. The other factors* $2^s, \pi^{s-1}, \Gamma(1-s), \zeta(1-s)$ *are non-zero and finite at* $s = -2n$*.*

Sketch. At $s = -2n$, $\pi s/2 = -n\pi$, so $\sin(-n\pi) = 0$ constructively (rational multiple of π with even multiplier — unary-decidable). The remaining factors are non-zero by direct constructive evaluation: $\Gamma(1+2n)$ is the unary factorial $(2n)!$ ($\mathsf{Prime}^\uparrow$, chapter 64); $\zeta(1+2n)$ lies in the half-plane $\Re(s) > 1$ where ζ is non-zero (chapter 71). □

9342.7 The application certificate

Definition 9342.10 (Zeta continuation application certificate)**.** *The application certificate consists of: (i) input spec — the basic ζ certificate of* $\mathsf{ZetaBasic}^{\uparrow}$ *(chapter 71); (ii) output spec — the holomorphic extension of ζ on* $\mathsf{Complex}^{\uparrow} \setminus \{1\}$ *with simple pole and residue 1 at $s = 1$; (iii) classifier —* hsame *pointwise on the extended domain; (iv) operation laws — eta-relation, functional equation, chain continuation; (v) ledger policy — pole at 1, trivial zeros at negative even integers, the constructive Gamma horizon.*

Theorem 9342.11 (Concrete $\mathsf{ZetaCont}^{\uparrow}$ application certificate)**.** *The data above forms an application certificate of* $\mathsf{AnaCont}^{\uparrow}$ *on* $\mathsf{ZetaBasic}^{\uparrow}$ *producing the extended ζ function on* $\mathsf{Complex}^{\uparrow} \setminus \{1\}$.

Sketch. Verification of each step of the two-stage continuation in the preceding sections; the constructive-Gamma factor in the functional equation is exposed as a schema-only horizon. The application uses no Classical.choice, no Quot.sound, and no propext, so the application's Lean targets fall under the project's axiom-purity gate. □

Theorem 9342.12 (Semantic $\mathsf{ZetaCont}^{\uparrow}$ application certificate)**.** *The concrete certificate of Definition 9342.11 satisfies the semantic application-certificate schema obtained by adapting* NameCert *(chapter 9) to operation-application inputs/outputs.*

Sketch. Direct verification of the schema fields using the constructions of this chapter and the hsame-respect of the underlying $\mathsf{ZetaBasic}^{\uparrow}$, $\mathsf{AnaCont}^{\uparrow}$, and $\mathsf{Complex}^{\uparrow}$ classifiers. □

Concretized in §580: The eta-continuation, pole, functional-equation, trivial-zero, and Gamma-horizon routes are packaged as a finite witness NameCert.

Concretized in §581: The functional-equation ledger is realized as a finite NameCert packet for eta continuation, Gamma boundary, contour provenance, and trivial-zero consumption.

Concretized in §570: Zeta continuation is realized as a finite NameCert socket packet over zeta-basic, eta, analytic-continuation, pole, functional-equation, Gamma, and trivial-zero ledger rows.

Concretized in §588: Zeta continuation application is realized as a finite NameCert packet over eta continuation, functional-equation continuation, pole and zero ledgers, Gamma horizon rows, and application-certificate non-escape.

Concretized in §1101: Gamma-Zeta factor seals realize the functional-equation Gamma factor as a finite NameCert packet over Gamma-domain, reflected-input, zeta-application, transport, replay, provenance, and local naming rows.

Chapter 9343

Exploratory RH Route Ledger

This chapter records the exploratory RH route developed in a 169-turn working session. The purpose is archival and diagnostic. It separates ideas that are already covered by existing BEDC formal surfaces from heuristic geometry, conjectural bridge obligations, and full-strength restatements. It does not prove the Riemann Hypothesis, does not assert proximity to a proof, and does not introduce Lean targets for philosophical or analogy-driven material.

9343.1 Audit Convention

Each item below is assigned one of four statuses.

Definition 9343.1 (Route ledger status)**.** *A route item is* covered *when its formal kernel is already represented by an existing RH chapter or by an existing* BEDC.Derived.RHRoute *module. It is* heuristic *when it gives geometric, physical, or ontological guidance without a present theorem. It is* conditional *when it gives a valid implication from an explicit bridge obligation to* RH *or to a zero-exclusion target. It is* full-strength restatement *when the proposed bridge is, after quantification strong enough to do work, another form of the no-off-line-zero problem.*

The four statuses are intentionally not arranged as a progress scale. "Covered" does not mean that RH is proved; it means that the particular small datum has already been formalized or recorded. "Heuristic" does not mean false; it means that no certificate-bearing mathematical statement is being claimed. "Conditional" records an honest theorem shape whose hypotheses remain open. "Full-strength restatement" records a useful diagnostic translation rather than a reduction of difficulty.

9343.2 Three Boundaries and the Prime-Unitary Surface

The earliest stable correction in the exploration was the separation of three objects:

$$\mathrm{Fix}(J), \qquad \prod_s \mathsf{Decidable}(\mathsf{ZetaZero}(s)), \qquad \mathsf{RH}.$$

The first is the geometric fixed surface of the functional-equation mirror

$$J(s) = 1 - \overline{s}.$$

The second is an exact zero decision operator. The third is the global rigidity statement that a certified critical-strip zero lands on the fixed surface.

Status: covered. The fixed-surface computation is the subject of chapter 9240, whose Lean-side kernel is the module BEDC.Derived.RHRoute.FunctionalEquationSymmetry. That module verifies the fixed-surface calculation identifying J-fixedness with the critical-line predicate. The same chapter also records why exact zero decidability is a different object from the RH proposition.

The prime-unitary readout was also stabilized. For a displayed base $a > 1$,

$$|a^{1/2-s}| = 1 \quad \Longleftrightarrow \quad \Re(s) = 1/2.$$

For primes this is the centered Euler-channel readout $U_p(s) = p^{1/2-s}$. The point of the ledger is the negative boundary: this calculation is a critical-line reparameterization, not an RH mechanism by itself. It applies for every displayed $a > 1$ and says nothing about whether s carries a zeta-zero packet.

Status: covered. The prime-local surface is recorded in chapter 9243 and chapter 9240. Its Lean-side carrier is the existing BEDC.Derived.RHRoute.UnitaryBalance module. The route becomes RH-facing only after a zero-ledger bridge supplies a reason why an off-line zero cannot coexist with the displayed prime-channel defect.

9343.3 Located Process Geometry and Type Boundaries

The session repeatedly used a geometric language in which a rational value axis is distinguished from a process axis. In BEDC terms, the strict content is this: located real data are not bare rational points but approximation processes with explicit moduli. A rational value is the degenerate case with a constant approximation and trivial modulus. Comparing two located reals is therefore comparison of two approximation processes to a displayed tolerance, not an unrestricted trichotomy of exact completed points.

Status: heuristic as imagery, covered as infrastructure. The language of orthogonal axes, shadows, and process directions is only a visualization. The certificate content is the ordinary BEDC discipline already used by the located real and zeta-box modules: finite tolerance, apartness, and explicit moduli stay inside the constructive fragment; exact global comparison and unrestricted point extraction belong to a separate boundary.

The same discussion produced a useful caution about Classical.choice, Quot.sound, and propext. The honest statement is not that classical mathematics is erroneous, nor that these names are proved necessary for zeta. The statement is only that such constants measure implementation footprints for particular classical encodings: choice extracts data from existence, quotients identify processes as points, and propositional extensionality collapses proof distinctions. BEDC avoids those collapses in the kernel.

Status: heuristic and governance-facing. The transcript's strongest versions of this point are philosophy of implementation, not RH lemmas. No Lean target is attached to them here.

9343.4 Common Carrier and Zeta as a Projection Chain

The middle part of the session organized triangles, circles, elliptic normalizations, Fourier and Laplace transforms, and zeta as a chain of compatible projections rather than as a literal holomorphic continuation from one object to the next. The valid BEDC reading is:

$$\text{shared carrier rows} \quad \rightsquigarrow \quad \text{compatible algebraic, geometric, spectral, and analytic readouts.}$$

For zeta this means that the Dirichlet series, Euler product, eta row, analytic continuation, archimedean completion, functional equation, pole ledger, zero ledger, and branch-transport rows are compatible readings of a recovered carrier.

Status: covered. The recovered-carrier discipline is already recorded in chapter 9243, chapter 9241, and chapter 9250. The taxonomy side is represented by the existing BEDC.Derived.RHRoute.ZetaLikeProjec module. This does not imply that properties of a triangle, a circle, a finite elliptic model, or a Fourier transform transfer automatically to Riemann zeta. Such transfer requires displayed carrier maps, overlap laws, and tail or continuation estimates.

The finite quartic spectral-curve example was used as a guide for what a closed finite model looks like: recurrence data, spectral polynomial, normalization, projection, dominant branch, and endpoint zero law are all in the same finite ledger. The honest lesson for RH is negative as much as positive. Riemann ξ is an order-one entire transcendental function with infinitely many zeros; a finite algebraic branch argument does not transfer through the finite-to-infinite boundary without a separate convergence, dominance, or positivity theorem.

Status: heuristic for RH, useful as finite-model discipline. It is not a proof template that can be applied by analogy alone.

9343.5 Object Induction, Three Invariants, and No-Split Zeros

Another arc described a triad of object-level invariants: observation/time, distinction/prime locality, and symmetry/transport. In BEDC vocabulary this can be read as a route through histories and continuation, gap or apartness data, and hsame-respecting transport. The proposed RH reading was that a zero fiber should have no additional same-layer normal degree of freedom.

Status: covered as a conditional route, heuristic as philosophy. Existing modules already record the usable conditional kernel: ObjectRealityInductionRoute packages the object-induction route; ZeroGenerationInitiality packages the initiality route; and ZeroSignatureFaithfulness records signature-faithfulness obligations. The paper-side references are chapter 9255 and the neighboring zero-generation chapters.

The missing theorem is not a slogan about there being only three invariants. It is a zero-fiber exactness theorem. One possible form says: every accepted critical-strip zero packet is generated by pre-RH constructors, and those constructors preserve the fixed-half subcarrier. Another possible form says: a mirror-split off-line zero would expose a defect row that the completed carrier cannot accept. Both are conditional bridges; neither is currently closed for Riemann zeta.

Status: conditional. The session's "pigeonhole" language is best read as classifier faithfulness. It is not a proof that two mirror-related off-line zeros must be the same point.

9343.6 Finite Prime Windows, Odd Defects, and Even Energy

The most concrete non-analytic core of the session was the normal-defect calculation. Write

$$s = \frac{1}{2} + \delta + i\tau.$$

Then each centered prime channel satisfies

$$|p^{1/2-s}| = p^{-\delta}.$$

Consequently a nonzero δ produces a coherent amplitude defect in every displayed nonempty prime window. A mirror pair sends δ to $-\delta$; signed first-order defect can cancel between the two mirror reads, but the even energy δ^2 cannot be removed by that sign change.

Status: covered as finite readout. The window and defect apparatus is already recorded in chapter 9244, chapter 9249, and chapter 9245. Existing Lean modules cover the finite machinery: FinitePrimeWindow, PrimeSkewDefect, OddZeroDefect, EvenDefectEnergy, and FiniteToInfinitePhaseEnergyTower.

The finite conclusion is not RH. It says that off-line bias is locally visible. The missing analytic carrier theorem is

$$\mathsf{ZetaZero}(s) \times \mathsf{PositiveNormalDefect}(s) \to \bot,$$

or an equivalent completed-carrier exclusion. This is the same hinge isolated in the local-global exclusion chapters. It is recorded here as conditional, not as a checked theorem.

9343.7 Far-End, Solenoid, and Lee–Yang Readings

The far-end discussion produced two separate items that must not be confused. First, it gave a useful discipline: the infinite end is not a point, a warehouse, or an untyped place where a finite defect can disappear. Second, when expressed as "no far-end absorption for zeta," it becomes a restatement of the no-off-line-zero problem unless an independent positivity or domination theorem is supplied.

Status: full-strength restatement when quantified strongly enough for zeta. The existing OnticBoundaryLedger module already records this boundary as a ledger entry rather than a proof. The far-end unity and energy socket modules record finite normalization interfaces, but they do not discharge the zeta-specific zero-exclusion theorem.

The solenoid and Lee–Yang turn was more precise. For a finite prime set S, an S-localized solenoid has a visible circle and a compact p-adic fiber. A finite Lee–Yang stable resonance can force its zeros to land on the unit boundary. In the s-coordinate, a local factor of the form

$$z = e^{-(s-1/2)H}, \qquad H > 0,$$

lands on the unit circle only when $\Re(s) = 1/2$.

Status: conditional. Finite solenoid or Lee–Yang mechanisms are genuine mathematical structures, and existing RHRoute ledgers contain finite solenoid-bound and source-gap records. The missing bridge is to show that Riemann ξ admits a zero-relevant solenoid Lee–Yang capture: on each off-line compact region, a stable solenoid main term dominates a tail term, or a sequence of finite Lee–Yang stable approximants converges to Ξ. Without that bridge, the mechanism does not prove RH.

9343.8 Dyadic Truncations, Jensen, Hilbert–Polya, and Weil Positivity

The final technical arc audited several standard route families. All of them can be made honest by expressing their bridge obligations directly.

Principle 9343.2 (Dyadic Laguerre–Polya bridge)**.** *If a family of completed dyadic truncations Ξ_K converges locally uniformly to Ξ and every Ξ_K belongs to the Laguerre–Polya class, then Hurwitz-type reasoning gives real zeros for Ξ and hence RH.*

Status: bridge sound, premise false for the sharp truncation route recorded in this paper. chapter 9338 records why the tempting all-K sharp-cutoff Laguerre–Polya premise does not hold. Thus the dyadic arc is preserved as a negative route ledger, not as a pending proof.

Principle 9343.3 (Jensen and Laguerre–Polya audit)**.** *Showing all Jensen polynomials attached to Ξ are hyperbolic is a classical Laguerre–Polya route to RH. Fixed-degree high-shift hyperbolicity is informative, but the all-degree all-shift family is the hard object.*

Status: full-strength restatement as a global criterion. It is not a BEDC shortcut.

Principle 9343.4 (Hilbert–Polya and spectral determinant audit)**.** *A self-adjoint or unitary spectral realization whose determinant is Riemann ξ would force the required real-line or unit-circle zero placement. Finite CMV, Jacobi, and determinant interfaces demonstrate the shape of such mechanisms but do not construct the required infinite operator for ξ.*

Status: conditional. The finite spectral interface is useful; the determinant-equals-ξ theorem is not present.

Principle 9343.5 (Weil and Li positivity audit)**.** *Weil positivity and Li coefficient positivity are faithful RH criteria. They are valuable because they identify the correct positive form or coefficient sequence. They become proof mechanisms only when the positivity is derived from an independent structure rather than assumed in a form coextensive with the fixed RH target.*

Status: full-strength restatement as global positivity; potentially useful as a target if an independent semi-local domination theorem is produced. The last turns of the session therefore correctly moved toward semi-local Weil positivity, finite matrix criteria, Birman–Schwinger bounds, and low/high-frequency estimates. Those are bridge obligations, not checked results in this paper.

9343.9 Lean Decision

No Lean module accompanies this chapter. The session contains many phrases that can be given formal-looking names, but the only parts that are currently suitable for 0-axiom BEDC formalization are already represented by existing RHRoute modules: the functional-equation fixed surface, the prime-unitary readout, finite prime-window gluing, odd and even defect rows, object-induction and zero-generation conditional routes, route-closure separation, zeta projection taxonomy, and finite solenoid-bound ledgers.

The remaining items require one of the following before they become Lean targets:

a zeta-specific defect-zero incompatibility theorem,
a zero-presentation exactness theorem for a pre-RH generator,
a solenoid Lee–Yang capture theorem for Ξ,
a full Laguerre–Polya or Jensen hyperbolicity proof,
an independent Weil or Li positivity theorem,
or a spectral realization whose determinant is ξ.

None of these is available in the repository as a closed 0-axiom theorem. They are therefore recorded as route obligations and not as Lean stubs.

9343.10 Summary

The session is valuable as a route ledger because it repeatedly found the same boundary from different directions. The critical line is already the functional-equation fixed surface. Prime-unitary

balance and finite windows read that surface cleanly, but do not by themselves carry a zeta-zero exclusion. Geometric language about common carriers, process axes, far-ends, resonances, and no-hair principles is useful only when translated into displayed carrier maps, stability, positivity, or tail domination. When such translation is strong enough to rule out off-line zeros, it is exactly where the RH difficulty lives.

Thus the honest current state is:

$$\boxed{\text{finite and conditional RHRoute kernels are already recorded;}}$$

$$\boxed{\text{the session contributes no separate 0-axiom theorem beyond existing coverage;}}$$

$$\boxed{\text{the unresolved work is analytic rigidity, not terminology.}}$$

Concretized in §7545: The critical-strip oscillation packet realizes the finite zero-window boundary used by the RH route.

Chapter 9344

The Unary-Direction Bridge $\mathsf{Nat}^{\uparrow} \leftrightarrow \mathsf{AxisNat}^{\uparrow}$

This chapter introduces a kernel-distinct comparison interface between the $\mathsf{E1}$-spine carrier behind $\mathsf{Nat}^{\uparrow}$ (Chapter 28) and the $\mathsf{E0}$-spine carrier behind $\mathsf{AxisNat}^{\uparrow}$ (Chapter 276). The bridge does NOT identify the two carriers inside the BEDC finite kernel; it records that the two interfaces are isomorphic in the standard model, while remaining propositionally distinct on histories.

9344.1 Carrier intersection

Theorem 9344.1 (Unary and zero-spine meet only at the empty history)**.** *For every history h, if both* $\mathsf{Unary}(h)$ *and* $\mathsf{ZeroSpine}(h)$ *hold, then* $h = \mathsf{e}$.

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Bridge.unary and zeroSpine only meet at empty`

Proof. By cases on the zero-spine derivation. In the empty case the conclusion is immediate. In the $\mathsf{E0}$-step case the unary witness on $\mathsf{E0}(h')$ contradicts unary no-zero-extension. □

Lemma 9344.2 (Unary at $\mathsf{E1}(\mathsf{e})$ is not zero-spine)**.** $\mathsf{ZeroSpine}(\mathsf{E1}(\mathsf{e}))$ *does not hold.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Bridge.unary e1 not zeroSpine at step`

Proof. Direct from zero-spine no-one-extension applied at $h = \mathsf{e}$. □

Lemma 9344.3 (Zero-spine at $\mathsf{E0}(\mathsf{e})$ is not unary)**.** $\mathsf{Unary}(\mathsf{E0}(\mathsf{e}))$ *does not hold.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Bridge.zeroSpine e0 not unary at step`

Proof. Direct from unary no-zero-extension applied at $h = \mathsf{e}$. □

9344.2 The bridge interface

Definition 9344.4 (Unary-direction bridge)**.** *The bridge* $\mathsf{UnaryDirectionBridge}$ *records:*

1. *the carrier* Unary *of* $\mathsf{Nat}^{\uparrow}$*;*
2. *the carrier* $\mathsf{ZeroSpine}$ *of* $\mathsf{AxisNat}^{\uparrow}$*;*
3. *the kernel-distinctness witness, that the two carriers intersect only at* e.

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Bridge.UnaryDirectionBridge`
↪ variant `BEDC.Derived.AxisZeckendorf.Bridge.unaryDirectionBridge`

Remark 9344.5 (Bridge is kernel-distinct, not kernel-identification)**.** *The bridge records witnesses, not equalities. The* $\mathsf{Nat}^{\uparrow}$ *and* $\mathsf{AxisNat}^{\uparrow}$ *carriers remain distinct as history predicates inside the finite kernel. Any attempt to identify them at the kernel level conflicts with Theorem 9344.1.*

9344.3 Standard-model isomorphism (horizon)

The bridge is licensed by an isomorphism in the standard model: each non-empty unary history $\mathsf{E1}^n(\mathsf{e})$ corresponds to a non-empty zero-spine history $\mathsf{E0}^n(\mathsf{e})$, and the correspondence is bijective and continuation-preserving in the standard model. The proof of this correspondence at paper level, together with its zero-spine pattern variant, is a horizon obligation queued for the formalize pipeline.

Theorem 9344.6 (Standard-model isomorphism, horizon)**.** *There is a length-preserving bijection between non-empty unary histories and non-empty zero-spine histories, and this bijection commutes with the additive interfaces* $\mathsf{Add}^{\uparrow}$ *and* $\mathsf{AxisAdd}^{\uparrow}$ *in the standard model.*

Remark 9344.7 (Bridge does not retire either chapter)**.** *The bridge does not collapse Chapters 28 and 276 into a single chapter. Both certificates remain independent inside the finite kernel; the bridge only relates them at the standard-model boundary.*

Concretized in §530: The unary-direction bridge is realized as a finite NameCert packet relating NatUp unary spines, AxisNatUp zero spines, and kernel-distinctness witnesses.

Concretized in §572: The unary-zero-spine standard-boundary comparison is represented as a finite NameCert packet with length-match rows, two finite continuation routes, and a kernel nonidentification boundary.

Concretized in §599: AxisUnarySpineNormalizer packets realize the unary-to-zero-spine standard boundary as finite BHist, hsame, Cont, Pkg, and NameCert rows without identifying the carriers.

Concretized in §700: Unary-direction routers realize the consumer-side choice between unary-to-axis and axis-to-unary standard-boundary reads as a finite NameCert packet without identifying the carriers.

Concretized in §1010: Unary direction normalizers realize the axis-Zeckendorf bridge as finite axis, zero-spine, carry, direction, transport, route, provenance, and NameCert rows.

Chapter 9345

A Concrete Naming Certificate for $\mathsf{ZCarry}^{\uparrow}$

This chapter introduces the Zeckendorf carry classifier $\mathsf{ZCarry}(h, k)$, generated by the local rewrite `word_011` $\to$ `word_100` (cf. Definition 278.2). The crucial property of this classifier is that it is NOT history-sameness: $\mathsf{ZCarry}(h, k)$ does not entail $\mathsf{hsame}(h, k)$. The Fibonacci value-preservation reading is a horizon target.

9345.1 The carry classifier

Definition 9345.1 (Zeckendorf carry classifier)**.** *The classifier* $\mathsf{ZCarry}(h, k)$ *is generated by the single base rule*

$$\mathsf{ZCarry}(\texttt{word_011}, \texttt{word_100}).$$

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.ZCarry`

Lemma 9345.2 (The display carry is generated)**.** $\mathsf{ZCarry}(\texttt{word_011}, \texttt{word_100})$ *holds.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.zCarry 011 100`

Proof. First (and only) generator of ZCarry. □

9345.2 Carry is not history-sameness

Theorem 9345.3 (`word_011` and `word_100` are not hsame)**.** $\mathsf{hsame}(\texttt{word_011}, \texttt{word_100})$ *does not hold.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.zCarry 011 100 not hsame`

Proof. Recall that hsame is propositional history identity. The first history has top constructor $\mathsf{E1}$; the second has top constructor $\mathsf{E0}$. The two top constructors are distinct, so the histories are unequal, and hsame does not hold. □

Theorem 9345.4 (Carry is not history-sameness)**.** *For every* h *and* k*,* $\mathsf{ZCarry}(h, k)$ *implies* $\neg\mathsf{hsame}(h, k)$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.zCarry not hsame`

Proof. By the unique generator, any $\mathsf{ZCarry}(h, k)$ instance has $h = \texttt{word_011}$ and $k = \texttt{word_100}$. The conclusion follows from Theorem 9345.3. □

9345.3 Carry transports normal-form status

Theorem 9345.5 (Carry target is normal)**.** *For every h, k, if* $\mathsf{ZCarry}(h, k)$*, then* $\mathsf{ZNormal}(k)$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.zCarry target normal`

Proof. The unique generator pins $k =$ `word_100`; apply Theorem 278.3. □

Theorem 9345.6 (Carry source is non-normal)**.** *For every h, k, if* $\mathsf{ZCarry}(h, k)$*, then* $\neg\mathsf{ZNormal}(h)$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.zCarry source not normal`

Proof. The unique generator pins $h =$ `word_011`; apply Theorem 278.4. □

9345.4 The certificate

Definition 9345.7 (Carry source specification)**.** *The source specification* ZCarrySource *consists of histories h with* $\neg\mathsf{ZNormal}(h)$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.ZCarrySourceSpec`

Definition 9345.8 (Carry pattern specification)**.** *The pattern specification* ZCarryPattern *is the carry generator* $\mathsf{ZCarry}(h, k)$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.ZCarryPatternSpec`

Definition 9345.9 (Carry classifier specification)**.** *The classifier specification* ZCarryClassifier *records, on each carry pair, that the target is normal, the source is non-normal, and the source is not* hsame *to the target.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.ZCarryClassifierSpec`

Definition 9345.10 (Carry stability certificate)**.** *The stability certificate* ZCarryStability *consists of:*

1. *carry-not-*hsame *(Theorem 9345.4);*
2. *target normal (Theorem 9345.5);*
3. *source non-normal (Theorem 9345.6);*
4. *Fibonacci value preservation, horizon obligation.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.ZCarryStabilityCert`
↪ variant `BEDC.Derived.AxisZeckendorf.Carry.zCarryStabilityCert`

Definition 9345.11 (Carry ledger policy)**.** *The ledger policy* ZCarryLedger *records the non-normal preimage and the carry witness behind any visible carry-classification.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.ZCarryLedgerPolicy`

Theorem 9345.12 (Concrete $\mathsf{ZCarry}^{\uparrow}$ naming certificate)**.** *The tuple*

$$\mathsf{NameCert}_{\mathsf{ZCarry}^{\uparrow}} := (\mathsf{ZCarrySource}, \mathsf{ZCarryPattern}, \mathsf{ZCarryClassifier}, \mathsf{ZCarryStability}, \mathsf{ZCarryLedger})$$

forms a valid naming certificate for the derived classifier interface $\mathsf{ZCarry}^{\uparrow}$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.Carry.zCarry namecert`

Proof. The five fields are supplied by the preceding definitions. The stability field includes three checked theorems and one explicit horizon obligation. □

Corollary 9345.13 ($\mathsf{ZCarry}^{\uparrow}$ is licensed, not primitive)**.** *The interface* $\mathsf{ZCarry}^{\uparrow}$ *is licensed by* $\mathsf{NameCert}_{\mathsf{ZCarry}^{\uparrow}}$*. It is a classifier, not a kernel equality, and it is not a primitive object of the finite kernel.*

Remark 9345.14 (Carry must remain a classifier)**.** *The crucial discipline of this chapter is that* ZCarry *is a classifier between non-*hsame *histories. Any future extension that promotes the carry to a kernel-level identification—either by replacing* hsame *on* ZNormal *histories or by inserting a global rewrite into the kernel—conflicts with Theorem 9345.4 and is rejected by the bridge discipline.*

Concretized in §567: Zeckendorf carry classifiers are realized as finite BHist carry-window NameCert packets separating carry-relatedness from history sameness.

Concretized in §606: The displayed carry row is realized as a finite value-preservation NameCert packet that keeps carry-relatedness separate from history sameness.

Concretized in §608: Zeckendorf carry normalization is realized as a finite NameCert packet separating carry, normal-form target, value ledger, and non-hsame boundary rows.

Concretized in §692: AxisZeckendorf carry budgets realize the finite carry-window, normal-form, value-ledger, non-hsame, transport, route, provenance, and NameCert packet behind the carry classifier.

Concretized in §713: Axis carry confluence is realized as a finite BHist NameCert packet for two displayed carry-normalization routes, their shared normal target, value ledger, and non-escape boundary.

Concretized in §1049: Axis carry route separation is realized as a finite NameCert packet separating carry-relatedness, normal-form routing, and history-sameness refusal.

Concretized in §1118: Axis carry diamond routes realize two displayed carry-normalization paths, shared normal target rows, value ledgers, and non-history-sameness boundaries as a finite NameCert packet.

Concretized in §7072: Overlapping Zeckendorf carry windows are realized as a finite local critical-pair packet with route, shared normal target, value-ledger, and non-hsame boundary rows.

Chapter 9346

Zeckendorf Golden Phase Projection

This chapter records a vision-level derived interface attached to the Axis-Zeckendorf route. It reads the no-adjacent-11 grammar as a finite visible surface, keeps the raw binary microstates in a residual fiber ledger, and assigns a golden-ratio phase only as an external projection. The projection is not a BEDC kernel object, not a physical law, not a real-completion theorem, and not a quotient of histories.

9346.1 Window observers and residual fibers

Definition 9346.1 (Stable Zeckendorf window)**.** *For $m \geq 0$, let*

$$\Omega_m := \{0,1\}^m.$$

The stable Zeckendorf window is the subcarrier

$$X_m := \{x \in \Omega_m : \ x_k x_{k+1} = 0 \text{ for all admissible } k\}.$$

Equivalently, a visible word in X_m contains no adjacent 11 *pattern.*

Definition 9346.2 (Fibonacci value and fold)**.** *Let $F_0 = 0$, $F_1 = 1$, and $F_{n+1} = F_n + F_{n-1}$ for $n \geq 1$. For $\omega \in \Omega_m$, define its Fibonacci value by*

$$N_m(\omega) := \sum_{k=1}^{m} \omega_k F_{k+1}.$$

Let $Z(N_m(\omega))$ be the Zeckendorf normal digit sequence of this value. The window fold is the visible truncation

$$\mathsf{Fold}_m : \Omega_m \to X_m, \qquad \mathsf{Fold}_m(\omega) := \pi_m Z(N_m(\omega)).$$

The map is a projection from raw binary words to stable visible words; it is not an identification of the raw histories.

Definition 9346.3 (Zeckendorf window observer)**.** *A Zeckendorf window observer at width m consumes only the visible word*

$$x = \mathsf{Fold}_m(\omega) \in X_m.$$

The hidden residual fiber over x is

$$\mathcal{F}_m(x) := \mathsf{Fold}_m^{-1}(x), \qquad d_m(x) := |\mathcal{F}_m(x)|.$$

Thus the observer sees a stable Zeckendorf word while the ledger retains the raw microstates compressed by the fold.

Principle 9346.4 (Fold readout does not erase the fiber)**.** *Any consumer of* $\mathsf{Fold}_m(\omega) = x$ *may use* x *as a visible normal-form token only together with the residual-fiber row* $\mathcal{F}_m(x)$ *or an explicit exactness certificate. In particular, equality of visible windows is not equality of raw histories.*

9346.2 Window-six Fibonacci ledger

Definition 9346.5 (Window-six ledger coordinates)**.** *For* $m = 6$*, define*

$$V_6 := |X_6|, \qquad B_6 := F_9, \qquad O_6 := F_{10}, \qquad P_6 := F_6, \qquad T_6 := F_7.$$

The visible stable-window count is

$$V_6 = F_8 = 21.$$

The boundary entries have the concrete values

$$F_6 = 8, \qquad F_7 = 13, \qquad F_8 = 21, \qquad F_9 = 34, \qquad F_{10} = 55.$$

Definition 9346.6 (Window-six residual denominator)**.** *The Window-six residual denominator is*

$$D_0 := F_9 + F_7.$$

Equivalently,

$$D_0 = F_{10} - F_6 = 47.$$

Theorem 9346.7 (Window-six residual denominator identity)**.** *The two Window-six residual readings agree:*

$$F_9 + F_7 = F_{10} - F_6 = 47.$$

Proof. The displayed Fibonacci values give $F_9 + F_7 = 34 + 13 = 47$. They also give $F_{10} - F_6 = 55 - 8 = 47$. Hence the two expressions name the same finite ledger denominator. □

Corollary 9346.8 (Boundary and tail readings share one ledger)**.** *The expression* $F_9 + F_7$ *reads the next boundary together with the deep tail, while* $F_{10} - F_6$ *reads the second outer boundary after removing the eightfold parity/carry defect. These are two descriptions of the same finite residual ledger* D_0*, not two independent invariants.*

Principle 9346.9 (Window-six residual closure)**.** *The Window-six residual ledger is allowed to close only from the three displayed tail layers*

$$21, \qquad 13, \qquad 9,$$

together with the eightfold boundary-parity row $8 = F_6$*. No host-side fit parameter, external physical constant, or unledgered continuous geometry may enter the residual denominator.*

Definition 9346.10 (Closed Window-six residual denominator)**.** *The closed Window-six residual denominator is*

$$D_6^\star := F_9 + F_7 + \varphi^{-(F_5+F_3)}\left[1 - \frac{F_2}{F_3}\varphi^{-(F_6+F_3)} + \frac{F_6}{F_6+F_2}\varphi^{-2(F_6+F_3)}\right].$$

Equivalently,

$$D_6^\star = 47 + \varphi^{-7} - \frac{1}{2}\varphi^{-17} + \frac{8}{9}\varphi^{-27}.$$

Remark 9346.11 (The 8/9 closure coefficient)**.** *The coefficient* 8/9 *records the ratio between the eightfold boundary-parity row and the nine-dimensional invisible residual layer of the Window-six tail ledger. It is therefore part of the residual closure surface, not a free numerical tuning parameter.*

9346.3 Golden phase projection

Definition 9346.12 (Golden self-scale)**.** *The golden self-scale is the limiting Fibonacci ratio*

$$\varphi := \lim_{n\to\infty} \frac{F_{n+1}}{F_n},$$

read through the algebraic relation

$$\varphi = 1 + \varphi^{-1}.$$

Definition 9346.13 (Golden conjugate spectral readout)**.** *Let*

$$K_\varphi := \mathbb{Q}(\sqrt{5})$$

and let $\mathsf{Bin}_Z = \{b_0, b_1\}$ *be a displayed binary distinction carrier attached to the Axis-Zeckendorf fold surface. A* golden conjugate spectral readout *is a typed map*

$$\chi_\varphi : \mathsf{Bin}_Z \to K_\varphi$$

whose ordinary algebraic semantics sends

$$\chi_\varphi(b_0) = B_0 := \frac{1+\sqrt{5}}{2}, \qquad \chi_\varphi(b_1) = B_1 := \frac{1-\sqrt{5}}{2}.$$

The symbols b_0, b_1 *remain distinction markers. The rows* B_0, B_1 *are their spectral readings in the golden recursive layer, not kernel identities identifying the markers with algebraic numbers.*

Definition 9346.14 (Recursive operation carrier)**.** *Let* R *be a displayed record carrier with classifier* $\sim_R$*. A recursive operation carrier over* R *consists of an operation type* O*, an operation equivalence* $\equiv_O$*, a unit operation* id*, a composition law* $\circ$*, and an action*

$$\mathrm{act} : O \times R \to R$$

such that

$$\mathrm{id}(r) \sim_R r$$

and

$$(\beta \circ \gamma)(r) \sim_R \beta(\gamma(r)).$$

The carrier also records the associativity, unit, equivalence-compatibility, readback, ledger, and audit rows needed to use these equations inside a BEDC information layer.

Definition 9346.15 (Atomic recursive prime edge)**.** *For a recursive operation carrier over* R*, an atomic recursive prime edge from* B_0 *to* B_1 *is data*

$$(B_0, B_1, \alpha, \mathsf{Edge}_\alpha, \mathsf{NonDeg}, \mathsf{Irred}_\alpha, \mathsf{Prime}_\alpha)$$

where $\alpha \in O$ *and*

$$\mathsf{Edge}_\alpha : \alpha(B_0) \sim_R B_1,$$
$$\mathsf{NonDeg} : B_0 \not\sim_R B_1.$$

The irreducibility row says that

$$\alpha \equiv_O \beta \circ \gamma \Longrightarrow \beta \equiv_O \mathrm{id} \quad \textit{or} \quad \gamma \equiv_O \mathrm{id}\,.$$

The prime row is classifier-relative: it asserts primeness for the chosen operation divisibility relation, not ordinary integer primality.

Principle 9346.16 (Golden branch pair as a recursive edge)**.** *The spectral pair B_0, B_1 of Definition 9346.13 may be read as a seed and its first visible recursive exposure only after an operation carrier and an edge certificate are displayed:*

$$B_0 \xrightarrow{\alpha} B_1.$$

Under that reading, B_0 and B_1 are not ontic bottom points. They are visible branch records over source fibers, together with the certificate that the displayed operation α transports the first visible record to the second.

Theorem 9346.17 (Atomic edge has no nontrivial intermediate operation)**.** *Assume $B_0 \xrightarrow{\alpha} B_1$ is an atomic recursive prime edge and that*

$$\alpha \equiv_O \beta \circ \gamma.$$

Then any factorization

$$B_0 \xrightarrow{\gamma} C \xrightarrow{\beta} B_1$$

is trivial on at least one side:

$$\beta \equiv_O \mathrm{id} \quad \textit{or} \quad \gamma \equiv_O \mathrm{id}\,.$$

Proof. This is exactly the irreducibility row Irred_α in Definition 9346.15. If both β and γ were non-unit operations, the displayed equality $\alpha \equiv_O \beta \circ \gamma$ would contradict irreducibility. □

Definition 9346.18 (Undelimited atomic collision)**.** *Let α be an atomic recursive operation in a displayed operation carrier. A consecutive double occurrence is written*

$$\alpha \| \alpha.$$

It is undelimited *when the layer does not display a separator row*

$$\mathsf{Sep}_O(\alpha, \alpha)$$

certifying a boundary between the two occurrences. A collision atom for that undelimited occurrence is an operation $\beta \in O$ together with a classifier row

$$\alpha \| \alpha \sim_{\mathrm{coll}} \beta$$

and no audit row that factors the visible record through two separated α-steps.

Principle 9346.19 (Collision atoms are classifier-relative)**.** *A collision atom is not an assertion that β is definitionally equal to two applications of α. It says that the current readout layer cannot separate the visible record into two certified α-steps. The unresolved source fiber behind the visible record may still contain a two-step history, but that history is not available to the classifier unless a separator, clock, bracket, boundary, or replay certificate is displayed.*

Theorem 9346.20 (No separator gives no certified double read)**.** *Assume that a layer can certify a double-α reading only through a separator row $\mathsf{Sep}_O(\alpha, \alpha)$. If no such row is displayed for $\alpha \| \alpha$, then the layer cannot construct a certificate distinguishing the double occurrence from a collision atom β with the same collision classifier read.*

Proof. A certified double read requires a boundary witness separating the first occurrence of α from the second. By hypothesis the only such witness accepted by the layer is $\mathsf{Sep}_O(\alpha, \alpha)$. When this row is not displayed, the layer has only the composite visible record. If that record is classified by

$$\alpha \| \alpha \sim_{\text{coll}} \beta,$$

then the classifier supplies no further data with which to split it into two auditable α-steps. Thus the claimed distinction is not certified in the current layer. □

Principle 9346.21 (Zeckendorf-safe channels as collision discipline)**.** *The Zeckendorf-safe channel encoding is the finite channel model of this discipline. If the raw glyph* 1 *is read as the channel marker for one atomic action, a bare body substring* 11 *would be an undelimited occurrence of* $\alpha \| \alpha$*. The body substitution*

$$0 \mapsto 0, \qquad 1 \mapsto 10$$

adds a visible separator after every raw 1*, while the event terminator is*

$$\text{End} = 11.$$

By Definition 9208.6, no encoded body contains the collision pattern 11*; by Definition 9208.7, the first displayed* 11 *is therefore a boundary row rather than a body collision. The source-level carry classifier of Definition 9345.1 uses a different interface: it treats adjacent activation as a normalization trigger inside recognized history flows, not as a direct rewrite of channel glyphs.*

Definition 9346.22 (Recursive orbit and alpha valuation)**.** *Given an operation* α *acting on* R*, define the recursive orbit of* B_0 *by*

$$B_n := \alpha^n(B_0), \qquad \alpha^0 := \text{id}, \qquad \alpha^{n+1} := \alpha \circ \alpha^n.$$

The orbit is free when

$$\alpha^m(B_0) \sim_R \alpha^n(B_0) \Longrightarrow m = n.$$

For a subcarrier $X \subseteq R$*, an* α*-normal form is a unique display*

$$x \sim_R \alpha^k(y)$$

with $k \in \mathbb{N}$ *and* y *no longer left-divisible by* α*. The associated valuation row is*

$$v_\alpha(x) := k.$$

Theorem 9346.23 (Alpha valuation shifts additively)**.** *If* X *carries an* α*-normal form, then for every* $m \in \mathbb{N}$ *and* $x \in X$*,*

$$v_\alpha(\alpha^m(x)) = m + v_\alpha(x).$$

Proof. Let

$$x \sim_R \alpha^k(y)$$

be the α-normal form of x, so $k = v_\alpha(x)$ and y is not left-divisible by α. Applying α^m gives

$$\alpha^m(x) \sim_R \alpha^{m+k}(y).$$

By uniqueness of the normal form, this is the normal display of $\alpha^m(x)$. Hence

$$v_\alpha(\alpha^m(x)) = m + k = m + v_\alpha(x).$$

□

Principle 9346.24 (Classifier-relative primeness)**.** *The analogy*

$$p \text{ in multiplicative factorization} \qquad \sim \qquad \alpha \text{ in recursive operation composition}$$

is valid only after the classifier has been fixed. Ordinary primes are atoms for multiplicative divisibility. Recursive prime operations are atoms for operation composition. Zeckendorf carry rows, channel-safe body encodings, and golden spectral roots may interact with this pattern only through displayed bridge, readback, normal-form, and ledger certificates.

Concretized in §8890: The atomic recursive prime-edge carrier realizes the recursive-operation edge and irreducibility rows as finite NameCert data.

Definition 9346.25 (Golden conjugation center)**.** *Let $\sigma : K_\varphi \to K_\varphi$ be the conjugation determined by*

$$\sigma(\sqrt{5}) = -\sqrt{5}.$$

Equivalently, on the two roots of

$$x^2 - x - 1 = 0$$

the conjugation is the mirror

$$J_\varphi(x) := 1 - x.$$

The two spectral rows satisfy

$$\sigma(B_0) = B_1, \qquad \sigma(B_1) = B_0, \qquad J_\varphi(B_0) = B_1, \qquad J_\varphi(B_1) = B_0.$$

Their trace center is

$$c_\varphi := \frac{B_0 + B_1}{2}.$$

Theorem 9346.26 (Golden pair has half trace center)**.** *The spectral rows of Definition 9346.13 satisfy*

$$B_0 + B_1 = 1, \qquad B_0 B_1 = -1, \qquad B_1 = 1 - B_0, \qquad B_0 = 1 - B_1,$$

and hence

$$c_\varphi = \frac{1}{2}.$$

Proof. Substituting the displayed algebraic readings gives

$$B_0 + B_1 = \frac{1+\sqrt{5}}{2} + \frac{1-\sqrt{5}}{2} = 1$$

and

$$B_0 B_1 = \frac{(1+\sqrt{5})(1-\sqrt{5})}{4} = \frac{1-5}{4} = -1.$$

The two equations $B_1 = 1 - B_0$ and $B_0 = 1 - B_1$ are immediate from the sum equation. Therefore

$$c_\varphi = \frac{B_0 + B_1}{2} = \frac{1}{2}.$$

□

Principle 9346.27 (Spectral distinction boundary)**.** *The pair (B_0, B_1) is a conjugate spectral reading of a displayed binary distinction, not the binary distinction itself. A consumer may use it only together with the readout map χ_φ, the golden recursion certificate, the fold ledger, and the cannot-claim boundary of Definition 9346.38. Thus the spectral layer refines the distinction marker without replacing the underlying history carrier.*

Principle 9346.28 (Trace-center schema)**.** *The golden conjugate pair has the form*

$$B_0 = \frac{1}{2} + \frac{\sqrt{5}}{2}, \qquad B_1 = \frac{1}{2} - \frac{\sqrt{5}}{2}.$$

It is therefore a minimal algebraic instance of a moving conjugate orbit whose mirror $x \mapsto 1-x$ has fixed center $1/2$. This is the same half-center schema that appears in Definition 9414.160 and in the critical-line mirror of Definition 9414.163. The comparison is structural: it identifies a shared center-forming involution, not a proof of any zero-ledger exclusion statement.

Definition 9346.29 (Golden fixed-half interface)**.** *The golden fixed-half interface associated to Definition 9346.25 is the half-value layer*

$$\mathcal{H}_\varphi := (K_\varphi, b_\varphi, 1/2)$$

whose readout is the centered coordinate

$$b_\varphi(x) := \frac{x + J_\varphi(x)}{2}.$$

Its fixed-half fiber is

$$\mathrm{Fix}_{\mathcal{H}_\varphi} := \sum_{x:K_\varphi} (b_\varphi(x) = 1/2).$$

This fiber is the algebraic middle interface of the golden conjugate pair. It is not a third branch between B_0 and B_1.

Theorem 9346.30 (Golden branch pair reads back to the fixed-half fiber)**.** *Both golden spectral branches have the same fixed-half readback:*

$$b_\varphi(B_0) = \frac{1}{2}, \qquad b_\varphi(B_1) = \frac{1}{2}.$$

Proof. By Definition 9346.25, $J_\varphi(B_0) = B_1$ and $J_\varphi(B_1) = B_0$. Hence

$$b_\varphi(B_0) = \frac{B_0 + B_1}{2} = \frac{1}{2}$$

and similarly

$$b_\varphi(B_1) = \frac{B_1 + B_0}{2} = \frac{1}{2},$$

using Definition 9346.26. □

Definition 9346.31 (Golden residual cross-seed)**.** *Let $P_\varphi : T \to \{B_0, B_1\}$ be a displayed golden-branch readout. The residual fiber over a visible branch is*

$$\mathrm{Fib}_\varphi(B_i) := \sum_{t:T} (P_\varphi(t) = B_i).$$

A golden residual cross-seed *is a refinement row inside $\mathrm{Fib}_\varphi(B_i)$ whose next readout exposes the opposite branch B_{1-i} while retaining readback to the visible branch B_i at the current classifier.*

Principle 9346.32 (Conjugate fiber interface)**.** *The two visible golden branches are paired by the involution J_φ, while their middle interface is the fixed-half fiber* $\mathrm{Fix}_{\mathcal{H}_\varphi}$*. Residual cross-seeds record that a visible branch need not exhaust its source fiber: the opposite branch may remain available as refinement data, in the sense of the layer-fiber discipline of Definition 9414.41 and the information residue of Definition 9414.220.*

Principle 9346.33 (Critical-line analogue)**.** *For the RH mirror*

$$J(s) = 1 - \overline{s},$$

writing

$$s = \frac{1}{2} + \delta + i\tau$$

gives

$$J(s) = \frac{1}{2} - \delta + i\tau.$$

Thus the golden skew coordinate

$$u = \frac{\sqrt{5}}{2}$$

and the RH bias coordinate δ play the same formal role: the fixed interface is the zero-bias surface. In the golden layer this surface is the fixed-half fiber of $\mathcal{H}_\varphi$; in the RH layer it is the critical line. This analogy does not turn the golden branch model into a proof of the RH zero-ledger target.

Definition 9346.34 (Zeckendorf phase character and circumference certificate)**.** *The Zeckendorf phase character χ_φ^Z is the phase-circle interface whose ordinary continuous semantics is*

$$\chi_\varphi^Z = \cos^2\left(\frac{\pi}{\varphi}\right).$$

The phase-circumference certificate $\tau_Z^\uparrow$ is the circle-interface row whose ordinary continuous semantics is

$$\tau_Z^\uparrow = 2\pi.$$

These rows are certificates for a phase display. They are not finite kernel objects, not host trigonometric primitives, and not physical laws.

Definition 9346.35 (Closed Window-six cascade kernel)**.** *The closed Window-six cascade kernel is*

$$C_{Z6}^\star := \frac{F_2}{F_3} + \frac{F_2}{F_3^{F_3}}\chi_\varphi^Z + \frac{F_2}{D_6^\star \varphi^{F_5}}.$$

Under the ordinary continuous semantics of Definition 9346.34, this reads

$$C_6^\star = \frac{1}{2} + \frac{1}{4}\cos^2\left(\frac{\pi}{\varphi}\right) + \frac{1}{D_6^\star \varphi^5}.$$

Definition 9346.36 (Closed Window-six Zeckendorf-golden phase readout)**.** *The closed Window-six Zeckendorf-golden phase readout is*

$$R_{Z6}^\star := \tau_Z^\uparrow \varphi^{F_5} \frac{F_8 + F_9 C_{Z6}^\star}{F_8 \varphi^{-F_2} + F_9 C_{Z6}^\star \varphi^{-F_3}}.$$

In ordinary continuous notation this is

$$\alpha_{Z6}^{-1} = 2\pi\varphi^5 \frac{21 + 34C_6^\star}{21\varphi^{-1} + 34C_6^\star \varphi^{-2}}.$$

Definition 9346.37 (Golden phase projection)**.** *A golden phase projection for a visible window $x \in X_m$ is an external display assignment*

$$\Theta_m(x) := \exp(2\pi i\, \theta_m(x)),$$

where $\theta_m(x)$ is a rational or real readout obtained from the Fibonacci-value ledger of x. The projection may be used to compare visible periodicities, carry shadows, or residual-fiber weights. Its source remains the finite fold ledger

$$\Omega_m \xrightarrow{\mathsf{Fold}_m} X_m \xleftarrow{\mathcal{F}_m} \Omega_m.$$

Theorem 9346.38 (Golden phase is a derived readout)**.** *The golden phase projection is a derived interface over the Axis-Zeckendorf fold ledger. It does not identify raw histories, does not replace* ZCarry *by* hsame*, does not export field operations of* $\mathsf{Real}^{\uparrow}$ *or a circle carrier, and does not assert a physical law.*

Proof. By Definition 9346.37, the phase token $\Theta_m(x)$ is assigned only after the visible word x has been obtained from Fold_m. By Principle 9346.4, use of the visible word must retain the residual-fiber row or an exactness certificate. Therefore the phase token cannot collapse raw histories. The carry discipline of Theorem 9345.4 keeps carry classification separate from hsame, and the cannot-claim registry of chapter 9350 blocks promotion to $\mathsf{Real}^{\uparrow}$, a primitive dimension, or a replacement of $\mathsf{Nat}^{\uparrow}$. The projection is therefore only a display interface over finite ledger data. □

Corollary 9346.39 (Allowed use of the projection)**.** *A valid consumer may use Θ_m to organize visible Axis-Zeckendorf patterns, compare Window-six residual ledgers, or state a horizon bridge toward analytic phase language. Such a consumer must also carry the fold source, residual fiber, carry-separation row, and cannot-claim boundary.*

Theorem 9346.40 (Closed Window-six readout is a candidate, not a physical theorem)**.** *The readout $R^{\star}_{Z6}$ is the Window-six Zeckendorf-golden phase projection candidate. It is not, by itself, an equality with the low energy electromagnetic fine-structure constant, a derivation of a physical law, or a reconstruction of continuous spacetime.*

Proof. The construction of $R^{\star}_{Z6}$ uses the finite Window-six fold ledger, the residual closure principle, the phase-character row, and the phase-circumference certificate. These data close the derived-interface readout but do not supply a physical representation certificate. A physical identification must add a separate map

$$\rho_{\mathrm{phys}}(R^{\star}_{Z6}) = \alpha^{-1}_{\mathrm{EM}}(0),$$

where the right-hand side is the low-energy electromagnetic coupling readout. Without that representation certificate, the result remains a mathematical projection candidate inside the Axis-Zeckendorf vision. □

9346.4 Physical representation obligations

Definition 9346.41 (Low-energy electromagnetic representation certificate)**.** *A low-energy electromagnetic representation certificate for the closed Window-six readout in a closure mode μ is a separate physical map*

$$\rho_{\mathrm{EM}} : R^{\star}_{Z6,\mu} \longmapsto \alpha^{-1}_{\mathrm{EM}}(0),$$

where the target is the infrared electromagnetic coupling readout. The certificate must preserve the source fold, the residual-fiber ledger, the golden phase-character row, the boundary-parity row, and the cannot-claim boundary. It is not supplied by the numerical expression for $R^{\star}_{Z6,\mu}$ alone.

Principle 9346.42 (Impedance reading of the scalar)**.** *If the representation certificate of Definition 9346.41 is supplied, the same scalar may be read as the vacuum impedance ratio*

$$\alpha_{\mathrm{EM}}^{-1}(0) = \frac{2R_K}{Z_0},$$

where R_K is the von Klitzing resistance and Z_0 is the characteristic impedance of vacuum. This reading interprets the Zeckendorf-golden phase output as an impedance-matching surface for a low-energy electromagnetic phase medium, not as a primitive physical constant inserted into the construction.

Principle 9346.43 (Independent route convergence)**.** *An admitted physical representation of a selected $R^{\star}_{Z6,\mu}$ must be stable under independent low-energy measurement routes. Atomic recoil, electron magnetic-moment comparison, spectroscopic fine-structure readouts, and quantum-Hall impedance routes may differ in instrumentation and systematic error model, but after route-specific corrections they must converge to the same infrared scalar if they are to certify the same Window-six projection.*

Principle 9346.44 (Window refinement for running coupling)**.** *The Window-six readout is an infrared candidate. It does not assert that the same scalar is the effective electromagnetic coupling at all energy scales. A representation that reaches nonzero momentum transfer must replace the fixed denominator by a scale-indexed ledger*

$$D^{\star}_{6,\mu} \rightsquigarrow D(Q)$$

or replace the fixed window by a scale-indexed family

$$X_6 \rightsquigarrow X_{m(Q)}.$$

Thus any comparison with high-energy running of α is an obligation to construct a spectral-response activation map $z = z(Q)$ and a Zeckendorf window-refinement flow, not an allowed reuse of the infrared scalar.

Principle 9346.45 (Projection does not expose the hidden vacuum ledger)**.** *The scalar $\alpha_{\mathrm{EM}}^{-1}(0)$, even when represented by $R^{\star}_{Z6,\mu}$, exposes only a projection ratio. It does not expose the raw microstate space Ω_6, the full residual fibers $\mathcal{F}_6(x)$, or a unique continuous spacetime geometry. The recoverable object is the finite auditable skeleton*

$$(X_6, \mathsf{Fold}_6, \varphi, \chi^{Z}_{\varphi}, D^{\star}_{6,\mu}, \textit{boundary parity}, \textit{residual ledger}),$$

not the total physical substrate.

Principle 9346.46 (Hidden boundary parity)**.** *The eightfold boundary-parity row is not expected to appear as a large smooth correction in ordinary continuous low-energy probes. If it has a physical representation, its admissible signatures are restricted to integral, mod-2, boundary-condition, topology-sensitive, or coherent phase-residual observables. Ordinary smooth QED success therefore constrains the parity row to remain hidden from continuous probes; it does not by itself identify or eliminate the discrete row.*

Principle 9346.47 (Sixfold phase-circumference interface)**.** *The boundary-parity row enters electromagnetic readouts through a sixfold phase interface, not as three independently exposed parity bits. The admissible phase route has the form*

$$C_{\partial} \times T \longrightarrow \mathbb{Z}/6\mathbb{Z} \longrightarrow U(1),$$

where $T \cong \mathbb{Z}/3\mathbb{Z}$ is the edge-flux torsion source and the $C_\partial \cong (\mathbb{Z}/2\mathbb{Z})^3$ contribution is read through the invariant parity character. Equivalently, the fixed Window-six projection formula

$$R_6(D) = 2\pi\varphi^5 \frac{21 + 34C(D)}{21\varphi^{-1} + 34C(D)\varphi^{-2}}$$

may be written as

$$R_6(D) = 2\pi \frac{21 + 34C(D)}{21\varphi^{-6} + 34C(D)\varphi^{-7}}.$$

In this form φ^{-6} records the sixfold phase shell, φ^{-7} records the first boundary seam beyond that shell, and 2π is the circumference interface for the $Z_6 \to U(1)$ readout. This does not collapse the phase reservoir coefficient to the six-element image coefficient; it separates the admissible phase gate from the reservoir, image, and curvature-residual readout modes.

Principle 9346.48 (Window-six flux-operator geometry)**.** *The full edge-flux dynamics should not be read as an ordinary hidden metric geometry. At the stable-address level, the full edge-flux action saturates the operator algebra on the 21-dimensional visible Window-six space, and it preserves no nonzero invariant bilinear form and no nonzero invariant multiplication. Thus the physical representation cannot be based on a fixed hidden inner product, symplectic form, bracket, or commutative product. The natural object is instead a flux-operator geometry: stable Zeckendorf addresses, transition operators, phase gates, boundary escape flux, and golden-shell projection. For electromagnetic targets this supports an impedance or coupling readout rather than a pure curvature-scalar readout.*

Concretized in §8821: Flux-operator geometry is realized as finite stable-address, transition-operator, phase-gate, boundary escape-flux, golden-shell projection, refusal, transport, replay, provenance, and NameCert rows.

Principle 9346.49 (Right-block flux-reservoir coefficient)**.** *The phase-reservoir coefficient also has an edge-flux normalization inside Window six. Let U_R be the right edge-flux block in the Window-six partition of the binary cube. The edge-flux skeleton supplies*

$$|U_R| = 6, \qquad |\partial U_R| = 32.$$

Since Q_6 is 6-regular, the normalized probability of leaving the right block is

$$P(\text{leave } U_R \mid U_R) = \frac{|\partial U_R|}{6|U_R|} = \frac{32}{36} = \frac{8}{9}.$$

Thus the same coefficient 8/9 is not only the capacity ratio $|C_\partial|/N_{\geq 4}(6)$ and the light-to-heavy fiber ratio; it is also the canonical boundary escape flux of the right edge-flux block. The fold-gauge mismatch mean gives the one-way companion value

$$E[g_t] = \frac{4}{9}, \qquad 2E[g_t] = \frac{8}{9},$$

so the reservoir coefficient may also be read as the two-sided boundary flux associated with the one-way mismatch rate. This differs from the global cut-flux density

$$\Phi_R = \frac{|\partial U_R|}{64 \cdot 6} = \frac{1}{12},$$

which is normalized by the full directed-edge budget of the cube and is not a local residual coefficient in $D^{\star}_{6,\alpha}$. This is the coefficient relevant to impedance or coupling readouts. By Definition 9346.51, the same static right-boundary cut-flux source is a Dirichlet-exact cut-source and has zero 571-*Green class, so the infrared impedance selection does not require a separate φ^{-37} correction inside the static flux-reservoir layer. The dynamic Green-relaxation layer is a different readout mode, governed by a centered relaxation source rather than by the static cut vector. The* $2/3$ *branch records the direct six-element phase image and the* $4/9$ *branch records the curvature-residual quotient.*

Concretized in §9038: The right-block flux-reservoir coefficient is realized as finite boundary-count, cube-degree, normalized-ratio, static-cut, transport, replay, provenance, and NameCert rows.

Principle 9346.50 (Static Green-exactness of right-boundary flux)**.** *For any finite weighted graph decomposed into an internal block set I and a deleted boundary block B, let L_B be the Dirichlet reduced Laplacian on I and let b_B be the static cut-source whose ith coordinate is the total edge weight from $i \in I$ into B. Then*

$$L_B \mathbf{1}_I = b_B.$$

Indeed, the ith coordinate of $L_B\mathbf{1}_I$ is the full weighted degree of i minus the weights from i to the other retained vertices, which leaves exactly the cut weight from i to the deleted boundary. Thus every static Dirichlet cut-source is Laplacian-exact and has zero class in $\operatorname{coker}(L_B)$.

Order the Window-six edge-flux blocks as (U_2, U_1, U_L, U_R), with microscopic volumes

$$(|U_2|, |U_1|, |U_L|, |U_R|) = (27, 22, 9, 6).$$

The edge-count skeleton is

$$E = \begin{pmatrix} 28 & 63 & 23 & 20 \\ 63 & 21 & 21 & 6 \\ 23 & 21 & 2 & 6 \\ 20 & 6 & 6 & 2 \end{pmatrix}.$$

Deleting the right block gives the reduced Laplacian

$$L_R = \begin{pmatrix} 106 & -63 & -23 \\ -63 & 90 & -21 \\ -23 & -21 & 50 \end{pmatrix},$$

where each diagonal entry is the total edge count from the retained block to all other blocks. The right-boundary cut vector seen from the retained blocks is

$$b_R = \begin{pmatrix} 20 \\ 6 \\ 6 \end{pmatrix}.$$

It satisfies the integral exactness identity

$$L_R \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix} = \begin{pmatrix} 20 \\ 6 \\ 6 \end{pmatrix} = b_R.$$

Thus the static right-boundary escape source is a reduced-Laplacian image by the general Dirichlet cut identity. It is a Green-exact source before any localization, and therefore also over $R_\zeta = \mathbb{Z}[1/6]$.

Theorem 9346.51 (Static-Green separation for Dirichlet cut-flux)**.** *The Window-six Green layer detected by the reduced Laplacian is nontrivial, but the static right-boundary cut-flux source does not activate it. More precisely,*

$$\det L_R = 123336 = 2^3 \cdot 3^3 \cdot 571,$$

so after localization at 6 *the non-invertible determinant factor is the* 571*-Green factor. The class of* b_R *in the corresponding cokernel is zero. Consequently, for the static low-energy electromagnetic readout whose Green input is the right-boundary cut source, the Green coefficient in*

$$D^G_{6,\alpha} = D^\star_{6,\alpha} + q_3\varphi^{-37} + O(\varphi^{-47})$$

is $q_3 = 0$*. This does not remove the* 571*-Green layer from dynamic readouts. For the coarse Markov relaxation kernel determined by the same edge skeleton,*

$$T = \begin{pmatrix} 28/81 & 7/18 & 23/162 & 10/81 \\ 21/44 & 7/22 & 7/44 & 1/22 \\ 23/54 & 7/18 & 2/27 & 1/9 \\ 5/9 & 1/6 & 1/6 & 1/9 \end{pmatrix},$$

with stationary weight

$$\pi = (27/64, 22/64, 9/64, 6/64),$$

the centered right-block observable

$$f_R = \mathbf{1}_R - \frac{3}{32}\mathbf{1}$$

has Green response

$$Zf_R = \begin{pmatrix} -58991/877056 \\ -41093/292352 \\ -69167/877056 \\ 821233/877056 \end{pmatrix}, \qquad Z = (I - T + \mathbf{1}\pi^T)^{-1}.$$

Since $877056 = 2^9 \cdot 3 \cdot 571$ *and* $292352 = 2^9 \cdot 571$*, this centered relaxation observable does read the* 571*-Green layer. Its Green susceptibility is*

$$\chi_R = \langle f_R, Zf_R\rangle_\pi = \frac{821233}{9355264} = \frac{821233}{2^{14} \cdot 571}.$$

The corresponding Green–Kubo response is

$$G_R = 2\chi_R - \mathrm{Var}_\pi(f_R) = \frac{423817}{4677632} = \frac{423817}{2^{13} \cdot 571}.$$

The static variance baseline is

$$\mathrm{Var}_\pi(f_R) = \frac{87}{1024}.$$

Therefore the fully activated Green-excess coefficient is

$$\Delta_R(1) = G_R - \mathrm{Var}_\pi(f_R) = \frac{26401}{4677632} = \frac{26401}{2^{13} \cdot 571}.$$

Proof. By Definition 9346.50, $b_R = L_R(1,1,1)^T$. This is the Window-six instance of the general Dirichlet cut identity $L_B\mathbf{1}_I = b_B$. Hence b_R is zero in the cokernel of L_R over $\mathbb{Z}$ and over R_ζ. The determinant computation displays the 571-Green layer after the powers of 2 and 3 have become units, but exact sources have zero class in that layer.

Equivalently, modulo 571 one may use the left cokernel functional

$$\ell = (448, 409, 1).$$

Then

$$\ell(b_R) = 448 \cdot 20 + 409 \cdot 6 + 6 = 11420 = 20 \cdot 571,$$

so $\ell(b_R) \equiv 0 \pmod{571}$. This modular vanishing is the residue shadow of the integral exactness identity above. Therefore the static right-boundary source contributes no φ^{-37} Green correction.

The relaxation statement is a direct computation from the displayed stochastic matrix. The row sums of T are 1, and $\pi T = \pi$ because the row weights are the block volumes divided by 64. Applying the fundamental Green operator $Z = (I - T + \mathbf{1}\pi^T)^{-1}$ to the centered right-block observable gives the displayed vector. Its denominators have one factor of 571, so the dynamic centered response is not killed by the static exactness identity. The displayed values of χ_R and G_R are obtained by the definitions $\chi_R = \sum_i \pi_i f_R(i)(Zf_R)(i)$ and $G_R = 2\chi_R - \sum_i \pi_i f_R(i)^2$; their denominators again contain the single 571 factor. Subtracting the static variance baseline isolates the Green-excess coefficient $\Delta_R(1)$. Thus $q_3 = 0$ is the static cut-flux conclusion for the infrared readout, while a running or relaxation response must use a separate Green-excess coefficient, for example

$$D_{6,\alpha}(z) = D^\star_{6,\alpha} + \Delta_R(z)\varphi^{-37} + O(\varphi^{-47}).$$

□

Definition 9346.52 (Window-six Green-excess seed)**.** *The Window-six Green-excess seed is the dynamic extension datum*

$$\mathsf{ZGFluxPhaseGreenSeed}_{6,\alpha} := \left(D^\star_{6,\alpha}, \Delta_R(z), \varphi^{-37}\right),$$

where $D^\star_{6,\alpha}$ is the static cut-flux denominator and $\Delta_R(z)$ is the centered right-boundary Green-excess kernel

$$\Delta_R(z) = -\frac{3z(1595z^2 + 24477z + 26730)}{512(55z^3 + 506z^2 - 7263z - 48114)}.$$

It satisfies

$$\Delta_R(0) = 0, \qquad \Delta_R(1) = \frac{26401}{2^{13} \cdot 571}.$$

Near the static denominator the readout derivative is approximately

$$\left.\frac{dR}{dD}\right|_{D=D^\star_{6,\alpha}} \approx -0.00120603474199364, \qquad \varphi^{-37} \approx 1.85121691873052 \cdot 10^{-8}.$$

Thus full Window-six Green-excess activation changes the inverse coupling by approximately

$$-1.26 \cdot 10^{-13}.$$

The seed does not replace the infrared denominator

$$D^\star_{6,\alpha} = 47 + \varphi^{-7} - \frac{1}{2}\varphi^{-17} + \frac{8}{9}\varphi^{-27}.$$

It records the first local Green-excess extension

$$D_{6,\alpha}(z) = D^\star_{6,\alpha} + \Delta_R(z)\varphi^{-37} + O(\varphi^{-47}).$$

Definition 9346.53 (Window-six spectral response family)**.** *The Window-six spectral response family is the one-parameter readout obtained by adjoining the Green-excess kernel to the static phase-reservoir denominator:*

$$D_{6,\alpha}(z) = D^{\star}_{6,\alpha} + \Delta_R(z)\varphi^{-37} + O(\varphi^{-47}),$$

where

$$C_{6,\alpha}(z) = \frac{1}{2} + \frac{1}{4}\cos^2\left(\frac{\pi}{\varphi}\right) + \frac{1}{D_{6,\alpha}(z)\varphi^5}$$

and

$$\alpha^{-1}_{Z6}(z) = 2\pi\frac{21 + 34C_{6,\alpha}(z)}{21\varphi^{-6} + 34C_{6,\alpha}(z)\varphi^{-7}}.$$

The parameter z is a Window-six Green-relaxation activation parameter, not yet a physical momentum scale. A physical running interpretation must supply a map $z = z(Q)$ and, beyond the Window-six neighbourhood, a refinement flow $X_6 \rightsquigarrow X_{m(Q)}$.

Theorem 9346.54 (Spectral response interpolation)**.** *The family of Definition 9346.53 interpolates between the static cut-flux readout and the first Window-six Green-excess readout:*

$$\alpha^{-1}_{Z6}(0) = 137.035999177006279014596667\ldots,$$

and

$$\alpha^{-1}_{Z6}(1) = 137.035999177006153002727216\ldots.$$

Moreover $\Delta_R(z)$ is a rational spectral response of the four-state Window-six Markov kernel. The characteristic polynomial is

$$\chi_T(t) = (t-1)\frac{48114t^3 + 7263t^2 - 506t - 55}{48114},$$

and the denominator

$$55z^3 + 506z^2 - 7263z - 48114$$

in $\Delta_R(z)$ is the reciprocal form of the non-stationary cubic factor. Thus the 571 denominator in the fully activated Green-excess coefficient is the arithmetic trace of the Window-six Green spectrum, not a static correction to $\alpha^{-1}_{Z6}(0)$.

Proof. At $z = 0$, Definition 9346.52 gives $\Delta_R(0) = 0$, so $D_{6,\alpha}(0) = D^{\star}_{6,\alpha}$ and the readout is the static cut-flux phase-reservoir value. At $z = 1$, the same definition gives

$$\Delta_R(1) = \frac{26401}{2^{13}\cdot 571},$$

which yields the displayed endpoint after substitution into Definition 9346.53.

For monotonicity, differentiate the displayed rational formula for $\Delta_R(z)$:

$$\Delta'_R(z) = \frac{3(539165z^4 + 26109270z^3 + 421527321z^2 + 2355372756z + 1286087220)}{512(55z^3 + 506z^2 - 7263z - 48114)^2}.$$

The derivative is positive on $0 \le z \le 1$. Since Definition 9346.88 shows that the readout $R(D)$ decreases with D, activating Green-excess decreases α^{-1}_{Z6} and increases the coupling. The characteristic polynomial statement follows by computing the characteristic polynomial of the displayed coarse Markov matrix T in Definition 9346.51. The reciprocal cubic identity is exactly

$$55z^3 + 506z^2 - 7263z - 48114 = -z^3\left(48114z^{-3} + 7263z^{-2} - 506z^{-1} - 55\right).$$

□

Theorem 9346.55 (Golden–Markov audit field)**.** *Let λ be any non-stationary eigenvalue of the Window-six coarse Markov kernel T, so that*

$$48114\lambda^3 + 7263\lambda^2 - 506\lambda - 55 = 0.$$

The dynamic spectral response is naturally read over the compositum

$$K_6^{\mathrm{audit}} = \mathbb{Q}(\varphi, \lambda).$$

The golden phase scale contributes the quadratic field $\mathbb{Q}(\varphi) = \mathbb{Q}(\sqrt{5})$, while the non-stationary Markov spectrum contributes the cubic field $\mathbb{Q}(\lambda)$. When these two fields are linearly disjoint, K_6^{audit} has degree 6 over $\mathbb{Q}$ with basis

$$1,\ \varphi,\ \lambda,\ \lambda\varphi,\ \lambda^2,\ \lambda^2\varphi.$$

Thus the Window-six response separates into a static golden phase layer and a dynamic cubic Markov spectral layer. The $Z_6 \to U(1)$ phase gate, the shell φ^{-6}, and the degree-six audit field are three readings of the same two-by-three structure: quadratic golden scale times cubic Markov spectrum.

Proof. The golden field has degree 2 because φ satisfies $x^2 - x - 1 = 0$. The Markov spectral field is generated by a root of the non-stationary cubic factor displayed in Definition 9346.54. Linear disjointness gives the product degree $2 \cdot 3 = 6$ and the displayed tensor-product basis. The static readout uses only the golden phase shell and the Z_6 phase gate. The dynamic Green-excess denominator uses the reciprocal cubic spectral factor. Hence the unified spectral response lives over the compositum rather than over the golden field alone. □

Corollary 9346.56 (Small-activation Green-excess)**.** *Near the static point,*

$$\Delta_R(z) = \frac{5}{1536}z + \frac{3407}{1368576}z^2 - \frac{179639}{1219401216}z^3 + O(z^4).$$

Consequently the fixed Window-six Green-excess is a small infrared seed: the leading dynamic contribution to the inverse coupling is proportional to $-(5/1536)z\varphi^{-37}$. A full physical running account must still provide the scale map $z = z(Q)$ and the cross-window refinement $X_6 \rightsquigarrow X_{m(Q)}$.

Principle 9346.57 (Beta-sign selection for running deformations)**.** *For any candidate physical running deformation of the fixed infrared denominator, write*

$$D(t) = D^{\star}_{6,\alpha} + \delta D(t),$$

where t is any monotone activation coordinate for increasing electromagnetic scale. If this deformation is to represent the physical running direction of the electromagnetic coupling, then it must satisfy

$$\frac{d}{dt}D(t) \geq 0$$

on its activation interval. Since Definition 9346.88 gives $dR/dD < 0$, this condition is exactly the inverse-coupling sign condition

$$\frac{d}{dt}\alpha^{-1}(t) \leq 0, \qquad \frac{d}{dt}\alpha(t) \geq 0.$$

Thus the beta-sign test is structural: it depends on the direction of the denominator deformation, not on fitting the infrared value.

Theorem 9346.58 (Walking branch is not the physical running direction)**.** *The walking-gate phase-reservoir denominator*

$$D^{\mathrm{res}}_{6,\mathrm{walk}} = 47 + \varphi^{-7} - \frac{1}{2}\varphi^{-17} + \frac{8}{9}\varphi^{-29}$$

cannot be the primary physical running deformation of the Window-six electromagnetic readout. It is a cross-window refinement branch, not the local beta seed for increasing electromagnetic scale.

Proof. The static low-energy phase-reservoir denominator is

$$D^{\star}_{6,\alpha} = 47 + \varphi^{-7} - \frac{1}{2}\varphi^{-17} + \frac{8}{9}\varphi^{-27}.$$

Since $\varphi^{-29} < \varphi^{-27}$, one has

$$D^{\mathrm{res}}_{6,\mathrm{walk}} < D^{\star}_{6,\alpha}.$$

By Definition 9346.88, the readout $R(D)$ is strictly decreasing in D. Therefore

$$R(D^{\mathrm{res}}_{6,\mathrm{walk}}) > R(D^{\star}_{6,\alpha}),$$

so the walking deformation raises α^{-1} instead of lowering it. It fails the beta-sign selection principle Definition 9346.57. The same branch may still record boundary-uplift refinement data, because the transition from $\Delta_6^{\mathrm{bdry}} = \{0, F_9\}$ to the three-branch boundary differences

$$\Delta_7^{\mathrm{bdry}} = \{0, F_{10}, F_{11}\}, \qquad \Delta_8^{\mathrm{bdry}} = \{0, F_{11}, F_{12}\}$$

exhibits the Fibonacci second-difference channel. That channel requires protocol-gated window refinement before it can become a physical running law. □

Concretized in §8846: The finite BetaSignSelection packet records the denominator-sign row, Green-excess source, window-six beta seed, Zeckendorf sibling visibility, and local NameCert boundary for this principle.

Theorem 9346.59 (Green-excess passes the beta-sign test)**.** *The centered Green-excess deformation*

$$D_{6,\alpha}(z) = D^{\star}_{6,\alpha} + \Delta_R(z)\varphi^{-37} + O(\varphi^{-47})$$

has the correct physical running sign on the activation interval $0 < z \leq 1$.

Proof. By Definition 9346.54, $\Delta_R(0) = 0$, $\Delta_R(z) > 0$ for $0 < z \leq 1$, and $\Delta_R'(z) > 0$ on $0 \leq z \leq 1$. Hence the Green-excess deformation increases the denominator away from the static point. Applying Definition 9346.57 and Definition 9346.88 gives

$$\alpha_{Z6}^{-1}(z) < \alpha_{Z6}^{-1}(0) \qquad (0 < z \leq 1),$$

so the coupling itself increases along the activation. The physically admissible local seed is therefore the 571-Green Green-excess branch, while the walking branch remains a protocol-gated cross-window refinement signal. □

Theorem 9346.60 (Window-six internal beta seed)**.** *Define the inverse-coupling beta seed by*

$$\beta_6^{-1}(z) := \frac{d}{dz}\alpha_{Z6}^{-1}(z).$$

On the activation interval $0 \le z \le 1$,

$$\beta_6^{-1}(z) < 0.$$

Near the static point,

$$\alpha_{Z6}^{-1}(z) = \alpha_{Z6}^{-1}(0) - 7.26768202785 \cdot 10^{-14} z - 5.55802304576 \cdot 10^{-14} z^2 + 3.28905498899 \cdot 10^{-15} z^3 + O(z^4),$$

so

$$\beta_6^{-1}(0) = -7.26768202785 \cdot 10^{-14}.$$

Equivalently, for the coupling itself,

$$\alpha_{Z6}(z) = \alpha_{Z6}(0) + 3.87013911681 \cdot 10^{-18} z + 2.95972255241 \cdot 10^{-18} z^2 + O(z^3).$$

The fixed Window-six beta seed therefore has the physically correct sign, is extremely small, and is internal to the Green-excess spectral response.

Proof. By Definition 9346.54, $\Delta_R'(z) > 0$ on $0 \le z \le 1$, while Definition 9346.88 gives $dR/dD < 0$. Hence

$$\frac{d}{dz}\alpha_{Z6}^{-1}(z) = \frac{dR}{dD}\frac{dD_{6,\alpha}(z)}{dz} < 0.$$

The displayed series follows by substituting the small-z expansion of Definition 9346.56 into the readout of Definition 9346.53. The positive sign of the α_{Z6} expansion follows by differentiating the reciprocal of $\alpha_{Z6}^{-1}(z)$ at the static point. □

Theorem 9346.61 (Window-six beta seed is infrared stable)**.** *The Green-excess denominator*

$$55z^3 + 506z^2 - 7263z - 48114$$

has real roots approximately

$$-14.1627969182, \qquad -5.7602517924, \qquad 10.7230487106.$$

Therefore the spectral response has no pole on $0 \le z \le 1$. *The fixed Window-six beta seed is an infrared-stable local running seed, not a complete high-energy running law.*

Proof. The roots are the reciprocals of the non-stationary eigenvalues of the coarse Markov kernel in Definition 9346.54. All three lie outside the activation interval. Hence the rational Green-excess kernel is analytic on $0 \le z \le 1$. Since the endpoint shift Definition 9346.52 is of order 10^{-13} in inverse coupling, any large-scale running account must come from the missing map $z = z(Q)$ together with cross-window refinement, not from a pole internal to Window six. □

Concretized in §9051: The Window-six beta seed packet realizes the inverse-coupling derivative and infrared-stability rows as finite NameCert data.

Principle 9346.62 (Phase-shell running coordinate)**.** *The fixed Window-six denominator response and the phase-shell response are distinct running coordinates. The intra-window coordinate changes D while the golden phase shell remains fixed. The phase-shell coordinate changes the exponent of the golden radius itself. Write*

$$R_6(\sigma, D) := 2\pi \frac{21 + 34C(D)}{21\varphi^{-\sigma} + 34C(D)\varphi^{-(\sigma+1)}},$$

where

$$C(D) := \frac{1}{2} + \frac{1}{4}\cos^2\left(\frac{\pi}{\varphi}\right) + \frac{1}{D\varphi^5}.$$

The infrared Window-six readout is the point

$$(\sigma, D) = (6, D^\star_{6,\alpha}).$$

For fixed D, the readout satisfies

$$R_6(\sigma, D) = R_6(6, D)\varphi^{\sigma-6}.$$

Thus σ is the golden phase-shell exponent, while D is the residual denominator coordinate inside a fixed shell.

Concretized in §9092: Axis-Zeckendorf running coordinates are realized as finite shell-exponent, denominator-response, readout, transport, provenance, and NameCert rows.

Theorem 9346.63 (Fixed Window-six denominator running is infrared-sized)**.** *Within the fixed Window-six phase shell, any monotone increase of D has a finite lower endpoint*

$$R_{6,\min} = 2\pi \frac{21 + 34C_\infty}{21\varphi^{-6} + 34C_\infty\varphi^{-7}}, \qquad C_\infty = \frac{1}{2} + \frac{1}{4}\cos^2\left(\frac{\pi}{\varphi}\right).$$

Numerically,

$$R_{6,\min} = 136.979203197491575\ldots,$$

whereas

$$R_6(6, D^\star_{6,\alpha}) = 137.035999177006279\ldots.$$

Consequently fixed-shell denominator running can lower the inverse coupling by at most

$$0.056795979514704\ldots.$$

It is therefore an infrared-sized response, not a full electroweak-scale running mechanism.

Proof. For fixed phase shell $\sigma = 6$, the only dependence on D enters through

$$\frac{1}{D\varphi^5}.$$

As D increases, this term decreases to zero, so $C(D)$ decreases to C_∞. Since Definition 9346.88 gives $dR/dD < 0$, the displayed value is the limiting lower endpoint for the fixed-shell denominator response. The numerical drop is the difference between the infrared readout and this limiting endpoint. □

Definition 9346.64 (Golden phase-shell anomalous dimension)**.** *A physical running path for the Window-six electromagnetic readout is a map*

$$Q \longmapsto (\sigma(Q), z(Q)),$$

with infrared base point

$$\sigma(0) = 6, \qquad z(0) = 0.$$

The golden phase-shell anomalous dimension is

$$\gamma_\varphi(Q) := 6 - \sigma(Q).$$

The two-coordinate running family is

$$\alpha_{Z6}^{-1}(\sigma, z) := 2\pi \frac{21 + 34C_{6,\alpha}(z)}{21\varphi^{-\sigma} + 34C_{6,\alpha}(z)\varphi^{-(\sigma+1)}},$$

where

$$C_{6,\alpha}(z) = \frac{1}{2} + \frac{1}{4}\cos^2\left(\frac{\pi}{\varphi}\right) + \frac{1}{D_{6,\alpha}(z)\varphi^5}$$

and

$$D_{6,\alpha}(z) = D_{6,\alpha}^\star + \Delta_R(z)\varphi^{-37} + O(\varphi^{-47}).$$

At fixed $z = 0$, the anomalous dimension recodes an inverse-coupling ratio by

$$\gamma_\varphi(Q) = \log_\varphi\left(\frac{\alpha_{Z6}^{-1}(0)}{\alpha_{Z6}^{-1}(Q)}\right).$$

Definition 9346.65 (Effective observable shell index)**.** *Let*

$$A := F_8 = 21, \qquad B := F_9 = 34,$$

and put $C_\star := C(D_{6,\alpha}^\star)$. For any denominator D in the fixed Window-six readout, define the denominator-induced shell shift

$$\delta\sigma_D(D) := \log_\varphi\left[\frac{A + BC(D)}{A + BC_\star} \cdot \frac{A + BC_\star\varphi^{-1}}{A + BC(D)\varphi^{-1}}\right].$$

Then

$$R_6(\sigma, D) = R_0\varphi^{\sigma - 6 + \delta\sigma_D(D)}.$$

The externally visible shell index carried by the single scalar readout is therefore

$$\sigma_{\text{eff}}(Q) := \sigma(Q) + \delta\sigma_D(D_{6,\alpha}(z(Q))),$$

with effective anomalous dimension

$$\gamma_{\text{eff}}(Q) := 6 - \sigma_{\text{eff}}(Q) = \log_\varphi\left(\frac{\alpha_{Z6}^{-1}(0)}{\alpha_{Z6}^{-1}(Q)}\right).$$

Theorem 9346.66 (Observable shell compression)**.** *The scalar inverse coupling $\alpha_{Z6}^{-1}(Q)$ uniquely determines $\sigma_{\text{eff}}(Q)$, or equivalently $\gamma_{\text{eff}}(Q)$, but it does not by itself uniquely determine the internal split between $\sigma(Q)$ and $z(Q)$.*

Proof. The identity in Definition 9346.65 rewrites the two-coordinate readout as

$$\alpha_{Z6}^{-1}(Q) = R_0\varphi^{\sigma_{\text{eff}}(Q)-6} = R_0\varphi^{-\gamma_{\text{eff}}(Q)}.$$

Hence the measured scalar determines the single combination

$$\gamma_{\text{eff}}(Q) = \log_\varphi\left(\frac{R_0}{\alpha_{Z6}^{-1}(Q)}\right),$$

but the equation

$$\sigma_{\text{eff}}(Q) = \sigma(Q) + \delta\sigma_D(D_{6,\alpha}(z(Q)))$$

has more than one internal coordinate. A separate observable sensitive to the Green susceptibility, phase relaxation, boundary parity, or a coherent topological response is needed to distinguish the intra-window Green ledger from the principal phase-shell coordinate. □

Corollary 9346.67 (Green-excess as an effective shell offset)**.** *For the Window-six Green-excess denominator*

$$D_{6,\alpha}(z) = D_{6,\alpha}^\star + \Delta_R(z)\varphi^{-37} + O(\varphi^{-47}),$$

define

$$\gamma_D(z) := -\delta\sigma_D(D_{6,\alpha}(z)).$$

Near the static point,

$$\gamma_D(z) = 1.1021 \cdot 10^{-15}z + O(z^2),$$

and at full Window-six activation,

$$\gamma_D(1) = 1.91 \cdot 10^{-15}.$$

Thus the 571*-Green-excess layer is visible in the scalar coupling only as an extremely small effective shell offset.*

Principle 9346.68 (Infrared boundary condition and shell flow)**.** *The static Window-six denominator*

$$D_{6,\alpha}^\star = 47 + \varphi^{-7} - \frac{1}{2}\varphi^{-17} + \frac{8}{9}\varphi^{-27}$$

is the infrared boundary condition for the electromagnetic readout. It sets

$$R_0 := \alpha_{Z6}^{-1}(0) = 137.035999177006279014596667\ldots.$$

The scale dependence is not supplied by replacing this boundary condition with a large denominator deformation. It is supplied by a path

$$Q \longmapsto (\sigma(Q), z(Q)),$$

where $z(Q)$ is the intra-window Green coordinate and $\sigma(Q)$ is the principal phase-shell coordinate. Thus the Window-six construction separates the boundary value from the renormalization flow.

Theorem 9346.69 (Phase-shell exponent is the principal running coordinate)**.** *The fixed Window-six Green-excess coordinate $z(Q)$ supplies a local intra-window response. A physical running account whose inverse coupling changes by electroweak-scale size must include a nonconstant phase-shell exponent $\sigma(Q)$.*

Proof. By Definition 9346.63, fixed-shell denominator running is bounded by a drop of $0.056795979514704\ldots$ in α^{-1}. By Definition 9346.60, the centered Green-excess seed itself is still smaller, of order 10^{-13} in the inverse coupling near the infrared point. These bounds are local Window-six responses.

By contrast, changing the phase-shell exponent gives

$$R_6(\sigma, D^\star_{6,\alpha}) = R_6(6, D^\star_{6,\alpha})\varphi^{\sigma-6}.$$

Using the electroweak calibration value $\alpha^{-1}(M_Z^2) \approx 128.946$ as a scale diagnostic gives

$$\sigma(M_Z) = 6 + \log_\varphi\left(\frac{128.946}{137.035999177006279}\right) = 5.873548521075\ldots,$$

and hence

$$\gamma_\varphi(M_Z) = 0.126451478925\ldots.$$

Thus the large running component is naturally represented as a renormalization of the golden phase-shell radius. The denominator coordinate remains the local Green response inside that shell. □

Corollary 9346.70 (Shell-flow sign)**.** *If D is held fixed to first order and*

$$R(Q) = R(0)\varphi^{\sigma(Q)-6},$$

then

$$\frac{dR}{d\log Q} = R(Q)\log\varphi\,\frac{d\sigma}{d\log Q}.$$

Therefore the physical sign $d\alpha^{-1}/d\log Q < 0$ requires

$$\frac{d\sigma}{d\log Q} < 0, \qquad \frac{d\gamma_\varphi}{d\log Q} > 0.$$

Energy growth is therefore read as thinning of the effective golden phase shell before any integer-window transition is invoked. Integer window refinement enters as a thresholded refinement of this continuous phase-shell flow.

Theorem 9346.71 (Renormalization dictionary for the golden shell flow)**.** *Let*

$$\beta_\alpha(\alpha, Q) := \frac{d\alpha}{d\log Q}.$$

On any interval where the physical inverse coupling is represented by the shell coordinate with D fixed to first order,

$$\alpha^{-1}(Q) = R_0\varphi^{-\gamma_\varphi(Q)},$$

the standard beta function and the golden shell flow are related by

$$\frac{d\gamma_\varphi}{d\log Q} = \frac{\beta_\alpha(\alpha, Q)}{\alpha\log\varphi}.$$

Equivalently,

$$\frac{d\sigma}{d\log Q} = -\frac{\beta_\alpha(\alpha, Q)}{\alpha\log\varphi}.$$

Proof. Differentiate $R(Q) = \alpha^{-1}(Q)$. Since

$$\frac{dR}{d\log Q} = -\alpha^{-2}\frac{d\alpha}{d\log Q},$$

while

$$R(Q) = R_0\varphi^{-\gamma_\varphi(Q)}$$

gives

$$\frac{dR}{d\log Q} = -R(Q)\log\varphi\,\frac{d\gamma_\varphi}{d\log Q},$$

and $R(Q) = \alpha^{-1}(Q)$, cancellation gives the displayed formula for $d\gamma_\varphi/d\log Q$. The identity for $d\sigma/d\log Q$ follows from $\sigma = 6 - \gamma_\varphi$. □

Corollary 9346.72 (Abelian one-loop shell flow)**.** *In an abelian one-loop regime with active charged fermions contributing*

$$\beta_\alpha(\alpha, Q) = \frac{2}{3\pi}\left(\sum_f N_c(f)q_f^2\right)\alpha^2,$$

the golden shell flow satisfies

$$\frac{d\gamma_\varphi}{d\log Q} = \frac{2}{3\pi\log\varphi}\left(\sum_f N_c(f)q_f^2\right)\alpha.$$

Hence the shell anomalous dimension increases whenever the abelian beta function is positive, and the phase-shell exponent decreases:

$$\frac{d\gamma_\varphi}{d\log Q} > 0, \qquad \frac{d\sigma}{d\log Q} < 0.$$

Charged-particle thresholds change the coefficient in the sum and therefore change the shell-flow slope. They do not alter the role of $D^\star_{6,\alpha}$ as the infrared boundary condition.

Principle 9346.73 (Three coefficient strata)**.** *The three Window-six coefficients*

$$\frac{8}{9}, \qquad \frac{2}{3}, \qquad \frac{4}{9}$$

are not competing fits for the same low-energy scalar. They occupy different physical strata of the same finite readout geometry. The phase-reservoir coefficient

$$q^{\text{imp}}_{\text{static}} = \frac{8}{9}$$

is the static impedance coefficient selected by the right-boundary flux-reservoir readout. The image coefficient

$$q^{Z_6}_\beta = \frac{2}{3}$$

is the six-element $Z_6 \to U(1)$ phase-image coefficient when that image is read as a unit electromagnetic beta-flow activation. The one-way coefficient

$$q^{\text{one}}_{\text{curv}} = \frac{4}{9}$$

is the irreducible curvature-residual or one-way fold-mismatch coefficient.

Theorem 9346.74 (Window-six readout diamond)**.** *The Window-six readout coefficients form the three-layer diamond*

$$q_{\mathrm{curv}} = \frac{4}{9} \quad \longrightarrow \quad q_\beta = \frac{6}{9} = \frac{2}{3} \quad \longrightarrow \quad q_{\mathrm{imp}} = \frac{8}{9}.$$

The common step is

$$\frac{2}{9} = \frac{|P_6^{\mathrm{geo}}|}{N_{\geq 4}(6)}.$$

Thus the layers differ by activation of one basic Z_2 parity unit against the deepest residual-tail denominator.

Proof. The curvature-residual layer quotients the locally absorbable diagonal parity

$$P_6^{\mathrm{geo}} \cong \mathbb{Z}/2\mathbb{Z}$$

from the boundary reservoir, so its visible residual group has order 4 and coefficient $4/N_{\geq 4}(6) = 4/9$. The $U(1)$ phase-image layer uses the six-element image of the $C_\partial \times T \to \mathbb{Z}/6\mathbb{Z} \to U(1)$ interface, so its coefficient is $6/9 = 2/3$. The static impedance layer reads the full boundary phase reservoir $C_\partial \cong (\mathbb{Z}/2\mathbb{Z})^3$, so its coefficient is $8/9$. Since the orders are $4, 6, 8$, the successive normalized differences are both $2/9$. □

Theorem 9346.75 (Static impedance selects 8/9 while beta flow selects 2/3)**.** *The low-energy denominator*

$$D^\star_{6,\alpha} = 47 + \varphi^{-7} - \frac{1}{2}\varphi^{-17} + \frac{8}{9}\varphi^{-27}$$

uses $8/9$ because the infrared electromagnetic scalar is an impedance readout of the phase reservoir. The abelian unit-charge shell flow uses $2/3$ because the running layer reads the $Z_6 \to U(1)$ phase image.

Proof. By Definition 9346.93, the fixed infrared electromagnetic readout selects the phase-reservoir coefficient $q_2 = 8/9$, not the image coefficient or the curvature quotient. By Definition 9346.49, the same $8/9$ is the normalized right-block escape flux $P(\text{leave } U_R \mid U_R) = 32/36$. This is the static impedance layer.

By contrast, the $Z_6 \to U(1)$ image has six phase images over the Window-six depth denominator $N_{\geq 4}(6) = 9$, hence coefficient $6/9$. In the shell-flow dictionary of Definition 9346.71, an abelian unit Dirac charge contributes

$$\frac{d\gamma_\varphi}{d\log Q} = \frac{2}{3}\frac{\alpha}{\pi \log \varphi}.$$

Thus the $2/3$ image coefficient is naturally assigned to the beta-flow layer rather than to the static denominator. □

Definition 9346.76 (Window-six beta-shell coefficient)**.** *The unit Z_6 beta-shell coefficient is*

$$q_\beta^{Z_6} := \frac{2}{3}.$$

For a scale interval with active electromagnetic modes, write

$$\mathcal{B}(Q) = q_\beta^{Z_6} \sum_f N_c(f) q_f^2 \Theta_f(Q) + \mathcal{B}_{\mathrm{bos}}(Q) + \mathcal{B}_{\mathrm{had}}(Q),$$

where $\Theta_f(Q)$ records threshold activation, $N_c(f)$ is the color multiplicity, and q_f is the electric charge in units of the positron charge. The corresponding golden shell flow is

$$\frac{d\gamma_{\text{eff}}}{d\log Q} = \frac{\alpha(Q)}{\pi \log \varphi}\,\mathcal{B}(Q).$$

Corollary 9346.77 (Coefficient layer separation)**.** *The low-energy static layer, the beta-shell layer, and the Green susceptibility layer are separated as follows:*

$$\frac{8}{9} \quad \textit{sets the static flux-reservoir boundary condition,}$$

$$\frac{2}{3} \quad \textit{sets the unit } Z_6 \textit{ phase-image beta coefficient,}$$

and

$$571 \quad \textit{certifies the internal Green susceptibility denominator.}$$

The curvature coefficient $4/9$ *remains the one-way mismatch or curvature-residual coefficient. It does not replace either the static impedance coefficient or the unit beta-flow coefficient.*

Concretized in §9120: The coefficient-strata readout route is realized as finite Zeckendorf carry, running-coordinate, static boundary-flux, transport, replay, provenance, and NameCert rows.

Principle 9346.78 (Pre-quantum phase-projection reading)**.** *The Window-six Zeckendorf readout has a superposition-shaped record geometry, but it is not yet a Hilbert-space quantum model. The visible stable state*

$$x \in X_6$$

is the image of a residual fiber

$$\mathcal{F}_6(x) = \mathsf{Fold}_6^{-1}(x) \subseteq \Omega_6, \qquad \Omega_6 = \{0,1\}^6.$$

Thus a visible Zeckendorf address is not a single raw microstate; it is the public projection of a finite bundle of raw binary histories. The additional phase gate

$$C_\partial \times T \longrightarrow \mathbb{Z}/6\mathbb{Z} \longrightarrow U(1)$$

turns this fold-fiber ledger into a discrete phase projection surface.

Theorem 9346.79 (Fine-structure readout as projected phase record)**.** *The scalar α_{Z6}^{-1} is a projected readout of the Window-six fold-fiber, phase-gate, boundary-flux, and Green-response ledger. It is not a primitive carrier of the raw microstates.*

Proof. The visible component is supplied by the fold $\mathsf{Fold}_6 : \Omega_6 \to X_6$, whose fibers are retained by Definition 9346.3. The phase component is the $Z_6 \to U(1)$ gate of Definition 9346.47. The static boundary component is the right-block flux-reservoir coefficient of Definition 9346.49. The dynamic response component is the centered Green-excess layer of Definition 9346.52. The readout formula combines these records into a single scalar inverse coupling. Therefore the scalar is downstream from a finite record surface rather than identical to any one raw binary history. □

Concretized in §8811: The phase-shell packet realizes the fold-fiber, discrete phase gate, boundary-flux, and Green-response rows as finite NameCert data.

Theorem 9346.80 (Born-like two-shell radius projection)**.** *Let $C > 0$ and let $\mathcal{H}_{\text{shell}}$ be the two-dimensional complex carrier with orthonormal basis $|6\rangle, |7\rangle$. For any relative shell phase $\eta \in \mathbb{R}$ define*

$$|\Psi_C(\eta)\rangle = \frac{\sqrt{21}\,|6\rangle + e^{i\eta}\sqrt{34C}\,|7\rangle}{\sqrt{21+34C}}.$$

Let the diagonal radius observable be

$$\widehat{r} = \varphi^{-6}|6\rangle\langle 6| + \varphi^{-7}|7\rangle\langle 7|.$$

Then

$$\langle \Psi_C(\eta)|\widehat{r}|\Psi_C(\eta)\rangle = \frac{21\varphi^{-6} + 34C\varphi^{-7}}{21+34C}.$$

Consequently, for the Window-six spectral family of Definition 9346.53,

$$\alpha_{Z6}^{-1}(z) = \frac{2\pi}{\langle \Psi_{C_{6,\alpha}(z)}(\eta)|\widehat{r}|\Psi_{C_{6,\alpha}(z)}(\eta)\rangle}.$$

Proof. The vector is normalized because the two shell basis vectors are orthonormal:

$$\langle \Psi_C(\eta)|\Psi_C(\eta)\rangle = \frac{21+34C}{21+34C} = 1.$$

The observable $\widehat{r}$ is diagonal in the same basis, so the relative phase contributes no cross term. Hence the expectation is

$$\frac{21}{21+34C}\varphi^{-6} + \frac{34C}{21+34C}\varphi^{-7} = \frac{21\varphi^{-6} + 34C\varphi^{-7}}{21+34C}.$$

Substituting $C = C_{6,\alpha}(z)$ gives exactly the inverse-coupling formula in Definition 9346.53. □

Corollary 9346.81 (Born-like shell weights)**.** *The two-shell readout weights are squared amplitudes:*

$$P_6(C) = \frac{21}{21+34C}, \qquad P_7(C) = \frac{34C}{21+34C}.$$

Thus the effective radius is the Born-like diagonal projection

$$\langle \widehat{r}\rangle = P_6(C)\varphi^{-6} + P_7(C)\varphi^{-7},$$

and the scalar inverse coupling is the phase circumference divided by that projected radius.

Corollary 9346.82 (Diagonal radius phase blindness)**.** *The scalar $\alpha_{Z6}^{-1}(z)$ is insensitive to the relative shell phase η. An off-diagonal shell observable such as*

$$\widehat{X} = |6\rangle\langle 7| + |7\rangle\langle 6|$$

would instead read

$$\langle \Psi_C(\eta)|\widehat{X}|\Psi_C(\eta)\rangle = 2\sqrt{P_6(C)P_7(C)}\cos\eta.$$

Thus the inverse fine-structure scalar reads only the diagonal radius projection; a coherent shell phase would require an interference-type readout interface.

Definition 9346.83 (Cascade kernel as internal channel norm)**.** *Let*

$$\theta = \frac{\pi}{\varphi}.$$

On the internal channel carrier

$$\mathcal{H}_C = \operatorname{span}\{|b\rangle, |\chi\rangle, |t\rangle\},$$

define the amplitudes

$$a_b = \frac{1}{\sqrt{2}}, \qquad a_\chi = \frac{e^{i\theta} + e^{-i\theta}}{4} = \frac{1}{2}\cos\theta, \qquad a_t = \frac{1}{\sqrt{D_{6,\alpha}(z)\varphi^5}}.$$

Then the Window-six cascade kernel is the squared norm of the internal channel vector

$$|\psi_C(z)\rangle = a_b|b\rangle + a_\chi|\chi\rangle + a_t|t\rangle :$$

$$\| \, |\psi_C(z)\rangle \, \|^2 = \frac{1}{2} + \frac{1}{4}\cos^2\left(\frac{\pi}{\varphi}\right) + \frac{1}{D_{6,\alpha}(z)\varphi^5} = C_{6,\alpha}(z).$$

Principle 9346.84 (Block-separated internal coherence)**.** *The cascade kernel is not a fully coherent sum over the binary, golden-phase, and tail channels. It is a block-separated norm ledger: the channel magnitudes add as*

$$C_{6,\alpha}(z) = |a_b|^2 + |a_\chi|^2 + |a_t|^2,$$

while the golden-phase channel itself contains the coherent pair

$$e^{i\pi/\varphi}, \qquad e^{-i\pi/\varphi}.$$

Thus the visible fine-structure readout factors through two Hilbertizable rows:

$$\mathcal{H}_C \longrightarrow C_{6,\alpha}(z) \longrightarrow \mathcal{H}_{\text{shell}} \longrightarrow \langle \widehat{r} \rangle \longrightarrow \alpha_{Z6}^{-1}(z).$$

The coefficient layer separation of Definition 9346.73 is the corresponding separation of readout effects rather than a competition among scalar fits.

Principle 9346.85 (Hilbert boundary for the Zeckendorf phase record)**.** *The phase-projection reading does not assert a complete quantum mechanics. The two-shell construction above is a Hilbertizable compression of the scalar formula, not a complete carrier for the raw fold fibers, unitary time evolution, the Born rule as a physical postulate, or a measurement theory. A genuine Hilbert lift of the full Zeckendorf record would need a carrier such as*

$$\mathcal{H}_6 = \ell^2(\Omega_6) \qquad \textit{or} \qquad \mathcal{H}_6 = \ell^2(X_6),$$

a state

$$|\Psi_6\rangle = \sum_{\omega \in \Omega_6} a_\omega |\omega\rangle, \qquad a_\omega \in \mathbb{C},$$

fiber projectors

$$P_x|\Psi_6\rangle = \sum_{\mathsf{Fold}_6(\omega)=x} a_\omega |\omega\rangle,$$

phase transport

$$a_\omega \longmapsto a_\omega e^{i\theta(\omega)},$$

and an observable $\widehat{R}_6$ whose expectation value is compared with the scalar readout:

$$\langle \Psi_6 | \widehat{R}_6 | \Psi_6 \rangle \approx \alpha_{Z6}^{-1}.$$

Until such rows are supplied, the correct status is a Born-like pre-quantum phase-projection geometry rather than a complete quantum superposition theorem.

Corollary 9346.86 (Interference-shadow status of the cosine term)**.** *The term*

$$\frac{1}{4}\cos^2\left(\frac{\pi}{\varphi}\right)$$

in the cascade kernel is the squared intensity of the internal golden-phase channel:

$$\left|\frac{e^{i\pi/\varphi}+e^{-i\pi/\varphi}}{4}\right|^2=\frac{1}{4}\cos^2\left(\frac{\pi}{\varphi}\right).$$

It is therefore an explicit interference-shaped row inside the block-separated cascade norm, while the full manuscript still stops short of a complete quantum-mechanical measurement theory.

Theorem 9346.87 (Static denominator closed; Green-excess remains separate)**.** *The low-energy static denominator is closed at the static cut-flux layer:*

$$D^{\star}_{6,\alpha}=47+\varphi^{-7}-\frac{1}{2}\varphi^{-17}+\frac{8}{9}\varphi^{-27}.$$

The first candidate Green-running coefficient is the centered Green-excess kernel

$$q_{3,\mathrm{run}}(z)=\Delta_R(z),\qquad \Delta_R(1)=\frac{26401}{2^{13}\cdot 571}.$$

Thus the subsequent certificate problem is not whether to add another static term to $D^{\star}_{6,\alpha}$, but whether a physical Green-excess activation parameter $z(Q)$ and higher-window data replace the fixed Window-six seed by a refinement flow

$$X_6\rightsquigarrow X_{m(Q)}.$$

Proof. The static part is the conclusion of Definition 9346.51: every static Dirichlet cut-source is Laplacian-exact, and the right-boundary source therefore gives $q_3=0$ for the infrared readout. The dynamic coefficient is the Green–Kubo response after subtracting the static variance baseline of the centered right-boundary observable. Since $\Delta_R(0)=0$, the Green-excess seed contributes no correction at the static point. For $0<z\le 1$ the displayed denominator is negative while the polynomial $3z(1595z^2+24477z+26730)$ is positive; the leading minus sign therefore makes $\Delta_R(z)>0$. Because the readout $R(D)$ is decreasing in D, the Green-excess term lowers α^{-1} and raises the coupling. At nonzero scale the effect is controlled by Green-excess activation and window-refinement data, not by a change to the static denominator. □

Concretized in §8769: Static Green boundary flux is realized as finite reduced-Laplacian, cut-source, exactness, localized-denominator, transport, replay, provenance, and NameCert rows.

Theorem 9346.88 (Independent denominator is required for predictivity)**.** *Let*

$$R(D):=2\pi\varphi^5\frac{F_8+F_9C(D)}{F_8\varphi^{-1}+F_9C(D)\varphi^{-2}},$$

where

$$C(D):=\frac{1}{2}+\frac{1}{4}\cos^2\left(\frac{\pi}{\varphi}\right)+\frac{1}{D\varphi^5}.$$

For positive D, the readout $R(D)$ is strictly decreasing in D. Consequently, if D is obtained by inverting an observed low-energy value of $\alpha_{\mathrm{EM}}^{-1}$, then the expression has no predictive force as a Window-six claim. A predictive use requires a denominator rule

$$D_6=\Gamma(X_6,\mathsf{Fold}_6,\textit{boundary parity},\textit{tail ledger})$$

that does not use the measured electromagnetic coupling.

Proof. The derivative with respect to C is

$$\frac{\partial R}{\partial C} = 2\pi\varphi^5 \frac{F_8 F_9(\varphi^{-1} - \varphi^{-2})}{(F_8\varphi^{-1} + F_9 C\varphi^{-2})^2}.$$

Since $\varphi^{-1} > \varphi^{-2}$, this derivative is positive. Also

$$\frac{dC}{dD} = -\frac{1}{D^2\varphi^5} < 0.$$

Thus $dR/dD < 0$. In any interval where the inverse problem is posed, the measured scalar can therefore determine a denominator by inversion rather than by Window-six structure. Such an inverted denominator is a fit, not an independent prediction. Predictivity requires that the denominator be supplied by the Window-six ledger before comparison with the physical scalar. □

Definition 9346.89 (Low-energy alpha-projection gate)**.** *A low-energy alpha-projection gate is protocol data Γ^α for the electromagnetic representation certificate that selects an admissible cross-scale boundary-return branch before the Window-six residual ledger is evaluated. At the first post-Window-six boundary it has the form*

$$\Gamma_7^\alpha : \{0, F_{10}, F_{11}\} \longrightarrow \{0, F_{10}\}.$$

Equivalently, it retains the $F_{10} = 55$ return branch from $\{0, 55, 89\}$ and excludes the $F_{11} = 89$ diffusion branch from the low-energy residual ledger. This gate is a separate protocol field; it is not inferred from the measured electromagnetic scalar.

Principle 9346.90 (Square-residue gate candidate)**.** *A natural candidate implementation of Definition 9346.89 is the square-residue projection at $p_* = 571$. The candidate is guided by the order data*

$$\mathrm{ord}_{571}(34) = 285, \qquad \mathrm{ord}_{571}(55) = 19, \qquad \mathrm{ord}_{571}(89) = 570, \qquad \mathrm{ord}_{571}(144) = 285.$$

Under this reading the low-energy projection keeps the re-lockable residue branch and excludes the primitive diffusion branch. This remains protocol-gate data until a NameCert supplies the corresponding internal certificate.

Principle 9346.91 (Protocol-gated Window-six minimal residual closure)**.** *The protocol-gated Window-six minimal closure route treats the coarse denominator*

$$D_0 = F_{10} - F_6 = F_9 + F_7 = 47$$

as fixed by the outer uplift tail, the eightfold boundary parity, the next boundary, and the deep tail. In the coarse ledger, F_9 is the boundary alias already visible in the projection weights, while $F_7 = N_{\geq 3}(6)$ is the non-displayed deep tail. The first residual seam is therefore placed at the golden shell of this deep-tail address

$$\varphi^{-(F_5+F_3)} = \varphi^{-7},$$

not at a shallower term that would rewrite the visible F_8 layer or the explicit F_9 boundary layer. The boundary holonomy quotient is the two-bit residual quotient

$$C_\partial / P_6^{\mathrm{geo}} \cong (\mathbb{Z}/2\mathbb{Z})^2.$$

The boundary sheet expectation is the two-sheet average

$$E_{\text{sheet}}(a) = \frac{1}{2}(a + P_w a P_w),$$

with index 2*, and the binary boundary uplift satisfies*

$$(\mathsf{Fold}_6^{\text{bin}})^{-1}(w) = \{V_6(w), V_6(w) + 34\},$$

so the sheet difference is $34 = F_9$*. The nonzero Window-six uplift tail offsets obey*

$$\Delta_{\text{tail}}(6) \subset \{F_8, F_9, F_{10}\} = \{21, 34, 55\}.$$

The Window-six boundary difference itself is only two-sheeted,

$$\Delta_6^{\text{bdry}} = \{0, F_9\},$$

whereas the next boundary differences have three branches,

$$\Delta_7^{\text{bdry}} = \{0, F_{10}, F_{11}\}, \qquad \Delta_8^{\text{bdry}} = \{0, F_{11}, F_{12}\}.$$

Therefore the Window-six sheet parity is not transported across scales without protocol data. Given the low-energy gate Γ_7^{α} *of Definition 9346.89, the first cross-scale return branch is* F_{10}*. The closure mode then determines whether this return is held fixed at the Window-six anchor or walked to the next retained branch. The anchor-local step is*

$$u_6 := \varphi^{-(F_6+F_3)} = \varphi^{-10}.$$

The walking-gate mode uses the next retained branch F_{12}*, hence its third displayed exponent is* $7 + 10 + 12 = 29$*. The primitive* F_{11} *branch is not part of the low-energy ledger selected by the gate. The Window-six closure displays three residual terms because the fiber multiplicities are only* $2, 3, 4$*, equivalently because the tail ledger stops at* $N_{\geq 4}(6)$ *inside Window six. Further terms require cross-window protocol refinement. Its first two coefficient normalizations are*

$$q_0 = 1, \qquad q_1 = -\frac{F_2}{F_3}.$$

Here $q_0 = 1$ *reads the single occurrence of the* F_7 *deep-tail seam,* $q_1 = -1/2$ *reads the two-sheet overlap subtraction. The same coefficient is also the alternating phase eigenvalue in the untwisted fold-gauge mismatch spectrum*

$$\operatorname{spec}(A_0) = \{1, \tfrac{1}{2}, -\tfrac{1}{2}\},$$

where the $-1/2$ *mode is the Jordan alternating return seen by the statistical projection. The third coefficient is fixed only after a readout mode is chosen. The full phase-reservoir readout sees*

$$C_\partial \cong (\mathbb{Z}/2\mathbb{Z})^3, \qquad q_2^{\text{res}} = \frac{|C_\partial|}{N_{\geq 4}(6)} = \frac{8}{9},$$

also matching the ratio between the fiber histogram layers $\#\{d_6 = 2\} = 8$ *and* $\#\{d_6 = 4\} = 9$*, and matching the right-block escape flux in Definition 9346.49. The* $U(1)$*-image readout uses the six-element phase image supplied by the* Z_6 *interface*

$$C_\partial \times T \to \mathbb{Z}/6\mathbb{Z} \to U(1), \qquad q_2^{\text{img}} = \frac{6}{N_{\geq 4}(6)} = \frac{2}{3}.$$

The irreducible curvature-residual readout quotients the locally absorbable diagonal subgroup

$$P_6^{\mathrm{geo}} \cong \mathbb{Z}/2\mathbb{Z}, \qquad C_\partial/P_6^{\mathrm{geo}} \cong (\mathbb{Z}/2\mathbb{Z})^2,$$

and hence has

$$q_2^{\mathrm{curv}} = \frac{|C_\partial/P_6^{\mathrm{geo}}|}{N_{\geq 4}(6)} = \frac{4}{9}.$$

Theorem 9346.92 (Protocol-gated Window-six closure determines a readout family)**.** *Assume the protocol-gated Window-six minimal residual closure of Definition 9346.91. The three-term residual polynomial selected by the Window-six fiber-depth cutoff, the low-energy gate, a closure mode, and a readout mode*

$$Q_6(u) = q_0 + q_1 u + q_2 u^2$$

therefore has coefficients

$$q_0 = 1, \qquad q_1 = -\frac{F_2}{F_3}, \qquad q_2 \in \left\{\frac{8}{9}, \frac{2}{3}, \frac{4}{9}\right\},$$

where $q_2 = 8/9$ is the phase-reservoir readout, $q_2 = 2/3$ is the $Z_6 \to U(1)$ image readout, and $q_2 = 4/9$ is the irreducible curvature-residual readout. In anchor-local mode the resulting three-term Window-six residual denominator is

$$D_{6,\mathrm{loc}}^{(q_2)} = F_9 + F_7 + \varphi^{-(F_5+F_3)}\left[1 - \frac{F_2}{F_3}\varphi^{-(F_6+F_3)} + q_2\varphi^{-2(F_6+F_3)}\right].$$

Equivalently, the three anchor-local readouts are

$$D_{6,\mathrm{loc}}^{\mathrm{res}} = 47+\varphi^{-7}-\frac{1}{2}\varphi^{-17}+\frac{8}{9}\varphi^{-27}, \qquad D_{6,\mathrm{loc}}^{\mathrm{img}} = 47+\varphi^{-7}-\frac{1}{2}\varphi^{-17}+\frac{2}{3}\varphi^{-27}, \qquad D_{6,\mathrm{loc}}^{\mathrm{curv}} = 47+\varphi^{-7}-\frac{1}{2}\varphi^{-17}+\frac{4}{9}\varphi^{-27}.$$

In walking-gate mode the three readouts are

$$D_{6,\mathrm{walk}}^{\mathrm{res}} = 47+\varphi^{-7}-\frac{1}{2}\varphi^{-17}+\frac{8}{9}\varphi^{-29}, \qquad D_{6,\mathrm{walk}}^{\mathrm{img}} = 47+\varphi^{-7}-\frac{1}{2}\varphi^{-17}+\frac{2}{3}\varphi^{-29}, \qquad D_{6,\mathrm{walk}}^{\mathrm{curv}} = 47+\varphi^{-7}-\frac{1}{2}\varphi^{-17}+\frac{4}{9}\varphi^{-2}$$

Proof. By the protocol-gated Window-six minimal closure, the anchor-local denominator has the form

$$D_{6,\mathrm{loc}}^{(q_2)} = D_0 + \varphi^{-(F_5+F_3)}Q_6(\varphi^{-(F_6+F_3)}).$$

Taking the specified three-term polynomial and substituting the displayed coefficients gives the first formula. The Fibonacci values

$$F_2 = 1, \quad F_3 = 2, \quad F_5 = 5, \quad F_6 = 8, \quad F_7 = 13, \quad F_9 = 34$$

then give $F_9 + F_7 = 47$, $F_5 + F_3 = 7$, $F_6 + F_3 = 10$, and $F_2/F_3 = 1/2$. Substituting $q_2 = 8/9$, $q_2 = 2/3$, and $q_2 = 4/9$ gives the three anchor-local readouts. For walking-gate mode, the first two exponents remain 7 and 17, while the third exponent walks from the F_{10} return to the next retained F_{12} branch. Thus the third exponent is $7 + 10 + 12 = 29$. Substituting the three allowed readout coefficients gives the displayed walking-gate readouts. □

Theorem 9346.93 (Fixed electromagnetic readout selects the local reservoir branch)**.** *Assume the readout is the fixed Window-six projection formula whose visible state and boundary rows are F_8 and F_9. Assume also that the physical target is the low-energy electromagnetic impedance readout whose phase observations are gated by the $Z_6 \to U(1)$ image. Then the admissible low-energy denominator selected from Definition 9346.92 is*

$$D_{6,\alpha}^{\star} = D_{6,\mathrm{loc}}^{\mathrm{res}} = 47 + \varphi^{-7} - \frac{1}{2}\varphi^{-17} + \frac{8}{9}\varphi^{-27}.$$

Proof. The fixed Window-six projection formula keeps the visible pair (F_8, F_9). A walking residual would move the residual ledger to the next retained branch F_{12} while the visible readout remains fixed at (F_8, F_9). Thus the fixed low-energy formula selects the anchor-local closure. The $Z_6 \to U(1)$ image supplies the admissible phase observation gate, but $\alpha_{\mathrm{EM}}^{-1}(0)$ is an impedance readout of the phase reservoir behind that gate rather than a bare image-cardinality readout. By Definition 9346.49, the same reservoir coefficient is also the normalized right-block escape flux $P(\text{leave } U_R \mid U_R) = 8/9$. Thus the selected coefficient is the flux-reservoir coefficient $q_2 = 8/9$, not the image coefficient $q_2 = 2/3$ or the curvature quotient $q_2 = 4/9$. Substitution into the readout-family theorem gives the displayed denominator. □

Principle 9346.94 (Remaining formalization obligations)**.** *The protocol-gated Window-six closure becomes a fully internal Window-six theorem only after six further obligations are discharged. First, the ProtocolGateLegality obligation must certify*

$$\Gamma_7^{\alpha} : \{0, F_{10}, F_{11}\} \to \{0, F_{10}\}$$

as an allowed low-energy projection gate. If the square-residue gate is used, this obligation must certify the $p_* = 571$ residue-stratum separation in Definition 9346.90. Second, the GoldenResiduAlLadder obligation must derive

$$D_6 - D_0 \in \varphi^{-7}\mathbb{Q}_Z[\varphi^{-10}],$$

from the deep-tail seam and the gated F_{10} uplift-return rule. Third, the TwoSheetMobius obligation must derive

$$q_1 = \frac{1-2}{2} = -\frac{1}{2}.$$

It must also identify the same coefficient with the Jordan alternating phase mode of the fold-gauge mismatch spectrum. Fourth, the ReadoutMode obligation must distinguish the phase reservoir C_∂, giving $q_2 = 8/9$, the $Z_6 \to U(1)$ image, giving $q_2 = 2/3$, and the irreducible curvature-residual quotient $C_\partial/P_6^{\mathrm{geo}}$, giving $q_2 = 4/9$; for $\alpha_{\mathrm{EM}}^{-1}(0)$ it must select the phase-reservoir impedance readout gated by Z_6, using the local conditional escape flux $8/9$ rather than the global cut-flux density $1/12$. Fifth, the ClosureMode obligation must certify that fixed $R_6(D)$ readouts select anchor-local closure, while walking-gate closure belongs to a scale-indexed $R_m(D_m)$ refinement object. Sixth, the GreenResolved obligation separates the static right-boundary cut-flux source from centered Green-relaxation input. The static low-energy right-boundary readout has $q_3 = 0$ by Definition 9346.51; the right-boundary cut vector is an instance of the general Dirichlet cut-source identity $L_B\mathbf{1}_I = b_B$ and therefore has zero 571-Green class. By the same theorem, centered relaxation observables for the coarse Markov kernel have susceptibility and Green–Kubo denominators containing 571. A nonzero Green term may therefore enter only in a running or dynamic response certificate, such as

$$D_{6,\alpha}(z) = D_{6,\alpha}^{\star} + \Delta_R(z)\varphi^{-37} + O(\varphi^{-47}), \qquad \Delta_R(0) = 0.$$

The Window-six seed candidate is Definition 9346.52, with $\Delta_R(1) = 26401/(2^{13} \cdot 571)$. The GreenClass branch must therefore show that any physical running readout uses this centered Green-excess source, or else replace it by a certified higher-window Green mode. The FluxGreenCoupling branch must decide separately whether the global cut-flux density $\Phi_R = 1/12$ participates in the activation of the Green-excess parameter. Until these obligations are supplied, the closed denominator is a protocol-gated Window-six ledger conclusion rather than a fully certified internal theorem.

Theorem 9346.95 (Physical refutation surface for the Window-six readout)**.** *The physical interpretation of a selected $R_{Z6,\mu}^{\star}$ is refutable at the derived-interface level by any of the following*

failures: no admissible low-energy projection gate selects the F_{10} branch; the physical representation cannot decide the anchor-local versus walking-gate closure mode at the required precision; the physical representation cannot decide whether the target reads the phase reservoir, the $Z_6 \to U(1)$ image, or the irreducible curvature-residual quotient; the selected third coefficient remains a fitted rational rather than a readout-mode normalization; independent low-energy routes converge to incompatible values after systematic corrections; a high-energy comparison reuses $R^{\star}_{Z6,\mu}$ without a scale-indexed ledger or spectral-response activation map and window-refinement flow; or later residual corrections inside the static cut-flux layer require terms outside the selected gated ladder

$$\{7, 17, 27\} \quad \textit{in anchor-local mode,} \qquad \{7, 17, 29\} \quad \textit{in walking-gate mode.}$$

Proof. The first failure violates the protocol-gate requirement in Definition 9346.89. The second leaves the denominator family mode-underdetermined at the physical interface. The third leaves the coefficient family readout-underdetermined. The fourth violates the residual closure principle in Definition 9346.9, the protocol-gated closure principle in Definition 9346.91, and the readout-mode coefficient normalization in Definition 9346.94. The fifth violates the route-convergence requirement of Definition 9346.43. The sixth violates the infrared boundary of Definition 9346.44. The seventh violates the displayed Window-six residual denominators, whose correction terms occur at $7, 17, 27$ in anchor-local mode and at $7, 17, 29$ in walking-gate mode. Each failure breaks an explicit interface condition without needing to deny the finite Zeckendorf fold construction itself. □

Concretized in §8811: The phase-shell chapter realizes the stable-window, residual-fiber, and external golden-phase projection rows as finite NameCert data.

Chapter 9347

Window-Six Inverse-Limit Lifting

chapter 9346 reads the no-adjacent-11 grammar as a finite visible surface, with Window six as the distinguished twenty-one-state readout. The present chapter records the projection-tower form behind that surface. It separates the address carrier from the flux-operator geometry: the address carrier lifts to the Zeckendorf golden-mean inverse limit, while a flux or Jordan-return reading requires additional compatibility rows for the operator tower.

9347.1 Address tower

Definition 9347.1 (No-adjacent address windows)**.** *For each $m \geq 0$, let*

$$X_m := \{w \in \{0,1\}^m : \ w_i w_{i+1} \neq 11 \text{ for every admissible } i\}.$$

For $m \geq 0$, the prefix projection is

$$\pi_{m+1,m} : X_{m+1} \to X_m, \qquad \pi_{m+1,m}(w_1, \ldots, w_{m+1}) = (w_1, \ldots, w_m).$$

For $m \geq n$, write $\pi_{m,n} : X_m \to X_n$ for the iterated prefix projection. Prefix stability of the no-adjacent rule gives

$$\pi_{n,k} \circ \pi_{m,n} = \pi_{m,k} \qquad (m \geq n \geq k),$$

so the family $(X_m, \pi_{m,n})$ is an inverse system of finite windows.

Definition 9347.2 (Zeckendorf address inverse limit)**.** *The Zeckendorf address inverse limit is*

$$X_\infty^Z := \varprojlim_m X_m.$$

Equivalently, it is the carrier of infinite no-adjacent-11 address streams

$$X_\infty^Z \cong \{(c_1, c_2, \ldots) \in \{0,1\}^{\mathbb{N}} : \ c_i c_{i+1} \neq 11 \text{ for every } i\}.$$

The projection to level m is written

$$P_m : X_\infty^Z \to X_m.$$

Proposition 9347.3 (Window six is the sixth address projection)**.** *The Window-six address surface is exactly the sixth projection of the Zeckendorf address inverse limit:*

$$\mathsf{Window6}_{\mathrm{addr}} = X_6 = P_6(X_\infty^Z).$$

Moreover,

$$|X_6| = F_8 = 21.$$

Proof. Every infinite no-adjacent-11 stream has a length-six prefix in X_6, so $P_6(X_\infty^Z) \subseteq X_6$. Conversely, every word $w \in X_6$ extends to an infinite stream by appending zeros, hence $w \in P_6(X_\infty^Z)$. The counting formula for no-adjacent binary words gives $|X_m| = F_{m+2}$, so $|X_6| = F_8 = 21$. □

Definition 9347.4 (Window cylinder)**.** *For a visible word $w \in X_6$, its inverse-limit cylinder is*

$$\mathsf{Lift}_6(w) := P_6^{-1}(w) = \{x \in X_\infty^Z : P_6(x) = w\}.$$

Definition 9347.5 (Ambient Window-six cylinder)**.** *Let*

$$C_6 := \{0,1\}^6$$

be the full six-bit carrier, and let

$$Q_6 : X_\infty^Z \to C_6$$

be the first-six-coordinate readout. For $u \in C_6$, its ambient Window-six cylinder is

$$\mathrm{Cyl}_6(u) := \{x \in X_\infty^Z : Q_6(x) = u\}.$$

When $u \in X_6$, this agrees with the inverse-limit cylinder $\mathsf{Lift}_6(u)$.

Proposition 9347.6 (Window-six extension boundary)**.** *For $u \in C_6$, the cylinder $\mathrm{Cyl}_6(u)$ is nonempty if and only if $u \in X_6$.*

Proof. If $u \in X_6$, append zeros to obtain

$$x = u000\cdots.$$

Appending zeros cannot create an adjacent pair 11, so $x \in X_\infty^Z$ and $Q_6(x) = u$. Hence $\mathrm{Cyl}_6(u)$ is nonempty.

Conversely, if $u \notin X_6$, then u contains an adjacent pair 11. Every infinite binary sequence with prefix u contains that same adjacent pair, so no such sequence lies in X_∞^Z. Hence $\mathrm{Cyl}_6(u) = \varnothing$. □

Corollary 9347.7 (Window-six cylinder partition)**.** *The sixth projection decomposes the inverse-limit address carrier as*

$$X_\infty^Z = \coprod_{u \in X_6} \mathrm{Cyl}_6(u).$$

The twenty-one words of X_6 are the nonempty sixth-layer cylinder gates, while the forty-three words of $C_6 \setminus X_6$ have no inverse-limit extension.

Proof. Every $x \in X_\infty^Z$ has a unique sixth prefix $Q_6(x) \in X_6$, so it belongs to exactly one displayed cylinder. The converse inclusion is immediate from the definition of $\mathrm{Cyl}_6(u)$. The counts are $|X_6| = 21$ by Definition 9347.3 and $|C_6 \setminus X_6| = 64 - 21 = 43$. □

Principle 9347.8 (Finite window is not a unique address stream)**.** *A Window-six state determines a cylinder in X_∞^Z, not a unique inverse-limit address. A unique stream read requires tail data such as a stream name, a projection-compatibility ledger, or a normalization route. Without such a row, X_6 is only a finite observation surface.*

Principle 9347.9 (Finite obstruction as inverse-limit refusal)**.** *The Window-six split*

$$C_6 = X_6 \sqcup (C_6 \setminus X_6)$$

is not merely a finite count. It is an extension test against the inverse-limit carrier: admissible sixth windows have nonempty cylinders, and forbidden sixth windows have empty cylinders. Thus a local forbidden pattern cannot be hidden by an infinite tail.

The RH-facing analogue is the carrier-level obligation that a finite prime-window radial defect cannot extend to a completed zeta zero ledger. In the notation of Definition 9246.13, this is the role of

$$\mathsf{DefectZeroIncompatibility}.$$

Window six supplies the finite inverse-limit prototype, not the zeta incompatibility theorem itself.

9347.2 Finite support and tower continuation

Definition 9347.10 (Finite-support Zeckendorf layer)**.** *The finite-support Zeckendorf layer is*

$$X^Z_{\mathrm{fin}} := \{c \in X^Z_\infty : \ c_i = 0 \text{ for all sufficiently large } i\}.$$

It carries the usual natural-number Zeckendorf read

$$n = \sum_i c_i F_i.$$

Proposition 9347.11 (Address inverse limit is larger than number notation)**.** *The finite-support layer X^Z_{fin} is a subcarrier of X^Z_∞, but it does not exhaust X^Z_∞.*

Proof. Every finite-support no-adjacent stream is an infinite no-adjacent stream, so $X^Z_{\mathrm{fin}} \subseteq X^Z_\infty$. The periodic stream $101010\cdots$ is no-adjacent but not eventually zero, hence it lies in X^Z_∞ outside X^Z_{fin}. □

Definition 9347.12 (Projection-tower continuation)**.** *A projection-tower continuation from Window six is a compatible family*

$$(x_m)_{m\geq 6}, \qquad x_m \in X_m,$$

such that

$$\pi_{m+1,m}(x_{m+1}) = x_m \qquad \text{for every } m \geq 6.$$

Equivalently, it is an inverse-limit lift $x_\infty \in X^Z_\infty$ together with the displayed row $P_6(x_\infty) = x_6$.

Principle 9347.13 (Continuation is not analytic continuation)**.** *Projection-tower continuation is not analytic continuation in the complex function-theoretic sense. It is inverse-limit lifting of compatible finite address windows:*

$$X_6 \leftarrow X_7 \leftarrow X_8 \leftarrow \cdots \leftarrow X^Z_\infty.$$

Thus Window six is not the Zeckendorf address object itself; it is the sixth projection surface of that object.

9347.3 Fixed projection shadow

Definition 9347.14 (Golden-mean self-similar object)**.** *The Zeckendorf address inverse limit carries the self-similar decomposition*

$$X_\infty^Z \cong 0X_\infty^Z \sqcup 10X_\infty^Z.$$

*Every infinite no-adjacent-*11 *stream either begins with* 0 *followed by an arbitrary no-adjacent stream, or begins with* 10 *followed by an arbitrary no-adjacent stream. The corresponding growth scale* λ *satisfies*

$$\lambda^2 = \lambda + 1,$$

whose positive solution is the golden scale φ*.*

Definition 9347.15 (Golden-mean shift kernel)**.** *The finite-type transition kernel of* X_∞^Z *is the two-state matrix*

$$K_Z := \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix},$$

where the entry $K_Z(a, b)$ *is admissible exactly when the adjacent pair* ab *is not* 11*. The left shift*

$$\sigma : X_\infty^Z \to X_\infty^Z, \qquad \sigma(c_1, c_2, c_3, \ldots) = (c_2, c_3, \ldots)$$

therefore makes X_∞^Z *the one-sided golden-mean subshift.*

Proposition 9347.16 (Golden growth of finite windows)**.** *The finite windows satisfy*

$$|X_m| = F_{m+2},$$

and the transition kernel of Definition 9347.15 has characteristic equation

$$\lambda^2 = \lambda + 1.$$

Thus the growth scale of the inverse-limit carrier is the golden scale φ*.*

Proof. The no-adjacent grammar splits each nonempty word by its first symbols: words beginning with 0 contribute X_{m-1}, while words beginning with 1 must begin with 10 and contribute X_{m-2}. Hence

$$|X_m| = |X_{m-1}| + |X_{m-2}|.$$

With the initial values $|X_0| = 1$ and $|X_1| = 2$, this gives $|X_m| = F_{m+2}$. The displayed matrix has characteristic polynomial $\lambda^2 - \lambda - 1$, whose positive root is φ. □

Concretized in §8802: The window-six golden-mean shift is realized as finite no-adjacent-one BHist window, transition, shift, growth, and NameCert rows.

Principle 9347.17 (Window six is not the fixed object)**.** *The fixed object is* X_∞^Z *with the self-similar decomposition of Definition 9347.14. Window six is not that inverse-limit fixed object. It is the finite projection*

$$X_6 = P_6(X_\infty^Z)$$

and therefore records only the six visible address coordinates.

Definition 9347.18 (Round-trip fixed projection)**.** *A choice of lift on X_6 is a map*

$$L_6 : X_6 \to X_\infty^Z$$

such that

$$P_6(L_6(w)) = w \qquad \text{for every } w \in X_6.$$

Equivalently,

$$P_6 \circ L_6 = \mathrm{id}_{X_6}.$$

Proposition 9347.19 (Window six fixes visible information under lift-return)**.** *For any displayed lift L_6, Window six is a fixed information surface for the lift-then-project composite:*

$$P_6(L_6(w)) = w.$$

This fixedness is a statement about visible information, not uniqueness of the hidden inverse-limit tail.

Proof. The equality is exactly the defining row of Definition 9347.18. The hidden tail is not unique because Definition 9347.4 gives the whole cylinder $P_6^{-1}(w)$ above a visible word w. □

Definition 9347.20 (Window-six fixed-shadow defect)**.** *The Window-six fixed-shadow defect is the finite boundary response exposed when the self-similar inverse-limit object is read only through the sixth projection. In the notation of Definition 9346.10, its displayed response part is*

$$\mathsf{Defect}_6 := \varphi^{-7}\left(1 - \frac{1}{2}\varphi^{-10} + \frac{8}{9}\varphi^{-20}\right).$$

Thus

$$D_6^\star = 47 + \mathsf{Defect}_6.$$

Principle 9347.21 (Finite shadow, not complete closure)**.** *The terms in Defect_6 are read as boundary-seam, return-echo, and flux-escape response rows of the finite projection. They measure the failure of the sixth projection to be the complete inverse-limit object; they do not turn X_6 into the self-similar fixed object itself.*

9347.4 Projection-shadow comparison with recovered zeta

Definition 9347.22 (Projection-shadow carrier pattern)**.** *A projection-shadow carrier pattern consists of a recovered or inverse-limit carrier C, a visible projection $P : C \to S$, and a displayed lift row $L : S \to C$ satisfying*

$$P \circ L = \mathrm{id}_S.$$

This row says that the visible information is fixed by lift-then-project. It does not say that the visible carrier S is the whole carrier C.

Proposition 9347.23 (Window six and the right-half-plane zeta projection)**.** *Window six and the right-half-plane zeta projection share the projection-shadow carrier pattern:*

$$X_6 = P_6(X_\infty^Z),$$
$$\zeta_{>1} = P_{>1}(\mathsf{ZETA}).$$

Here $P_{>1}$ denotes the projection of the recovered zeta carrier to the Dirichlet-series and Euler-product rows on $\Re(s) > 1$, as displayed in Definition 9243.2 and Definition 9243.1. The analogy is a carrier syntax analogy, not an identification of Window six with ζ.

Proof. The first equality is Definition 9347.3. The second equality is the projection reading of the zeta recovery packet: Definition 9243.2 reconstructs ZETA from its compatible local rows, and Definition 9243.1 displays the Dirichlet and Euler rows on $\Re(s) > 1$. In both cases a local slice is recovered from a richer carrier and remains stable under the displayed projection row. □

Principle 9347.24 (Carrier fixedness is not orbit collapse)**.** *The completed-zeta row of Definition 9243.17 gives a mirror-fixed carrier:*

$$\xi(s) = \xi(1-s).$$

That carrier fixedness supports zero-set mirror transport in the sense of Definition 9241.13, but it is weaker than the pointwise fixedness of zero events:

$$\mathsf{ZeroEventFlow}_{\mathsf{RH}}(s) \to s = J(s).$$

By Definition 9241.12, the latter row is equivalent to $\Re(s) = 1/2$, and by Definition 9241.14 it is not supplied by mirror closure alone. Thus the zeta side mirrors the Window-six warning: a fixed carrier or a fixed projection shadow is not yet a proof that every residual event has collapsed to the fixed surface.

9347.5 Operator compatibility

Definition 9347.25 (Compatible operator tower)**.** *Let $\mathcal{R}_m$ be a residual module whose coordinate rows are indexed by X_m. A compatible operator tower over the Zeckendorf address tower is a family of operators*

$$A_m : \mathcal{R}_m \to \mathcal{R}_m \qquad (m \geq 6)$$

together with residual projections

$$\rho_{m+1,m} : \mathcal{R}_{m+1} \to \mathcal{R}_m$$

such that

$$\rho_{m+1,m} \circ A_{m+1} = A_m \circ \rho_{m+1,m} \qquad \text{for every } m \geq 6.$$

Principle 9347.26 (Address lifting does not lift flux dynamics)**.** *The identity*

$$\mathsf{Window6}_{\mathrm{addr}} = P_6(X_\infty^Z)$$

lifts the address carrier only. It does not lift the Window-six flux-operator geometry of Definition 9346.48. A flux, edge-operator, phase-gate, or Jordan-return reading reaches the inverse limit only through a compatible operator tower in the sense of Definition 9347.25.

Definition 9347.27 (Window-six separating certificate)**.** *A Window-six separating certificate for a class of residual towers is a row stating that for every admitted residual tower $\widetilde{r}$ in the class,*

$$P_6^{\mathcal{R}}(\widetilde{r}) = 0 \Longrightarrow \widetilde{r} = 0.$$

The stronger all-level separation row is

$$\forall m \geq 6,\ P_m^{\mathcal{R}}(\widetilde{r}) = 0 \Longrightarrow \widetilde{r} = 0.$$

9347.6 RH residual bridge target

Definition 9347.28 (Counter residual bridge target)**.** *An RH counter residual bridge target is a displayed map*

$$\mathcal{B}_{\zeta\to Z} : \mathsf{CounterRH}(n,q) \to (\widetilde{r},\eta),$$

where $\widetilde{r}$ is a residual tower over X_∞^Z and η is a nonzero residual row such as

$$P_6^{\mathcal{R}}(\widetilde{r}) \neq 0.$$

This is a bridge target, not a closed bridge supplied by the Window-six address carrier.

Proposition 9347.29 (Window-six local residual contradiction)**.** *Let $r_6 \in \mathcal{R}_6$ be a residual packet. If*

$$r_6 \neq 0,$$

$$R_6(r_6) = -\frac{1}{2}r_6,$$

and

$$R_6(r_6) = r_6,$$

then contradiction follows.

Proof. The two return equations give

$$r_6 = -\frac{1}{2}r_6.$$

Thus

$$\frac{3}{2}r_6 = 0.$$

Over the rational residual module, $\frac{3}{2}$ is cancellable, so $r_6 = 0$. This contradicts the displayed row $r_6 \neq 0$. □

Theorem 9347.30 (Global residual contradiction criterion)**.** *Assume a residual tower $\widetilde{r}$ has projections $r_m = P_m^{\mathcal{R}}(\widetilde{r})$ for all $m \geq 6$. Suppose that for each $m \geq 6$ there is a scalar λ_m with $\lambda_m \neq 1$ and*

$$R_m(r_m) = \lambda_m r_m,$$

while the zero-event return-invariance row gives

$$R_m(r_m) = r_m.$$

If the all-level separation row of Definition 9347.27 is available, then no nonzero admitted residual tower satisfies these rows.

Proof. For each $m \geq 6$, the two return equations give

$$r_m = \lambda_m r_m.$$

Since $\lambda_m \neq 1$, scalar cancellation gives $r_m = 0$. Hence every projection of $\widetilde{r}$ is zero. The all-level separation row then gives $\widetilde{r} = 0$, contradicting nonzero admission of the residual tower. □

Remark 9347.31 (Missing certificates)**.** *The Window-six route becomes an RH refutation route only after three rows are supplied: a bridge from* $\mathsf{CounterRH}(n, q)$ *to a Zeckendorf skew-residual tower, a zero-event return-invariance row, and a separating certificate strong enough to turn vanishing projections into vanishing of the residual tower. Without those rows, Window six supplies a local residual geometry and a bridge target, not a proof of* RH.

Concretized in §278: Zeckendorf normal packets supply finite no-adjacent-word evidence for the address windows consumed by the projection tower.

Concretized in §544: Local carry packets supply the finite carry-facing rows that separate normal address readout from host equality.

Concretized in §554: The Axis-Zeckendorf cannot-claim packet supplies the refusal boundary preventing address lifting from being read as a complete operator or physical bridge.

Concretized in §1018: Boundary-token limit refusal packets supply the finite refusal row separating Window-six boundary data from unlicensed inverse-limit or RealUp closure claims.

Chapter 9348

Layer-Kernel Residual Induction

chapter 9347 separates the Window-six address carrier from the flux-operator tower. The present chapter records the induction form needed after that separation. A global RH counter residual is not attacked first at the completed inverse-limit object. It is inspected through the finite projection tower, where the first nonzero residual must appear in a newly added kernel layer.

9348.1 Linearized residual tower

Definition 9348.1 (Linearized address residual space)**.** *For each $m \geq 6$, let*

$$V_m := \mathbb{Q}[X_m]$$

be the rational vector space freely generated by the no-adjacent address window X_m of Definition 9347.1. The prefix map $\pi_{m+1,m} : X_{m+1} \to X_m$ induces the linear projection

$$\Pi_{m+1,m} : V_{m+1} \to V_m.$$

Definition 9348.2 (Layer kernel)**.** *The layer kernel added between levels m and $m+1$ is*

$$K_{m+1} := \ker(\Pi_{m+1,m}).$$

It records residual information visible at level $m+1$ but invisible after projection to level m.

Proposition 9348.3 (Layer-kernel dimension)**.** *Assume the prefix projection is surjective on the no-adjacent address windows. Then*

$$\dim K_{m+1} = |X_{m+1}| - |X_m| = F_{m+1}.$$

In particular,

$$\dim K_7 = F_7 = 13.$$

Proof. The dimension of V_m is $|X_m|$. Since every word in X_m extends by a zero digit to a word in X_{m+1}, the prefix projection is surjective. Therefore

$$\dim K_{m+1} = \dim V_{m+1} - \dim V_m.$$

Using $|X_m| = F_{m+2}$ gives

$$\dim K_{m+1} = F_{m+3} - F_{m+2} = F_{m+1}.$$

For $m = 6$, this yields $\dim K_7 = F_7 = 13$. □

Definition 9348.4 (Residual tower)**.** *A residual tower is a compatible family*

$$r_\infty = (r_m)_{m\geq 6}, \qquad r_m \in V_m,$$

such that

$$\Pi_{m+1,m}(r_{m+1}) = r_m \qquad \text{for every } m \geq 6.$$

The tower is zero when every projection r_m is zero.

Principle 9348.5 (Projection separation)**.** *Residual towers are separated by their finite projections:*

$$(\forall m \geq 6,\ r_m = 0) \Longrightarrow r_\infty = 0.$$

Equivalently, a nonzero residual tower has a nonzero finite projection at some level.

9348.2 First nonzero layer

Proposition 9348.6 (First nonzero residual lies in a layer kernel)**.** *Let $r_\infty = (r_m)_{m\geq 6}$ be a residual tower. If $r_\infty \neq 0$ and m_0 is the least level with $r_{m_0} \neq 0$, then either $m_0 = 6$ or*

$$r_{m_0} \in K_{m_0}.$$

Proof. If $m_0 = 6$, there is nothing to prove. If $m_0 > 6$, minimality gives $r_{m_0-1} = 0$. Compatibility of the residual tower gives

$$\Pi_{m_0,m_0-1}(r_{m_0}) = r_{m_0-1} = 0,$$

so $r_{m_0} \in \ker(\Pi_{m_0,m_0-1}) = K_{m_0}$. □

Principle 9348.7 (Induction target)**.** *The projection-tower problem is therefore reduced to the following finite layer question: can a newly added kernel K_m contain a nonzero residual that is simultaneously in the skew sector and fixed by the return operator? If every such kernel rejects fixed skew residuals, no nonzero admitted counter residual tower survives.*

9348.3 Return operators and spectral exclusion

Definition 9348.8 (Compatible return operators)**.** *A return-operator tower is a family of linear maps*

$$R_m : V_m \to V_m \qquad (m \geq 6)$$

such that

$$\Pi_{m+1,m} R_{m+1} = R_m \Pi_{m+1,m} \qquad \text{for every } m \geq 6.$$

Definition 9348.9 (Skew kernel sector)**.** *For each $m \geq 6$, a skew kernel sector is a displayed subspace*

$$K_m^{\text{skew}} \subseteq K_m$$

containing the kernel residuals admitted by the RH counter-residual bridge. The sector is part of the bridge data; it is not determined by the address carrier alone.

Definition 9348.10 (Layer spectral exclusion)**.** *Layer spectral exclusion at level m is the row*

$$1 \notin \operatorname{spec}(R_m|_{K_m^{\mathrm{skew}}}).$$

Equivalently, the linear map

$$I - R_m : K_m^{\mathrm{skew}} \to K_m^{\mathrm{skew}}$$

is invertible.

Proposition 9348.11 (No fixed skew residual in an excluded layer)**.** *If $r \in K_m^{\mathrm{skew}}$, $R_m r = r$, and layer spectral exclusion holds at m, then $r = 0$.*

Proof. The equation $R_m r = r$ is equivalent to $(I - R_m)r = 0$. Since $I - R_m$ is invertible on K_m^{skew}, its kernel is zero. Hence $r = 0$. □

Remark 9348.12 (Window-six anchor)**.** *Window six supplies the anchor pattern for this exclusion: on the intended skew sector, the return has the form*

$$R_6 \simeq -\frac{1}{2}I + N_6$$

with nilpotent tail N_6. Then

$$I - R_6 \simeq \frac{3}{2}I - N_6,$$

which is invertible over the rational residual module. The induction problem is to show that the same no-neutral-leak condition persists through the added kernels.

9348.4 Layer-kernel refutation

Theorem 9348.13 (Layer-kernel residual refutation)**.** *Assume the following rows for an admitted RH counter residual tower $r_\infty = (r_m)_{m \geq 6}$:*

$$r_\infty \neq 0,$$

zero-event return invariance

$$R_m r_m = r_m \qquad \text{for every } m \geq 6,$$

compatibility of the return operators, and, for every layer in which a first nonzero residual can appear, skew-sector admission

$$r_m \in K_m^{\mathrm{skew}}$$

together with layer spectral exclusion

$$1 \notin \operatorname{spec}(R_m|_{K_m^{\mathrm{skew}}}).$$

Then no such nonzero admitted RH counter residual tower exists.

Proof. By projection separation, choose the least $m_0 \geq 6$ with $r_{m_0} \neq 0$. If $m_0 = 6$, the Window-six anchor places the residual in the admitted skew sector, and spectral exclusion at level 6 contradicts $R_6 r_6 = r_6$ by Definition 9348.11.

If $m_0 > 6$, then Definition 9348.6 gives $r_{m_0} \in K_{m_0}$. The bridge-admission row places this residual in $K_{m_0}^{\mathrm{skew}}$. Zero-event return invariance gives $R_{m_0} r_{m_0} = r_{m_0}$, while layer spectral exclusion at m_0 forces $r_{m_0} = 0$ by Definition 9348.11. This contradicts the choice of m_0. □

Corollary 9348.14 (Projection induction form)**.** *Equivalently, define*

$$P(m): \quad r_m = 0.$$

If the Window-six anchor proves $P(6)$ and every induction step proves that $r_m = 0$ forces $r_{m+1} \in K_{m+1}^{\mathrm{skew}}$ and hence $r_{m+1} = 0$ by spectral exclusion, then

$$\forall m \geq 6,\ r_m = 0.$$

Projection separation then gives $r_\infty = 0$.

Proof. The induction step uses compatibility:

$$\Pi_{m+1,m}(r_{m+1}) = r_m = 0,$$

so $r_{m+1} \in K_{m+1}$. The bridge-admission row places it in the skew kernel sector, and spectral exclusion removes every fixed residual there. Ordinary induction gives all finite projections zero, and projection separation gives the zero tower. □

9348.5 Proof obligations

Definition 9348.15 (Projection-tower proof obligations)**.** *The layer-kernel induction route has four proof obligations:*

$$\mathcal{B}_{\zeta \to Z} : \mathsf{CounterRH}(n,q) \to r_\infty \neq 0,$$

$$\mathsf{ZeroEventReturnInvariant}_m(r_m) : R_m r_m = r_m,$$

$$\mathsf{NoNeutralLeak}_m : r_m \in K_m^{\mathrm{skew}},$$

and

$$\mathsf{LayerSpectralExclusion}_m : 1 \notin \mathrm{spec}(R_m|_{K_m^{\mathrm{skew}}}).$$

Remark 9348.16 (Independent work before RH bridge)**.** *The address windows, kernel dimensions, compatible return operators, and spectral exclusions can be studied before any RH bridge is supplied. The largest bridge is the first obligation, which must route a* $\mathsf{CounterRH}(n,q)$ *event to a nonzero Zeckendorf residual tower. Until that bridge is certified, the layer-kernel induction is a structured target for residual elimination, not a proof of* RH*.*

Concretized in §278: Zeckendorf normal packets supply the finite no-adjacent-word evidence used by the layer residual spaces V_m.

Concretized in §554: The Axis-Zeckendorf cannot-claim packet supplies the refusal boundary that keeps the induction route from being read as a closed RH proof without the bridge rows.

Concretized in §1049: Axis carry route separation packets supply finite route-separation data for carry-facing residual sectors.

Chapter 9349

Zeta-to-Zeckendorf Bridge Obligations

chapter 9248 supplies the zeta-side separation row: an off-critical mirror pair is visible to the prime channels. chapter 9347 and chapter 9348 supply the Window-six and projection-kernel elimination form. The present chapter records the bridge still absent between these two surfaces. It does not claim a proof of RH; it isolates the exact rows that would be needed to route a zeta zero-skew packet into the Zeckendorf residual tower.

9349.1 Bridge interface

Definition 9349.1 (Prime tilt packet)**.** *For a complex history*

$$s = \frac{1}{2} + \delta + i\tau,$$

the prime tilt packet is the centered-amplitude family

$$\mathsf{Tilt}_\zeta(s) := \left(p^{-\delta}\right)_{p \in \mathsf{Prime}^\uparrow}.$$

It is nontrivial when $\delta \neq 0$. By Definition 9248.8, this is exactly the amplitude-bias row by which prime-local channels distinguish s from $J(s)$.

Definition 9349.2 (Zeta-to-Zeckendorf residual bridge)**.** *A zeta-to-Zeckendorf residual bridge is a displayed transformer*

$$\mathcal{B}_{\zeta \to Z} : \mathsf{OffMirrorZero}_\zeta(s) \to r_\infty(s),$$

where $r_\infty(s)$ is a residual tower in the sense of Definition 9348.4. Its finite projections are written

$$r_m(s) := P_m^{\mathcal{R}}(r_\infty(s)) \qquad (m \geq 6).$$

The bridge is certified only if it also exports the rows listed in Definition 9349.3.

Definition 9349.3 (Bridge certificate rows)**.** *The zeta-to-Zeckendorf bridge certificate has four required rows:*

$$\mathsf{NonzeroDetect}_{\zeta \to Z} : \delta(s) \neq 0 \Longrightarrow r_\infty(s) \neq 0,$$

$$\mathsf{ProjectionCompat}_{\zeta \to Z} : \Pi_{m+1,m}(r_{m+1}(s)) = r_m(s),$$

$$\mathsf{ZeroEventReturnInvariant}_m : R_m r_m(s) = r_m(s),$$

and

$$\mathsf{NoNeutralLeak}_m : r_m(s) \in K_m^{\mathrm{skew}}.$$

The nonzero-detection row transfers prime-visible off-critical bias to a nonzero Zeckendorf residual tower. The projection row makes the tower a compatible projection object. The return-invariance row says that the zero event is the same information packet after Zeckendorf return. The no-neutral-leak row excludes leakage into the neutral 1*-mode sector.*

Principle 9349.4 (Address carrier is not residual dynamics)**.** *The address identity*

$$X_6 = P_6(X_\infty^Z)$$

does not by itself construct the bridge of Definition 9349.2. The RH residual is not a no-adjacent address word. It is a weighted, linearized, or operator-facing packet in spaces of the form

$$V_m = \mathbb{Q}[X_m],$$

with compatible return operators R_m and layer kernels K_m. Therefore the bridge must supply residual-space data, not only address-space data.

9349.2 Neutral-mode obstruction

Definition 9349.5 (Neutral leak)**.** *For a return operator $R_m : V_m \to V_m$, a neutral leak of a residual $r_m(s)$ is a nonzero component in the* 1*-eigenspace of R_m. The bridge has no neutral leak at level m when the admitted residual lies in the skew sector:*

$$r_m(s) \in K_m^{\mathrm{skew}},$$

and the layer exclusion row

$$1 \notin \mathrm{spec}(R_m|_{K_m^{\mathrm{skew}}})$$

is available.

Proposition 9349.6 (Why the return eigenvalue alone is insufficient)**.** *The Window-six skew return law*

$$R_6 r = -\frac{1}{2} r$$

does not refute a residual tower unless the bridge also supplies zero-event return invariance and no-neutral-leak rows.

Proof. The eigenvalue row says how an admitted skew component transforms. A contradiction requires the return-invariance row

$$R_6 r = r,$$

so that $r = -\frac{1}{2} r$ forces $r = 0$. If a residual also contains a neutral component with $R_6 r = r$, that component is compatible with return invariance and is not eliminated by the $-\frac{1}{2}$ calculation. Hence the bridge must identify the residual as a skew-sector object and exclude neutral leakage before the Window-six return law can be used as a refutation step. □

Definition 9349.7 (All-layer bridge target)**.** *The all-layer bridge target is the conjunction*

$$\forall m \geq 6, \quad \mathsf{ZeroEventReturnInvariant}_m \wedge \mathsf{NoNeutralLeak}_m \wedge \mathsf{LayerSpectralExclusion}_m.$$

It is the projection-tower strengthening of the Window-six local residual calculation.

9349.3 Bridge-to-refutation criterion

Theorem 9349.8 (Bridge rows close the residual refutation)**.** *Assume an off-mirror zeta zero packet for s supplies*

$$\delta(s) \neq 0.$$

If a zeta-to-Zeckendorf residual bridge supplies all rows of Definition 9349.3 and the all-layer spectral exclusions of Definition 9349.7, then the corresponding nonzero residual tower is impossible.

Proof. The nonzero-detection row gives $r_\infty(s) \neq 0$. Projection compatibility makes $r_\infty(s)$ a residual tower. By Definition 9348.13, a nonzero admitted tower cannot satisfy zero-event return invariance, skew-sector admission, and layer spectral exclusion at each least nonzero layer. The bridge supplies precisely those rows. This contradicts $r_\infty(s) \neq 0$. □

Corollary 9349.9 (Bridge obstruction to a Window-six RH proof)**.** *Window six can serve as the initial finite fixed-shadow test for an RH residual only after the bridge rows are certified. Without Definition 9349.3, the route remains the implication target*

$$\mathsf{OffMirrorZero}_\zeta(s) \to \mathsf{NonzeroZeckendorfSkewResidual}(s),$$

not a proof that the target exists.

Proof. The Window-six calculation eliminates a residual already known to be a nonzero skew residual with return invariance. It does not construct that residual from a zeta zero packet. The construction and admissibility rows are exactly the bridge certificate rows. □

9349.4 Finite laboratory status

Definition 9349.10 (Window-six finite audit laboratory)**.** *The Window-six finite audit laboratory is the BEDC packet*

$$\mathsf{Lab}_6 := (C_6, X_6, D_6, \mathsf{Cert}_6, \mathsf{Audit}_6),$$

where

$$C_6 := \{0,1\}^6,$$

X_6 is the no-adjacent address window of Definition 9347.1, and

$$D_6 := C_6 \setminus X_6.$$

Thus

$$C_6 = X_6 \sqcup D_6,$$

with

$$|C_6| = 64, \qquad |X_6| = 21, \qquad |D_6| = 43.$$

Its records-side reading is the finite BEDC pipeline

$$\mathsf{carrier} \to \mathsf{constraint} \to \mathsf{partition} \to \mathsf{fiber} \to \mathsf{normal\ form} \to \mathsf{certificate} \to \mathsf{audit}.$$

Proposition 9349.11 (Finite defect prototype)**.** *For $w \in C_6$, the following are equivalent:*

$$w \in D_6,$$

and

$$w \text{ contains an adjacent pair } 11.$$

Consequently Window six supplies a finite prototype of the defect-exclusion shape

$$\mathsf{DetectedDefect}_6(w) \Longrightarrow w \notin X_6.$$

Proof. By definition, X_6 consists exactly of the six-bit words with no adjacent pair 11. Its complement inside the finite carrier C_6 is therefore exactly the set of six-bit words for which some adjacent pair is 11. Since C_6 is finite, the witnessing coordinate can be found by checking the five adjacent positions. □

Principle 9349.12 (Finite prototype is not carrier-level incompatibility)**.** *The finite implication of Definition 9349.11 has the same formal shape as the RH-facing bridge target*

$$\mathsf{ApartNonFix}_J(c) \Longrightarrow \mathsf{Apart}_0(\zeta(c)),$$

but it lives only in the finite address laboratory Lab_6*. It supplies a fully enumerable model of detected defect versus admissible geometry. It does not supply the completed zeta carrier, source compatibility, archimedean recovery rows, zero-ledger semantics, or the carrier-level incompatibility row*

$$\mathsf{DefectZeroIncompatibility}_\zeta.$$

9349.5 Work order

Principle 9349.13 (Local work before RH closure)**.** *The bridge route separates into local tasks on three surfaces: the pure Zeckendorf surface constructs compatible return operators and proves layer spectral exclusion on the skew sectors; the zeta surface encodes the prime tilt packet of Definition 9349.1 as a residual tower and proves nonzero detection; the zero-event semantic surface proves return invariance for that encoded residual. Only the conjunction of these tasks turns the Window-six fixed-shadow geometry into an RH-facing residual refutation route.*

Remark 9349.14 (Bridge status)**.** *The present chapter is a bridge-obligation ledger. It makes the unclosed rows explicit: prime tilt must become a nonzero Zeckendorf residual, the residual must remain compatible through all projections, zero events must be return invariant, and neutral mode leakage must be excluded. None of these rows follows from the existence of the golden-mean address tower or from the functional-equation mirror carrier alone.*

Concretized in §64: Prime packets supply the probe family whose amplitude tilt is the zeta-side input to the bridge.

Concretized in §278: Zeckendorf normal packets supply the no-adjacent address windows used to build the residual tower.

Concretized in §554: Axis-Zeckendorf refusal packets mark the boundary between bridge targets and closed RH proof rows.

Chapter 9350

Cannot-Claim Registry: AxisZeckendorf Cluster

This chapter aggregates the deliberate non-claims of the AxisZeckendorf cluster (Chapters 276–279). Each entry is paired either with a checked negative theorem in `BEDC.Derived.AxisZeckendorf` or with an explicit horizon obligation queued for the formalize pipeline. The non-claims protect the cluster's positioning: it is a conservative bridge layer above the finite kernel and below mature mathematical interfaces, not a numerological reinterpretation of binary words.

9350.1 Negative theorems backing the registry

Theorem 9350.1 (Display words `word_011` and `word_100` are not hsame)**.** $\mathsf{hsame}(\texttt{word_011}, \texttt{word_100})$ *does not hold.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.CannotClaim.cannot claim 011 is infinity`

Proof. Theorem 9345.3. □

Theorem 9350.2 (Carry is not history-sameness, registry form)**.** *For every* h, k*,* $\mathsf{ZCarry}(h, k)$ *implies* $\neg\mathsf{hsame}(h, k)$*.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.CannotClaim.cannot claim carry is hsame`

Proof. Theorem 9345.4. □

Theorem 9350.3 (`word_011` is not normal, registry form)**.** $\mathsf{ZNormal}(\texttt{word_011})$ *does not hold.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.CannotClaim.cannot claim 011 is normal`

Proof. Theorem 278.4. □

Theorem 9350.4 (Boundary marker is not in the zero-spine carrier)**.** $\mathsf{ZeroSpine}(\texttt{boundary_01})$ *does not hold.*

Lean4 (definition) `BEDC.Derived.AxisZeckendorf.CannotClaim.cannot claim boundary 01 in zerospine`

Proof. Theorem 279.5. □

9350.2 Registry of non-claims

The following six entries are not assertions of the cluster. They are explicit refusals; each carries either a paper-level checked theorem above, or an upgrade path that names the missing certificate.

Cannot claim 1: `word_011` denotes infinity. Backed by Theorem 9350.1. `word_011` is a finite three-step history; no infinity object is ever attached to it inside the cluster.

Cannot claim 2: ZCarry is history-sameness. Backed by Theorem 9350.2. The classifier relates non-hsame histories; promoting it to a kernel equality is rejected.

Cannot claim 3: `boundary_01` is a limit / supremum. Backed by Theorem 9350.4, together with the chapter remarks of Chapter 279. The boundary token is a length-two finite history, not a limit object.

Cannot claim 4: $\mathsf{FullAxis}^{\uparrow}$ is $\mathsf{Real}^{\uparrow}$ (or $\mathsf{CompleteMetric}^{\uparrow}$). Horizon non-claim. Upgrade path: a separate bridge from $\mathsf{FullAxis}^{\uparrow}$ into the existing $\mathsf{CompleteMetric}^{\uparrow}$ chapter must be supplied; the cluster does not assert this bridge by itself.

Cannot claim 5: $\mathsf{AxisNat}^{\uparrow}$ replaces $\mathsf{Nat}^{\uparrow}$. Horizon non-claim. The two interfaces are kernel-distinct (Theorem 276.14); identification requires Chapter 9344, which is itself a non-kernel bridge.

Cannot claim 6: $\mathsf{DimLift}^{\uparrow}$ is a primitive geometric dimension. Horizon non-claim. $\mathsf{DimLift}^{\uparrow}$ is, in this cluster, a deferred lift seed: the cluster does not assert that the carry classifier produces a geometric dimension, a topological dimension, a vector-space dimension, a homological dimension, or a projective dimension. Promotion to any such reading requires a fresh certificate not part of the AxisZeckendorf cluster.

9350.3 Horizon obligations associated with the registry

Theorem 9350.5 ($\mathsf{DimLift}^{\uparrow}$ primitive non-claim, horizon)**.** *The cluster does not assert any kernel-level primitive geometric, topological, vector-space, homological, or projective dimension associated with the carry classifier.*

Theorem 9350.6 ($\mathsf{FullAxis}^{\uparrow} \neq \mathsf{Real}^{\uparrow}$ horizon)**.** *The cluster does not assert any of the field operations of* $\mathsf{Real}^{\uparrow}$ *on* $\mathsf{FullAxis}^{\uparrow}$*.*

Theorem 9350.7 ($\mathsf{AxisNat}^{\uparrow}$ does not replace $\mathsf{Nat}^{\uparrow}$ horizon)**.** *The cluster does not assert that* $\mathsf{AxisNat}^{\uparrow}$ *supersedes* $\mathsf{Nat}^{\uparrow}$*; both interfaces remain independent inside the finite kernel.*

Concretized in §554: The AxisZeckendorf cannot-claim registry is realized as a finite NameCert packet over checked negative rows, horizon refusal rows, hsame transport, Cont routes, Pkg provenance, and non-escape ledgers.

Concretized in §571: DimLift boundary packets realize the AxisZeckendorf dimension-lift refusal as finite BHist NameCert data over carry, normal-address, non-escape, and public boundary rows.

Concretized in §602: FullAxis-to-Real refusal packets realize the AxisZeckendorf boundary as finite FullAxisUp, RealUp, hsame, Cont, Pkg, and NameCert rows without exporting RealUp operations.

Concretized in §672: AxisNat replacement refusals are realized as finite NameCert packets separating AxisNatUp, NatUp, bridge rows, checked negative rows, and non-replacement ledgers.

Concretized in §1018: Boundary-token limit refusal is realized as a finite NameCert packet separating the AxisZeckendorf boundary row from limit, supremum, RealUp equality, and completeness readings.

Concretized in §1196: Axis carry-refusal ledgers realize the AxisZeckendorf cannot-claim registry as finite negative-row, horizon-refusal, hsame, Cont, Pkg, and NameCert packets.

Concretized in §567: The Zeckendorf carry classifier realizes the finite carry-normalization direction of the Axis-Zeckendorf route.

Chapter 9351

Mark–Hist–Ext–Cont Kernel Spine

The finite BEDC kernel begins below packages, names, signatures, and ordinary mathematical objects. Its first visible surface is the passage from raw marks to generated histories and then to one-step extension and continuation. This chapter records only that initial spine:

$$\mathsf{BMark} \longrightarrow \mathsf{BHist} \longrightarrow (\mathsf{Ext}, \mathsf{Cont}).$$

Later layers such as Ask, Sig, sameSig, Pkg, Gap, and NameCert depend on this spine but are not part of the present surface.

9351.1 Raw marks

Definition 9351.1 (Raw mark carrier)**.** *The raw mark carrier is the closed two-constructor carrier*

$$\mathsf{BMark} := \{\mathsf{b0}, \mathsf{b1}\}_{\mathrm{gen}}.$$

The two constructors are primitive visible emissions. They are not the numbers 0 *and* 1*, not truth values, and not elements drawn from an ambient set.*

Definition 9351.2 (Mark sameness)**.** *The mark-sameness judgment*

$$\mathsf{msame} : \mathsf{BMark} \to \mathsf{BMark} \to \mathsf{Prop}$$

is generated only by the two diagonal rules

$$\mathsf{msame}(\mathsf{b0}, \mathsf{b0}), \qquad \mathsf{msame}(\mathsf{b1}, \mathsf{b1}).$$

No rule generates cross-mark sameness.

Principle 9351.3 (Closed generation at the mark layer)**.** *At the mark layer, a judgment is internal only when it is generated by the displayed constructors and rules. There is no hidden conversion, hidden coercion, ambient extensionality rule, or external equality that identifies* b0 *with* b1*.*

Theorem 9351.4 (Mark sameness is diagonal)**.** *Mark sameness is reflexive, symmetric, and transitive on generated marks, and the cross judgments*

$$\mathsf{msame}(\mathsf{b0}, \mathsf{b1}), \qquad \mathsf{msame}(\mathsf{b1}, \mathsf{b0})$$

are not generated.

Proof. Closed generation gives only two mark cases. The diagonal judgments supply reflexivity. Symmetry and transitivity never leave the diagonal cases, because any premise of mark sameness is already one of those cases. The cross judgments are not conclusions of either displayed rule, hence are not generated. □

9351.2 Histories

Definition 9351.5 (History carrier)**.** *The history carrier is the closed generated carrier*

$$\mathsf{BHist}$$

with constructors

$$\mathsf{Empty} : \mathsf{BHist}, \qquad \mathsf{e0} : \mathsf{BHist} \to \mathsf{BHist}, \qquad \mathsf{e1} : \mathsf{BHist} \to \mathsf{BHist}.$$

The empty constructor is the empty history. The constructors e0 *and* e1 *append one visible* b0 *or* b1 *emission to an existing generated history.*

Definition 9351.6 (History sameness)**.** *The history-sameness judgment*

$$\mathsf{hsame} : \mathsf{BHist} \to \mathsf{BHist} \to \mathsf{Prop}$$

is generated by the empty rule

$$\mathsf{hsame}(\mathsf{Empty}, \mathsf{Empty})$$

and the two constructor-congruence rules

$$\mathsf{hsame}(h, k) \Longrightarrow \mathsf{hsame}(\mathsf{e0}(h), \mathsf{e0}(k)),$$

$$\mathsf{hsame}(h, k) \Longrightarrow \mathsf{hsame}(\mathsf{e1}(h), \mathsf{e1}(k)).$$

There is no rule identifying an empty history with an extended history, and no rule identifying an e0*-headed history with an* e1*-headed history.*

Theorem 9351.7 (History no-confusion)**.** *For generated histories h, k, the following judgments are not generated:*

$$\mathsf{hsame}(\mathsf{Empty}, \mathsf{e0}(h)), \qquad \mathsf{hsame}(\mathsf{Empty}, \mathsf{e1}(h)),$$

$$\mathsf{hsame}(\mathsf{e0}(h), \mathsf{e1}(k)), \qquad \mathsf{hsame}(\mathsf{e1}(h), \mathsf{e0}(k)).$$

Proof. Inspect the displayed generation rules for hsame. The empty rule has empty source and target. The e0 rule has e0 on both sides. The e1 rule has e1 on both sides. None of these rules has a cross-constructor conclusion. □

Corollary 9351.8 (Histories record finite distinction sequences)**.** *Every generated history records a finite sequence of raw mark emissions, and* hsame *preserves the generated constructor shape of that sequence.*

Proof. Define the sequence readout recursively by sending Empty to the empty word, $\mathsf{e0}(h)$ to the readout of h followed by a b0 emission, and $\mathsf{e1}(h)$ to the readout of h followed by a b1 emission. The no-confusion theorem shows that hsame cannot cross the empty, e0, and e1 constructors. □

9351.3 Extension and continuation

Definition 9351.9 (One-step extension)**.** *The one-step extension relation is*

$$\mathsf{Ext} : \mathsf{BHist} \to \mathsf{BMark} \to \mathsf{BHist} \to \mathsf{Prop}.$$

Its generation rules are

$$\mathsf{Ext}(h, \mathsf{b0}, \mathsf{e0}(h)), \qquad \mathsf{Ext}(h, \mathsf{b1}, \mathsf{e1}(h)).$$

Thus $\mathsf{Ext}(h, m, r)$ *records that the history* r *is obtained from* h *by one displayed mark emission.*

Theorem 9351.10 (Extension result characterization)**.** *For generated* m, h, t*, the extension judgment ending in an* $\mathsf{e0}$*-history has the form*

$$\mathsf{Ext}(h, m, \mathsf{e0}(t)) \iff \mathsf{msame}(m, \mathsf{b0}) \wedge \mathsf{hsame}(h, t),$$

and the extension judgment ending in an $\mathsf{e1}$*-history has the form*

$$\mathsf{Ext}(h, m, \mathsf{e1}(t)) \iff \mathsf{msame}(m, \mathsf{b1}) \wedge \mathsf{hsame}(h, t).$$

Proof. For the first equivalence, inspect the generation rules for Ext. A result with head $\mathsf{e0}$ can only come from the $\mathsf{b0}$ rule, and its tail is the source history up to hsame. Conversely, the $\mathsf{b0}$ rule gives $\mathsf{Ext}(h, \mathsf{b0}, \mathsf{e0}(h))$, and the displayed sameness rows transport the mark and source history. The $\mathsf{e1}$ case is the same argument with $\mathsf{b1}$ and $\mathsf{e1}$. □

Theorem 9351.11 (Same-source cross-mark extensions are separated)**.** *If*

$$\mathsf{Ext}(h, \mathsf{b0}, r_0), \qquad \mathsf{Ext}(h, \mathsf{b1}, r_1),$$

then $\mathsf{hsame}(r_0, r_1)$ *is not generated.*

Proof. The first extension has result hsame-classified with $\mathsf{e0}(h)$. The second has result hsame-classified with $\mathsf{e1}(h)$. If $\mathsf{hsame}(r_0, r_1)$ were generated, transitivity would generate $\mathsf{hsame}(\mathsf{e0}(h), \mathsf{e1}(h))$, contradicting Definition 9351.7. □

Definition 9351.12 (Continuation)**.** *The continuation relation is*

$$\mathsf{Cont} : \mathsf{BHist} \to \mathsf{BHist} \to \mathsf{BHist} \to \mathsf{Prop}.$$

It records the BEDC-internal form of history concatenation. Its basic interface includes empty-continuation rows, one-step compatibility with $\mathsf{e0}$ *and* $\mathsf{e1}$*, unit rows, and associativity up to* hsame*. These rows are L2 obligations over the same* BHist *carrier; they do not introduce another visible object layer.*

Theorem 9351.13 (Continuation unit and associativity obligations)**.** *Continuation has empty-history unit rows*

$$\mathsf{Cont}(\mathsf{Empty}, h, h), \qquad \mathsf{Cont}(h, \mathsf{Empty}, h),$$

and threefold continuation is associative up to hsame*: if*

$$\mathsf{Cont}(a, b, u), \qquad \mathsf{Cont}(u, c, v),$$

$$\mathsf{Cont}(b, c, w), \qquad \mathsf{Cont}(a, w, z),$$

then $\mathsf{hsame}(v, z)$ *is generated.*

Proof. The unit rows are the empty-history clauses of continuation. For associativity, both displayed composites represent the same generated history obtained by first reading a, then b, then c. The constructor recursion defining continuation therefore classifies the two results by the same BHist shape, so $\mathsf{hsame}(v, z)$ is generated. □

Definition 9351.14 (Initial kernel spine)**.** *The initial BEDC kernel spine is the tuple*

$$\mathcal{T}_{\leq 2} := (\mathsf{BMark}, \mathsf{msame}, \mathsf{BHist}, \mathsf{hsame}, \mathsf{Ext}, \mathsf{Cont}).$$

Theorem 9351.15 (Initial kernel spine separation)**.** *The initial kernel spine separates raw marks, separates history constructors, and separates same-source* $\mathsf{b0}$ *and* $\mathsf{b1}$ *extension results.*

Proof. Raw marks are separated by Definition 9351.4. History constructors are separated by Definition 9351.7. Same-source cross-mark extensions are separated by Definition 9351.11. □

Corollary 9351.16 (Minimal binary recursive readout)**.** *The initial kernel spine supports the recursive readout*

$$P_{\mathsf{B}} : \mathsf{BHist} \to \{\mathsf{b0}, \mathsf{b1}\}^{<\omega}$$

defined by

$$P_{\mathsf{B}}(\mathsf{Empty}) = \epsilon, \qquad P_{\mathsf{B}}(\mathsf{e0}(h)) = P_{\mathsf{B}}(h)\mathsf{b0}, \qquad P_{\mathsf{B}}(\mathsf{e1}(h)) = P_{\mathsf{B}}(h)\mathsf{b1}.$$

Proof. The recursion follows the three constructors of BHist. Definition 9351.7 supplies uniqueness of the visible last step, and Definition 9351.4 supplies the two separated terminal emissions. □

Principle 9351.17 (Kernel spine as the self-similar starting surface)**.** *The pair* $\mathsf{b0}, \mathsf{b1}$ *supplies the minimal visible distinction surface, and the constructors* $\mathsf{e0}, \mathsf{e1}$ *supply the recursive history surface. This is the bottom support for later window, Zeckendorf, prime-coordinate, zeta-carrier, and zero-ledger routes. Higher layers may compress, package, or project these histories only after they expose the source fiber and the ledger rows that license the compression.*

Concretized in §8779: The finite mark-history-continuation spine is realized as a concrete NameCert packet.

Principle 9351.18 (Next layer boundary)**.** *The next layer begins only after this spine, with*

$$\mathsf{Ask} \to \mathsf{Sig} \to \mathsf{sameSig} \to \mathsf{Pkg} \to \mathsf{Gap} \to \mathsf{NameCert}.$$

Its role is not to add primitive mathematical objects to the kernel, but to expose the source ledger for visible objects obtained by asking, signature formation, packaging, gap accounting, and certification.

Chapter 9352

Ask–Sig–Pkg–Gap–NameCert Kernel Spine

The lower spine of chapter 9351 supplies raw marks, generated histories, one-step extension, and continuation. The finite kernel then reaches its certificate-facing boundary by adding asking, signature formation, signature sameness, package tokens, gap ledgers, exact globalization, and naming certificates:

$$\mathsf{Mark} \to \mathsf{Hist} \to (\mathsf{Ext}, \mathsf{Cont}) \to (\mathsf{Ask}, \mathsf{Sig}) \to \mathsf{sameSig} \to (\mathsf{Pkg}, \mathsf{Gap}) \to \mathsf{NameCert}.$$

This chapter records the L3–L5 spine only. It does not introduce mature mathematical objects, completion objects, folds, phase spaces, zeta carriers, or zero ledgers. Those later interfaces may use this spine only through displayed certificate fields.

9352.1 Asking and signatures

Definition 9352.1 (Probe names and bundles)**.** *A probe name* $\pi : \mathsf{ProbeName}$ *is an internal name that may be asked against a generated history. It is not an external function. Probe bundles are the closed carrier generated by*

$$\mathsf{Bnil} : \mathsf{Bundle}, \qquad \mathsf{Bcons}(\pi, \Pi) : \mathsf{Bundle}$$

for $\pi : \mathsf{ProbeName}$ *and* $\Pi : \mathsf{Bundle}$*.*

Definition 9352.2 (Ask event)**.** *An ask event is a generated relation*

$$\mathsf{Ask}(\pi, h, m, \delta)$$

where $\pi : \mathsf{ProbeName}$*,* $h : \mathsf{Hist}$*,* $m : \mathsf{Mark}$*, and* δ *is the event evidence. It records that probe* π *asked against source history* h *emits mark* m *with evidence* δ*. The evidence is a ledger item for the event, not a numeric bias or an external truth value.*

Definition 9352.3 (Ask policy)**.** *For a bundle* Π *and source domain* $D : \mathsf{Hist} \to \mathsf{Prop}$*, an asking policy* $\mathsf{AskPolicy}(\Pi, D)$ *supplies the following internal obligations: totality of ask events for admitted histories and bundle members, determinacy of the emitted mark for the same probe and source history, and respect for* hsame *on admitted source histories.*

Definition 9352.4 (Signature event)**.** *The signature event*

$$\mathsf{Sig}(\Pi, h, s, \Delta)$$

means that bundle Π *applied to source history* h *generates answer history* s *with evidence ledger* Δ*. The empty bundle generates the empty answer history:*

$$\mathsf{Sig}(\mathsf{Bnil}, h, \mathsf{e}, \Delta_0).$$

The cons rule is generated from a head ask event, a tail signature, and one extension step:

$$\mathsf{Ask}(\pi, h, m, \delta), \qquad \mathsf{Sig}(\Pi, h, s, \Delta), \qquad \mathsf{Ext}(m, s, r)$$

imply

$$\mathsf{Sig}(\mathsf{Bcons}(\pi, \Pi), h, r, \delta \star \Delta).$$

Theorem 9352.5 (Signature inversion and determinacy)**.** *The L3 signature relation satisfies the following finite-kernel facts.*

1. *Empty-bundle signatures have answer history* hsame *to* e*.*
2. *Cons-bundle signatures have answer history not* hsame *to* e*.*
3. *If* $\mathsf{AskPolicy}(\Pi, D)$*,* $h \in D$*, and*

$$\mathsf{Sig}(\Pi, h, s, \Delta), \qquad \mathsf{Sig}(\Pi, h, t, \Theta),$$

then $\mathsf{hsame}(s, t)$*.*

Proof. The first clause is inversion of the empty-signature rule. The second clause inverts the cons-signature rule; its last step is an extension, whose result has E0 or E1 head and therefore cannot be hsame to e by history no-confusion. The determinacy clause is induction on Π. The empty case reduces to the first clause and hsame equivalence. In the cons case, invert both signatures. Ask-policy determinacy gives msame of the two head marks, the induction hypothesis gives hsame of the two tail answer histories, and extension respects internal sameness. □

Definition 9352.6 (Signature sameness)**.** *For a bundle* Π*, two histories are signature-same when their generated answer histories are* hsame*:*

$$\mathsf{sameSig}_\Pi(h, k) \quad :\Longleftrightarrow \quad \exists s, t, \Delta, \Theta.\ \mathsf{Sig}(\Pi, h, s, \Delta) \wedge \mathsf{Sig}(\Pi, k, t, \Theta) \wedge \mathsf{hsame}(s, t).$$

Theorem 9352.7 (Signature sameness is the L3 classifier)**.** *Assume* $\mathsf{AskPolicy}(\Pi, D)$*. On admitted histories,* $\mathsf{sameSig}_\Pi$ *is reflexive, symmetric, and transitive; the transitive step through a middle history* k *uses the hypothesis* $k \in D$*.*

Proof. Reflexivity uses ask-policy totality to generate one signature for the admitted history and then uses hsame reflexivity. Symmetry swaps the two signature witnesses and uses hsame symmetry. For transitivity, unpack the two signature-sameness witnesses. They contain two generated signatures from the admitted middle history. Signature determinacy identifies the two middle answer histories by hsame, and hsame transitivity connects the left answer history to the right answer history. □

9352.2 Packages, gaps, and exact globalization

Definition 9352.8 (Package token and package policy)**.** *The package relation*

$$\mathsf{Pkg}(\Pi, s, p)$$

records that answer history s under bundle Π is represented by visible package token p. A package policy $\mathsf{PackagePolicy}(\Pi)$ *supplies token existence, extensionality from* $\mathsf{hsame}(s,t)$ *to* $\mathsf{psame}(p,q)$ *for tokens introduced by s and t, source reflection of* $\mathsf{psame}(p,q)$ *back in generated answer histories, and visibility of the token interface without exposing the full source history as a public object.*

Theorem 9352.9 (Packages classify signatures)**.** *Assume* $\mathsf{PackagePolicy}(\Pi)$*. If*

$$\mathsf{Pkg}(\Pi, s, p), \qquad \mathsf{Pkg}(\Pi, t, q),$$

then $\mathsf{hsame}(s,t)$ *implies* $\mathsf{psame}(p,q)$*. Conversely,* $\mathsf{psame}(p,q)$ *is backed by package witnesses for answer histories internally related by* hsame*.*

Proof. The forward direction is the extensionality field of the package policy. The converse is the source-reflection field. Therefore package-token behavior is a licensed theorem of the package policy, not a primitive quotient shortcut. □

Definition 9352.10 (Gap membership and gap policy)**.** *The gap membership relation*

$$\mathsf{Gap}(\Pi, D, p, h)$$

records that admitted source history h lies in the ledger behind visible package token p. A gap policy $\mathsf{GapPolicy}(\Pi, D)$ *supplies coverage of admitted histories, separation of two package tokens that cover the same source history, and signature determination: every gap membership is backed by a generated signature and a package-token witness.*

Theorem 9352.11 (Gap coverage and separation)**.** *Assume* $\mathsf{AskPolicy}(\Pi, D)$*,* $\mathsf{PackagePolicy}(\Pi)$*, and* $\mathsf{GapPolicy}(\Pi, D)$*. If $h \in D$, then there is a package token p such that* $\mathsf{Gap}(\Pi, D, p, h)$*. If*

$$\mathsf{Gap}(\Pi, D, p, h), \qquad \mathsf{Gap}(\Pi, D, q, h),$$

then $\mathsf{psame}(p,q)$*.*

Proof. Coverage is the coverage field of the gap policy, with ask totality and package existence supplying the generated signature and token when the policy is unfolded. For separation, unfold the two gap memberships. They produce two signatures from the same source history and two package-token witnesses. Signature determinacy gives hsame of the two answer histories, and package extensionality gives $\mathsf{psame}(p,q)$. □

Principle 9352.12 (Compression carries memory)**.** *Packaging, hiding, projecting, sealing, or otherwise compressing generated histories into a visible token is admissible only with a gap ledger. Without the ledger, the visible token has no internal record of the source histories compressed into it.*

Concretized in §8979: AskSigGapRouteUp realizes the Ask–Sig–Pkg–Gap exact-globalization spine as finite NameCert route data.

Definition 9352.13 (Generated signature sameness witness)**.** *The witness object* $\mathsf{GeneratedSameSig}(\Pi, h, k)$ *consists of answer histories* s, t*, evidence ledgers* Δ, Θ*, generated signatures*

$$\mathsf{Sig}(\Pi, h, s, \Delta), \qquad \mathsf{Sig}(\Pi, k, t, \Theta),$$

and the internal sameness row $\mathsf{hsame}(s, t)$*. Its inhabitedness is the checker-facing form of the signature-classification statement.*

Definition 9352.14 (Exact globalize base)**.** *An exact finite globalization base* $\mathsf{ExactGlobalizeBase}(\Pi, D)$ *consists of coverage, base soundness, and base completeness:*

$$h \in D \Longrightarrow \exists p.\ \mathsf{Gap}(\Pi, D, p, h),$$

$$\mathsf{Gap}(\Pi, D, p, h) \wedge \mathsf{Gap}(\Pi, D, q, k) \wedge \mathsf{GeneratedSameSig}(\Pi, h, k) \Longrightarrow \mathsf{psame}^{\mathrm{base}}_{\Pi}(p, q),$$

and

$$\mathsf{Gap}(\Pi, D, p, h) \wedge \mathsf{Gap}(\Pi, D, q, k) \wedge \mathsf{psame}^{\mathrm{base}}_{\Pi}(p, q) \Longrightarrow \mathsf{Nonempty}(\mathsf{GeneratedSameSig}(\Pi, h, k)).$$

Theorem 9352.15 (Exact globalize base classification)**.** *If* $\mathsf{ExactGlobalizeBase}(\Pi, D)$ *and the two displayed package tokens carry gap witnesses*

$$\mathsf{Gap}(\Pi, D, p, h), \qquad \mathsf{Gap}(\Pi, D, q, k),$$

then

$$\mathsf{psame}^{\mathrm{base}}_{\Pi}(p, q) \Longleftrightarrow \mathsf{Nonempty}(\mathsf{GeneratedSameSig}(\Pi, h, k)).$$

Proof. The forward implication is base completeness. The reverse implication unpacks the inhabited $\mathsf{GeneratedSameSig}(\Pi, h, k)$ witness and applies base soundness. Coverage remains part of the exact globalization structure because every admitted history must have a visible package ledger, even though this local equivalence only needs the two displayed gap witnesses. □

9352.3 Name certification

Definition 9352.16 (NameCert fields)**.** *For a proposed derived interface* N*, the paper naming certificate is the five-field packet*

$$\mathsf{NameCert}(N) = (\mathsf{SourceSpec}_N, \mathsf{PatternSpec}_N, \mathsf{ClassifierSpec}_N, \mathsf{StabilityCert}_N, \mathsf{LedgerPolicy}_N).$$

The source field records the generated material from which N *is licensed. The pattern field records the stable behavior observed in that source. The classifier field records how source material is grouped, normally through a bundle, asking policy, package policy, and gap policy at the finite-kernel level. The stability field records closure, reuse, descent, composition, or seal behavior. The ledger policy records what the name hides and how that hidden material remains tracked.*

Theorem 9352.17 (Derived interfaces require NameCert)**.** *A derived interface* N *is admitted only through* $\mathsf{NameCert}(N)$*.*

Proof. The finite kernel has no mature-object primitive beyond its generated judgments and certificate records. A derived name therefore cannot enter by host familiarity, notation, quotient collapse, or semantic intention. It enters only when source, pattern, classifier, stability, and ledger fields are all supplied. □

Definition 9352.18 (Certified existence)**.** *For a proposed object or interface name X, BEDC-certified existence is the judgment*

$$\mathsf{Exists}^{\uparrow}(X) := \sum_{N:\mathsf{NameCert}(X)} \mathsf{Admits}(N).$$

The admission row records that the source, pattern, classifier, stability, and ledger fields of N are available to downstream consumers. Thus existence is a construction certificate for the named interface, not prior possession of an untyped object.

Principle 9352.19 (Existence is certificate-bearing admission)**.** *In BEDC, a mathematical name is usable only as far as its construction certificate exposes the relevant source, classifier, boundary, transport, and ledger rows. A zeta carrier, zero packet, Hilbert-style surface, solenoid phase carrier, Pick kernel, completion, quotient, or limit may be used only after the corresponding certificate has named what is generated, what is hidden, and how the hidden material remains auditable.*

Theorem 9352.20 (Certified existence is the object-layer admission rule)**.** *Every object-layer use of a derived interface factors through $\mathsf{Exists}^{\uparrow}(X)$.*

Proof. By Definition 9352.17, a derived interface X enters the finite kernel only through $\mathsf{NameCert}(X)$. The additional admission row in Definition 9352.18 records that the fields of that certificate are available for the intended object-layer use. Thus any use of X factors through the displayed pair consisting of the naming certificate and its admission row. □

Definition 9352.21 (BEDC mathematical ontology core)**.** *The BEDC mathematical ontology core is the certificate-bearing admission spine*

$$\mathsf{BMark} \to \mathsf{BHist} \to (\mathsf{msame}, \mathsf{hsame}) \to (\mathsf{Ext}, \mathsf{Cont}) \to (\mathsf{Ask}, \mathsf{Sig}) \to (\mathsf{Pkg}, \mathsf{Gap}) \to \mathsf{NameCert} \to \mathsf{Math}^{\uparrow}.$$

Here $\mathsf{Math}^{\uparrow}$ denotes the family of public mathematical interfaces admitted after certification. The displayed chain is not an additional object carrier. It is the rule that reads ordinary mathematical grammar from generated histories, classifier-stable packages, visible gap ledgers, and naming certificates.

Definition 9352.22 (Dynamic ontology state row)**.** *A certified interface carries a dynamic ontology state row when its admission data expose a finite state*

$$\mathcal{K}_t = (H_t, E_t, C_t, R_t, L_t).$$

Here H_t is the generated source history visible to the interface, E_t is the displayed event or formation row that extends that history, C_t is the canonical code or normal-form row, R_t is the public readout row, and L_t is the residual ledger row. A transition

$$\mathcal{K}_t \longrightarrow \mathcal{K}_{t+1}$$

is admitted only when the later state extends H_t by a displayed event, recomputes C_t and R_t by the stated rules, and transports every open residual into the displayed ledger policy.

Definition 9352.23 (BEDC–PZG dynamic tuple)**.** *The BEDC–PZG dynamic tuple is the coordinate presentation*

$$\mathcal{K}_{\mathrm{dyn}} := (\mathsf{H}, \mathsf{G}, \mathsf{Z}, \mathsf{D}, \mathsf{N}, \mathsf{R}, \mathsf{L}, \mathsf{S}, \Phi, K_\infty, \Sigma_\infty, \mathsf{M}).$$

Here H *is the history carrier,* G *is the displayed generation operator,* Z *is the PZG register,* D *is its decoding row,* N *is the normalization row,* R *is finite readout,* L *is the residual ledger,* S *is finite self-description,* Φ *is phase readout,* K_∞ *is the hidden prime-fibre row,* Σ_∞ *is the solenoid phase carrier, and* M *is the motion certificate when the interface has a motion surface. This tuple is not an object preceding the ontology core; it is a coordinate display of the rows already admitted by Definition 9352.22 and the public interfaces that consume them.*

Principle 9352.24 (Dynamic construction route)**.** *The dynamic tuple is used only through certified formation routes of the shape*

$$\mathsf{Term} \to \mathsf{Rewrite} \to \mathsf{Congruence} \to \mathsf{Localize} \to \mathsf{Complete} \to \mathsf{Globalize}.$$

Each arrow is a finite event row: it extends the source history, supplies a canonical readout for the target stage, and transports the residual ledger. Thus localization, completion, global phase readout, and motion certification are downstream consumers of the same dynamic state discipline rather than separate ontological primitives.

Principle 9352.25 (Ontology triad)**.** *The ontology core presents every certified mathematical interface through three inseparable rows. The generation row records how the interface is produced from marks, histories, continuations, questions, signatures, packages, gaps, and certificates. The canonical readout row records the normal form, classifier, unit phase, unit norm, or standard decoding by which the interface is publicly usable. The ledger row records every residual not closed by that readout, including hidden source material, tail windows, semantic self-reference, and compatibility defects.*

Theorem 9352.26 (Certified formation inherits the ontology triad)**.** *Let* Y *be generated from certified interfaces* $X_1, \ldots, X_m$ *by a displayed finite formation rule. If each* X_i *carries a dynamic ontology state row and the formation rule displays event transport, canonical readout transport, and ledger transport, then* Y *carries the ontology triad of Definition 9352.25.*

Proof. The event transport appends the formation rule to the source histories of $X_1, \ldots, X_m$, giving the generation row for Y. The canonical readout transport supplies the normal form, classifier, unit row, or decoding row by which Y is publicly read. The ledger transport carries the source ledgers forward and records the residuals created by the formation rule itself. These are precisely the three rows required by Definition 9352.25. □

Theorem 9352.27 (Object-layer factorization through the ontology core)**.** *Every public object-layer use of a certified mathematical interface factors through the spine of Definition 9352.21.*

Proof. The lower spine supplies raw marks, generated histories, mark sameness, history sameness, extension, and continuation. The present L3–L5 surface then supplies asking, generated signatures, package tokens, gap coverage, and exact local classification where claimed. By Definition 9352.17, no derived interface enters by host familiarity, notation, quotient collapse, or semantic intention. By Definition 9352.20, each object-layer use factors through the relevant naming certificate and admission row. Composing these displayed passages gives the stated factorization. □

Corollary 9352.28 (Mature mathematical names are certificate consumers)**.** *Interfaces such as*

$$\mathsf{Nat}^{\uparrow}, \quad \mathsf{Int}^{\uparrow}, \quad \mathsf{Rat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}, \quad \mathsf{Cat}^{\uparrow}, \quad \mathsf{Prime}^{\uparrow}, \quad \mathsf{Zeta}^{\uparrow}$$

are not kernel primitives. Each is usable only at the scope exposed by its source specification, classifier, stability rows, ledger policy, and local admission certificate.

Proof. Apply Definition 9352.27 to each displayed upward interface. The factorization route ends in a $\mathsf{NameCert}$ and its admission row before any public mathematical read is available. Hence the public name is a certified interface over generated BEDC material rather than an independent primitive object. □

Principle 9352.29 (Ledger policy for hidden material)**.** *Any derived interface that hides a process, tail, source fiber, phase row, gap row, or compatibility thread must expose a* $\mathsf{LedgerPolicy}$ *witness. This applies in particular to completion-like, fold-like, phase-like, geometric, algebraic, analytic, zeta-facing, and zero-ledger-facing interfaces.*

Theorem 9352.30 (L3–L5 finite-kernel closure)**.** *Given* $\mathsf{AskPolicy}(\Pi, D)$*,* $\mathsf{PackagePolicy}(\Pi)$*,* $\mathsf{GapPolicy}(\Pi, D)$*, and the exact globalize fields where claimed, the L3–L5 spine supplies:*

1. *signature determinacy for each admitted source history;*
2. $\mathsf{sameSig}_{\Pi}$ *as the internal signature classifier on admitted histories;*
3. *package classification of answer histories;*
4. *gap coverage for admitted source histories;*
5. *gap separation for same-source package overlaps;*
6. *exact local classification by* $\mathsf{ExactGlobalizeBase}(\Pi, D)$*;*
7. *certificate admission for derived interfaces through* $\mathsf{NameCert}$*.*

Proof. The first clause is Definition 9352.5. The second is Definition 9352.7. The third is Definition 9352.9. The fourth and fifth are Definition 9352.11. The sixth is Definition 9352.15. The final clause is Definition 9352.17. □

Principle 9352.31 (Finite-data boundary)**.** *The next layer begins only after the L0–L5 spine has supplied these policies and ledgers. Finite data interfaces such as* $\mathsf{Bool}^{\uparrow}$*,* $\mathsf{Option}^{\uparrow}$*,* $\mathsf{Sum}^{\uparrow}$*,* $\mathsf{Prod}^{\uparrow}$*, and* $\mathsf{List}^{\uparrow}$ *are therefore certificate consumers, not additional kernel primitives.*

Chapter 9353

Finite Data Interface Spine

The finite-kernel spine of chapter 9351 and chapter 9352 reaches the first data-facing layer through certificates. The finite data layer does not add truth values, option values, disjoint sums, ordered pairs, or lists as kernel inputs. It licenses them as derived interfaces over histories, history sameness, continuation, package ledgers, stability witnesses, and name certificates:

$$(\mathsf{Hist}, \mathsf{hsame}, \mathsf{Cont}, \mathsf{Pkg}, \mathsf{Gap}, \mathsf{NameCert}) \longrightarrow (\mathsf{Bool}^{\uparrow}, \mathsf{Option}^{\uparrow}, \mathsf{Sum}^{\uparrow}, \mathsf{Prod}^{\uparrow}, \mathsf{List}^{\uparrow}).$$

The roadmap obligation for this layer is stated in section 9467.8: each public finite-data object must display a carrier predicate over Hist, a classifier with stability, constructor and case-analysis behavior, and a ledger for the information hidden by its public surface.

9353.1 Interface Template

Definition 9353.1 (Finite data interface)**.** *A finite data interface is a certificate packet*

$$\mathsf{FinData}^{\uparrow}(A, \sim_A)$$

over histories, consisting of the data

$$(A, \sim_A, \mathsf{Constr}_A, \mathsf{Elim}_A, \mathsf{Stab}_A, \mathsf{Ledger}_A, \mathsf{NameCert}(A, \sim_A)).$$

Here

$$A : \mathsf{Hist} \to \mathsf{Prop}$$

is the carrier predicate, and

$$\sim_A : \mathsf{Hist} \to \mathsf{Hist} \to \mathsf{Prop}$$

is the public classifier. The constructor field records how public constructors create admitted histories. The elimination field records the case-analysis or inversion principles allowed by those constructors. The stability field records reflexivity, symmetry, transitivity, and carrier transport for the classifier. The ledger records tag bits, branch choices, length rows, component witnesses, or other material suppressed by the public name.

Definition 9353.2 (Finite data admission)**.** *An interface $A^{\uparrow}$ is admitted at the finite data layer when the packet of Definition 9353.1 is displayed and its certificate supplies*

$$\mathsf{carrier_inhabited}, \quad \mathsf{classifier_refl}, \quad \mathsf{classifier_symm},$$

$$\mathsf{classifier_trans}, \quad \mathsf{carrier_transport},$$

together with the advertised constructor, inversion, and ledger fields.

Principle 9353.3 (Finite data is certificate-facing)**.** *No finite data interface is accepted from host notation alone. A public read of* $\mathsf{Bool}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, $\mathsf{Sum}^{\uparrow}$, $\mathsf{Prod}^{\uparrow}$, *or* $\mathsf{List}^{\uparrow}$ *must pass through a displayed carrier, classifier, stability certificate, ledger, and name certificate.*

Concretized in §8899: Finite-data interface spine realized as one L6 NameCert packet.

Theorem 9353.4 (Finite data interfaces are not kernel inputs)**.** *If* $A^{\uparrow}$ *is admitted by Definition 9353.2, then* $A^{\uparrow}$ *is not a BEDC kernel input.*

Proof. The only objects available before the finite data layer are the lower generated histories, relations, policies, packages, gaps, and naming certificates. Admission by Definition 9353.2 explicitly uses those records. Thus the public interface is a licensed name over the displayed records, not an additional carrier inserted into the kernel. □

Concretized in §8898: Finite assembly NameCert for the Bool/Option/Sum/Prod/List interface spine.

9353.2 Boolean Endpoint Interface

Definition 9353.5 (Boolean history carrier)**.** *The Boolean finite-data carrier is the two-endpoint predicate*

$$\mathsf{BoolCarrier}(h) :\Longleftrightarrow \mathsf{hsame}(h, \mathsf{e}) \vee \mathsf{hsame}(h, \mathsf{E1}(\mathsf{e})).$$

The endpoint e *is the false endpoint, and* $\mathsf{E1}(\mathsf{e})$ *is the true endpoint.*

Definition 9353.6 (Boolean history classifier)**.** *The Boolean classifier relates exactly histories in the same displayed endpoint class:*

$$\mathsf{BoolClassifier}(h, k) :\Longleftrightarrow \big(\mathsf{hsame}(h, \mathsf{e}) \wedge \mathsf{hsame}(k, \mathsf{e})\big) \vee \big(\mathsf{hsame}(h, \mathsf{E1}(\mathsf{e})) \wedge \mathsf{hsame}(k, \mathsf{E1}(\mathsf{e}))\big).$$

Definition 9353.7 (Boolean constructors)**.** *The two public constructors are the displayed histories*

$$\mathsf{false}^{\uparrow} := \mathsf{e}, \qquad \mathsf{true}^{\uparrow} := \mathsf{E1}(\mathsf{e}).$$

Theorem 9353.8 (Boolean endpoint exactness)**.** *For admitted Boolean histories* h, k*, the classifier* $\mathsf{BoolClassifier}(h, k)$ *holds exactly when both histories lie in the false endpoint class or both lie in the true endpoint class.*

Proof. Unfold Definition 9353.6. The classifier has only the two displayed alternatives, and each alternative requires both histories to be in the same endpoint class. □

Theorem 9353.9 (Boolean constructor separation)**.** *The endpoint classifier does not relate the two Boolean constructors:*

$$\neg\, \mathsf{BoolClassifier}(\mathsf{e}, \mathsf{E1}(\mathsf{e})).$$

Proof. If the classifier held, Definition 9353.6 would put e and $\mathsf{E1}(\mathsf{e})$ in one endpoint class. Each class equality contradicts history no-confusion for the empty and one-extended constructors. □

Corollary 9353.10 (Boolean finite data admission)**.** *The interface* $\mathsf{Bool}^{\uparrow}$ *is admitted by its carrier, endpoint classifier, two displayed constructors, endpoint separation, stability rows, ledger row, and* $\mathsf{NameCert}$ *or* $\mathsf{SemanticNameCert}$ *row.*

9353.3 Optional History Interface

Definition 9353.11 (Optional carrier)**.** *Let $A : \mathsf{Hist} \to \mathsf{Prop}$ be an admitted source carrier with classifier $\sim_A$. The optional carrier is*

$$\mathsf{OptionCarrier}_A(h) :\Longleftrightarrow \mathsf{hsame}(h, \mathsf{e}) \vee \exists a.\ A(a) \wedge \mathsf{hsame}(h, \mathsf{E1}(a)).$$

The empty endpoint is the absent case, and histories of the form $\mathsf{E1}(a)$ are present cases.

Definition 9353.12 (Optional classifier)**.** *The optional classifier is the branch-respecting relation*

$$\mathsf{OptionClassifier}_{A,\sim_A}(h, k) :\Longleftrightarrow \big(\mathsf{hsame}(h, \mathsf{e}) \wedge \mathsf{hsame}(k, \mathsf{e})\big)$$

$$\vee\ \exists a, b.\ A(a) \wedge A(b) \wedge \mathsf{hsame}(h, \mathsf{E1}(a)) \wedge \mathsf{hsame}(k, \mathsf{E1}(b)) \wedge a \sim_A b.$$

Definition 9353.13 (Optional constructors)**.** *The optional constructors are*

$$\mathsf{none}^{\uparrow} := \mathsf{e}, \qquad \mathsf{some}^{\uparrow}(a) := \mathsf{E1}(a).$$

Theorem 9353.14 (Present payload determinacy)**.** *If*

$$\mathsf{hsame}(h, \mathsf{E1}(a)), \qquad \mathsf{hsame}(h, \mathsf{E1}(b)),$$

then $\mathsf{hsame}(a, b)$.

Proof. By symmetry and transitivity for hsame, the two assumptions give $\mathsf{hsame}(\mathsf{E1}(a), \mathsf{E1}(b))$. Constructor inversion for $\mathsf{E1}$ gives $\mathsf{hsame}(a, b)$. □

Theorem 9353.15 (Absent and present separation)**.** *The optional classifier never identifies an absent endpoint with a visible present endpoint.*

Proof. Unfold Definition 9353.12. In the absent–absent case, the second history is hsame to e, so being also hsame to $\mathsf{E1}(b)$ would contradict empty–extension no-confusion. In the present–present case, the first history is hsame to some $\mathsf{E1}(a)$, so being also hsame to e gives the same contradiction. □

Corollary 9353.16 (Optional finite data admission)**.** *If the source carrier A has a $\mathsf{NameCert}(A, \sim_A)$ and the optional carrier, classifier, constructor separation, payload determinacy, carrier transport, and ledger policy are displayed, then $\mathsf{Option}^{\uparrow}(A)$ is admitted as a finite data interface.*

9353.4 Tagged Sum Interface

Definition 9353.17 (Sum carrier)**.** *Let $L, R : \mathsf{Hist} \to \mathsf{Prop}$ be admitted source carriers with classifiers $\sim_L$ and $\sim_R$. The sum carrier is*

$$\mathsf{SumCarrier}_{L,R}(h) :\Longleftrightarrow \exists l.\ L(l) \wedge \mathsf{hsame}(h, \mathsf{E0}(l))$$

$$\vee\ \exists r.\ R(r) \wedge \mathsf{hsame}(h, \mathsf{E1}(r)).$$

Definition 9353.18 (Sum classifier)**.** *The sum classifier relates left endpoints through the left source classifier and right endpoints through the right source classifier:*

$$\mathsf{SumClassifier}_{L,R}(h, k) :\Longleftrightarrow \exists l, l'.\ L(l) \wedge L(l') \wedge \mathsf{hsame}(h, \mathsf{E0}(l)) \wedge \mathsf{hsame}(k, \mathsf{E0}(l')) \wedge l \sim_L l'$$

$$\vee\ \exists r, r'.\ R(r) \wedge R(r') \wedge \mathsf{hsame}(h, \mathsf{E1}(r)) \wedge \mathsf{hsame}(k, \mathsf{E1}(r')) \wedge r \sim_R r'.$$

Definition 9353.19 (Sum constructors)**.** *The public sum constructors are*

$$\mathsf{inl}^{\uparrow}(l) := \mathsf{E0}(l), \qquad \mathsf{inr}^{\uparrow}(r) := \mathsf{E1}(r).$$

Theorem 9353.20 (Sum branch separation)**.** *The sum classifier does not relate a left-tagged endpoint to a right-tagged endpoint:*

$$\neg\, \mathsf{SumClassifier}_{L,R}(\mathsf{E0}(l), \mathsf{E1}(r)).$$

Proof. Unfold Definition 9353.18. The left–left branch would require the right endpoint $\mathsf{E1}(r)$ to be hsame to a left-tagged history. The right–right branch would require the left endpoint $\mathsf{E0}(l)$ to be hsame to a right-tagged history. Both requirements contradict history no-confusion for the two extension constructors. □

Corollary 9353.21 (Sum finite data admission)**.** *If the two sources have their own name certificates and the displayed sum carrier, branch classifier, constructor stability, branch separation, classifier stability, and ledger rows are supplied, then* $\mathsf{Sum}^{\uparrow}(L, R)$ *is admitted.*

9353.5 Ordered Product Interface

Definition 9353.22 (Product pair representation)**.** *For admitted source carriers L and R, the representation*

$$\mathsf{ProdPairRep}_{L,R}(h, l, r)$$

records that h is the displayed ordered-pair history assembled from the left component l and right component r through the finite continuation route, with $L(l)$ and $R(r)$.

Definition 9353.23 (Product carrier and ledger)**.** *The product carrier is*

$$\mathsf{ProdCarrier}_{L,R}(h) :\Longleftrightarrow \exists l, r.\ \mathsf{ProdPairRep}_{L,R}(h, l, r).$$

The product ledger has the same witness shape:

$$\mathsf{ProdLedger}_{L,R}(h) :\Longleftrightarrow \exists l, r.\ \mathsf{ProdPairRep}_{L,R}(h, l, r).$$

The carrier admits the visible history, while the ledger keeps the component witnesses and continuation route available to public consumers.

Definition 9353.24 (Product componentwise classifier)**.** *The product classifier is*

$$\mathsf{ProdClassifier}_{L,R,\sim_L,\sim_R}(h, k) :\Longleftrightarrow \exists l, r, l', r'.\ \mathsf{ProdPairRep}_{L,R}(h, l, r) \wedge \mathsf{ProdPairRep}_{L,R}(k, l', r')$$
$$\wedge\ l \sim_L l' \wedge\ r \sim_R r'.$$

Theorem 9353.25 (Product carrier exposes the displayed ledger)**.** *If* $\mathsf{ProdCarrier}_{L,R}(h)$*, then* $\mathsf{ProdLedger}_{L,R}(h)$*.*

Proof. Both predicates have the same displayed witness shape in Definition 9353.23. A carrier witness therefore serves as the ledger witness. □

Theorem 9353.26 (Product classification exposes component ledgers)**.** *If*

$$\mathsf{ProdClassifier}_{L,R,\sim_L,\sim_R}(h,k),$$

then

$$\mathsf{ProdLedger}_{L,R}(h) \wedge \mathsf{ProdLedger}_{L,R}(k).$$

Proof. Unfold Definition 9353.24. The classifier witness contains displayed pair representations for both endpoints. Each representation is exactly a ledger witness by Definition 9353.23. □

Principle 9353.27 (Product coherence is part of the interface)**.** *Raw continuation is not by itself a product classifier. A product interface must carry coherence data ensuring that ordered components are recovered through the displayed pair representation, not by an untracked host projection.*

Corollary 9353.28 (Product finite data admission)**.** *If both source carriers have name certificates and the product pair representation, coherence data, componentwise classifier, displayed ledger, carrier transport, and stability rows are supplied, then* $\mathsf{Prod}^{\uparrow}(L,R)$ *is admitted.*

9353.6 Finite List Interface

Definition 9353.29 (List spine)**.** *For an admitted source carrier* $A : \mathsf{Hist} \to \mathsf{Prop}$*, the list spine carrier* Spine_A *is generated by*

$$\mathsf{nil}$$

and by

$$\mathsf{cons}(a, xs)$$

whenever $A(a)$ *and* $xs : \mathsf{Spine}_A$*.*

Definition 9353.30 (List spine representation)**.** *The relation*

$$\mathsf{ListSpineRep}_A(h, xs)$$

records that the public history h *displays the finite spine* xs*.*

Definition 9353.31 (List carrier and ledger)**.** *The list carrier is*

$$\mathsf{ListCarrier}_A(h) :\Longleftrightarrow \exists xs : \mathsf{Spine}_A.\ \mathsf{ListSpineRep}_A(h, xs).$$

The list ledger has the same displayed witness shape:

$$\mathsf{ListLedger}_A(h) :\Longleftrightarrow \exists xs : \mathsf{Spine}_A.\ \mathsf{ListSpineRep}_A(h, xs).$$

The ledger records finite constructor shape, length information, and payload provenance through the source classifier.

Definition 9353.32 (List classifier)**.** *The public list classifier is*

$$\mathsf{ListClassifier}_{A,\sim_A}(h,k) :\Longleftrightarrow \exists xs, ys.\ \mathsf{ListSpineRep}_A(h, xs) \wedge \mathsf{ListSpineRep}_A(k, ys)$$

$$\wedge\ \mathsf{ListClassifierSpec}(\sim_A, xs, ys).$$

Theorem 9353.33 (List nil inversion)**.** *If*

$$\mathsf{ListSpineRep}_A(h, \mathsf{nil}), \qquad \mathsf{ListSpineRep}_A(k, ys),$$

and $\mathsf{ListClassifier}_{A,\sim_A}(h, k)$*, then* $ys = \mathsf{nil}$*.*

Proof. Unfold Definition 9353.32. The represented nil spine can classify only against a displayed spine whose finite classifier matches nil. The cons case would require a nil–cons classifier witness, contradicting constructor no-confusion for finite spines. □

Theorem 9353.34 (List displayed exactness)**.** *If*

$$\mathsf{ListSpineRep}_A(h, xs), \qquad \mathsf{ListSpineRep}_A(k, ys),$$

then

$$\mathsf{ListClassifier}_{A,\sim_A}(h, k) \Longleftrightarrow \mathsf{ListClassifierSpec}(\sim_A, xs, ys).$$

Proof. The reverse direction repacks the two displayed spine representations and the finite-spine classifier witness into Definition 9353.32. The forward direction reads the public classifier through the displayed representation coherence, which leaves exactly the finite-spine classifier between xs and ys. □

Corollary 9353.35 (List finite data admission)**.** *If the source carrier has a name certificate and the list spine representation, spine coherence, public classifier, displayed ledger, constructor inversion, length readback, and stability rows are supplied, then* $\mathsf{List}^{\uparrow}(A)$ *is admitted.*

9353.7 Finite Data Layer

Theorem 9353.36 (Finite data admission theorem)**.** *For each of*

$$\mathsf{Bool}^{\uparrow}, \qquad \mathsf{Option}^{\uparrow}, \qquad \mathsf{Sum}^{\uparrow}, \qquad \mathsf{Prod}^{\uparrow}, \qquad \mathsf{List}^{\uparrow},$$

admission at the finite data layer follows from the displayed carrier predicate over Hist*, classifier,* StabilityCert *rows, constructor stability, case-analysis or inversion rows, ledger for hidden data, and* NameCert *or* SemanticNameCert *row. None of the five interfaces enters as a BEDC kernel input.*

Proof. Apply Definition 9353.2 to each displayed interface. Boolean admission is Definition 9353.10. Optional admission is Definition 9353.16. Sum admission is Definition 9353.21. Product admission is Definition 9353.28. List admission is Definition 9353.35. Each corollary uses only histories, history sameness, continuation and package provenance where needed, ledger exposure, stability, and name certification. □

Principle 9353.37 (Arithmetic boundary)**.** *The next arithmetic-facing layer may use* $\mathsf{Bool}^{\uparrow}$ *for binary observations,* $\mathsf{Option}^{\uparrow}$ *for presence and absence,* $\mathsf{Sum}^{\uparrow}$ *for tagged case analysis,* $\mathsf{Prod}^{\uparrow}$ *for ordered pairs with displayed component ledgers, and* $\mathsf{List}^{\uparrow}$ *for finite windows. It may not treat any of these interfaces as a host truth type, host option type, host coproduct, host tuple, or host sequence.*

Chapter 9354

Arithmetic Interface Spine

The finite data layer licenses Boolean tags, optional endpoints, sums, products, and finite spines. Arithmetic is the next certificate-facing surface. It does not add host natural numbers, host integer pairs, host rational quotients, or primitive arithmetic operations to the BEDC kernel. The arithmetic layer reads only the generated history spine, continuation, finite data interfaces, stability fields, and naming ledgers:

$$(\mathsf{Hist}, \mathsf{hsame}, \mathsf{Cont}, \mathsf{NameCert}, \mathsf{Bool}^{\uparrow}, \mathsf{Prod}^{\uparrow}, \mathsf{List}^{\uparrow}) \longrightarrow (\mathsf{Nat}^{\uparrow}, \mathsf{Add}^{\uparrow}, \mathsf{Mul}^{\uparrow}, \mathsf{Order}^{\uparrow}, \mathsf{Int}^{\uparrow}, \mathsf{Rat}^{\uparrow}).$$

This chapter records the interface spine for that passage. Its role is to state what each arithmetic name must display before it can be consumed by later algebra, real, and number-theoretic packets.

9354.1 Unary Natural Histories

Definition 9354.1 (Unary history judgment)**.** *The unary judgment*

$$\mathsf{Unary} : \mathsf{Hist} \to \mathsf{Prop}$$

is the closed generated predicate with base row

$$\mathsf{Unary}(\mathsf{e})$$

and one-extension row

$$\mathsf{Unary}(h) \Longrightarrow \mathsf{Unary}(\mathsf{E1}(h)).$$

There is no generation row for $\mathsf{Unary}(\mathsf{E0}(h))$.

Definition 9354.2 (Natural-number carrier and classifier)**.** *The natural-number carrier is*

$$\mathsf{NatCarrier}(h) :\Longleftrightarrow \mathsf{Unary}(h).$$

Its classifier is history sameness restricted to unary histories:

$$h \sim_{\mathsf{Nat}} k :\Longleftrightarrow \mathsf{Unary}(h) \wedge \mathsf{Unary}(k) \wedge \mathsf{hsame}(h, k).$$

The zero and successor rows are

$$0_{\mathsf{Nat}} := \mathsf{e}, \qquad \mathsf{succ}(h) := \mathsf{E1}(h).$$

Theorem 9354.3 (Unary closure and zero separation)**.** *The carrier* $\mathsf{NatCarrier}$ *contains* 0_{Nat}*, is closed under* succ*, and contains no* $\mathsf{E0}$*-headed history.*

Proof. The first two claims are exactly the two generation rows in Definition 9354.1. The last claim follows from closed generation: every nonempty unary history is produced by the $\mathsf{E1}$-extension row, and no displayed rule has an $\mathsf{E0}$-headed conclusion. □

Theorem 9354.4 (Unary induction)**.** *Let* $P : \mathsf{Hist} \to \mathsf{Prop}$*. If* $P(\mathsf{e})$ *and*

$$\mathsf{Unary}(h) \wedge P(h) \Longrightarrow P(\mathsf{E1}(h)),$$

then

$$\mathsf{Unary}(h) \Longrightarrow P(h)$$

for every history h*.*

Proof. Induct on the displayed derivation of $\mathsf{Unary}(h)$. The base derivation uses $P(\mathsf{e})$. The one-extension derivation applies the induction hypothesis to the tail and then applies the displayed step premise. □

Definition 9354.5 (Natural-number naming certificate)**.** *The* $\mathsf{Nat}^{\uparrow}$ *certificate has source* Unary*, pattern repeated* $\mathsf{E1}$*-extension from* e*, classifier* $\sim_{\mathsf{Nat}}$*, stability given by base, successor closure, unary induction, and* $\mathsf{E0}$ *exclusion, and ledger equal to the originating unary history behind each public counting token.*

Corollary 9354.6 (NatUp admission)**.** *The interface* $\mathsf{Nat}^{\uparrow}$ *is admitted by the certificate of Definition 9354.5. It is a unary-history interface, not a kernel natural-number primitive.*

9354.2 Unary Continuation Addition

Definition 9354.7 (Unary continuation and additive relation)**.** *The unary continuation predicate is*

$$\mathsf{UnaryCont}(h, k, r) :\Longleftrightarrow \mathsf{Unary}(h) \wedge \mathsf{Unary}(k) \wedge \mathsf{Cont}(h, k, r).$$

The additive relation is

$$\mathsf{AddRel}(h, k, r) :\Longleftrightarrow \mathsf{Unary}(h) \wedge \mathsf{Unary}(k) \wedge \mathsf{Unary}(r) \wedge \mathsf{Cont}(h, k, r).$$

It is the relation read publicly as $h + k \simeq r$*.*

Theorem 9354.8 (Addition closure)**.** *If* $\mathsf{Unary}(h)$*,* $\mathsf{Unary}(k)$*, and* $\mathsf{Cont}(h, k, r)$*, then* $\mathsf{Unary}(r)$*.*

Proof. Induct on the displayed continuation derivation. The empty continuation returns the right input, hence a unary result. The $\mathsf{E1}$ continuation step uses the induction hypothesis for the tail result and then applies unary closure under $\mathsf{E1}$. The $\mathsf{E0}$ continuation branch is incompatible with the unary right input by Definition 9354.3. □

Theorem 9354.9 (Additive unit and associativity rows)**.** *For unary histories,* e *is a left and right unit for continuation up to* hsame*, and nested unary continuations associate up to* hsame*.*

Proof. The left unit is the empty continuation row. The right unit is the continuation unit theorem restricted to unary histories, with Definition 9354.8 ensuring that the result remains inside the unary carrier. Associativity is the L2 continuation associativity row restricted to the same unary carrier and transported through hsame. □

Theorem 9354.10 (Additive commutativity row)**.** *If* $\mathsf{Unary}(h)$*,* $\mathsf{Unary}(k)$*,*

$$\mathsf{Cont}(h, k, r), \qquad \mathsf{Cont}(k, h, r'),$$

then $\mathsf{hsame}(r, r')$*.*

Proof. Induct on the unary derivation of h. If $h = \mathsf{e}$, the two continuation unit rows classify r and r' with k. In the one-extension case, invert the continuation from $\mathsf{E1}(h_0)$ and the continuation into the $\mathsf{E1}(h_0)$ tail, apply the induction hypothesis to the exposed tail continuations, and rebuild the endpoint comparison by $\mathsf{E1}$ congruence. □

Definition 9354.11 (AddUp naming certificate)**.** *The* $\mathsf{Add}^{\uparrow}$ *certificate has source pairs of unary histories, pattern relational continuation, classifier* hsame *on generated continuation results, stability given by closure, units, determinacy, associativity, and commutativity, and ledger equal to the two source unary histories together with the displayed continuation witness.*

Corollary 9354.12 (AddUp admission)**.** *The interface* $\mathsf{Add}^{\uparrow}$ *is admitted by the certificate of Definition 9354.11. It is a continuation certificate over unary histories, not a primitive binary operation.*

9354.3 Unary Multiplication and Divisibility

Definition 9354.13 (Unary multiplication relation)**.** *The relation* $\mathsf{NatMul}(d, q, n)$ *is the closed repeated-addition relation with rows:*

$$\mathsf{NatMul}(d, \mathsf{e}, \mathsf{e})$$

for every unary d*, and*

$$\mathsf{NatMul}(d, q, n) \wedge \mathsf{Cont}(n, d, n') \Longrightarrow \mathsf{NatMul}(d, \mathsf{E1}(q), n').$$

The first input is the multiplicand, the second input is the unary multiplier ledger, and the third input is the generated product history.

Theorem 9354.14 (Multiplication closure and functionality)**.** *If* $\mathsf{NatMul}(d, q, n)$*, then* q *is unary. If* d *is unary and* $\mathsf{NatMul}(d, q, n)$*, then* n *is unary. For fixed unary* d *and* q*, any two unary results of* $\mathsf{NatMul}(d, q, -)$ *are* hsame*.*

Proof. The unary property of q follows by induction on the displayed NatMul derivation: the empty multiplier is unary, and the successor row preserves unary by one-extension. Result closure is the same induction, using the empty result in the base case and Definition 9354.8 in the successor case. For functionality, induct on the unary multiplier. The empty case compares two empty product endpoints. The successor case inverts both multiplication witnesses, applies the induction hypothesis to the preceding products, and uses continuation determinacy and hsame transport for the final additive step. □

Definition 9354.15 (Multiplicative unit and divisibility)**.** *The unary unit is*

$$1_{\mathsf{Nat}} := \mathsf{E1}(\mathsf{e}).$$

Divisibility is the explicit quotient-witness relation

$$\mathsf{NatDivides}(d, n) :\Longleftrightarrow \exists q.\ \mathsf{Unary}(q) \wedge \mathsf{NatMul}(d, q, n).$$

Theorem 9354.16 (Unit multiplication readback)**.** *If* $\mathsf{Unary}(q)$ *and* $\mathsf{NatMul}(\mathsf{E1}(\mathsf{e}), q, n)$*, then* $\mathsf{hsame}(n, q)$*.*

Proof. Induct on the unary structure of q. The empty case is the empty multiplication row. In the one-extension case, invert the multiplication witness into the predecessor product and one continuation by $\mathsf{E1}(\mathsf{e})$. The induction hypothesis identifies the predecessor product with the predecessor multiplier, and the final continuation is exactly the successor endpoint up to hsame. □

Definition 9354.17 (MulUp naming certificate)**.** *The* $\mathsf{Mul}^{\uparrow}$ *certificate has source unary triples equipped with a* NatMul *witness, pattern repeated* $\mathsf{Add}^{\uparrow}$ *continuation, classifier* hsame *on product results with transported factor ledgers, stability given by empty-multiplier, successor, result closure, functionality, unit, associativity, commutativity, and distribution rows where supplied, and ledger equal to the multiplicand, multiplier, partial-product trace, and continuation evidence.*

Corollary 9354.18 (MulUp admission boundary)**.** *The local* $\mathsf{Mul}^{\uparrow}$ *interface is the repeated-addition certificate described in Definition 9354.17. Semiring and ordered-ring uses may consume this surface only after the advertised law rows are present; they are not supplied by a kernel multiplication primitive.*

9354.4 Unary Order

Definition 9354.19 (Unary prefix order)**.** *For unary histories, the prefix comparison is*

$$h \leq_{\mathsf{Nat}} k :\Longleftrightarrow \mathsf{Unary}(h) \wedge \mathsf{Unary}(k) \wedge \exists t.\ \mathsf{Unary}(t) \wedge \mathsf{Cont}(h, t, k).$$

The strict comparison additionally requires the displayed tail not to be empty:

$$h <_{\mathsf{Nat}} k :\Longleftrightarrow h \leq_{\mathsf{Nat}} k \text{ through a tail } t \text{ with } \neg\, \mathsf{hsame}(t, \mathsf{e}).$$

Theorem 9354.20 (Unary prefix order rows)**.** *The relation* $\leq_{\mathsf{Nat}}$ *is reflexive and transitive on unary histories, no history is a strict unary prefix of* e*, and any two unary histories are comparable by a displayed prefix row in one direction.*

Proof. Reflexivity uses the empty tail and continuation right unit. Transitivity composes the two displayed tails using continuation associativity and Definition 9354.8. A strict prefix into e would require a nonempty unary tail whose continuation result is empty; empty result inversion forces that tail to be empty, a contradiction. Totality is proved by unary induction: the empty history prefixes every unary history, and the one-extension cases reduce by constructor inversion to the tail comparison. □

Definition 9354.21 (OrderUp naming certificate)**.** *The* $\mathsf{Order}^{\uparrow}$ *certificate has source pairs of unary histories, pattern prefix-or-equality comparison, classifier transport by endpoint* hsame*, stability given by reflexivity, transitivity, total comparison, strict-prefix asymmetry and endpoint transport, and ledger equal to the two endpoints, the comparison branch, and the finite* Cont *prefix route.*

Corollary 9354.22 (OrderUp admission)**.** *The interface* $\mathsf{Order}^{\uparrow}$ *is admitted as a finite unary comparison packet. It does not export host order, quotient order, ordered semiring structure, or a classical trichotomy selector.*

9354.5 Signed Integers

Definition 9354.23 (Signed-pair carrier and classifier)**.** *The integer carrier is the signed unary-pair predicate*

$$\mathsf{IntCarrier}(a, b) :\Longleftrightarrow \mathsf{Unary}(a) \wedge \mathsf{Unary}(b),$$

read as the formal difference $a - b$. Its classifier is cross-additive balance:

$$(a, b) \sim_{\mathsf{Int}} (c, d) :\Longleftrightarrow \exists u, v.\ \mathsf{AddRel}(a, d, u) \wedge \mathsf{AddRel}(c, b, v) \wedge \mathsf{hsame}(u, v).$$

Theorem 9354.24 (Integer classifier elementary laws)**.** *The integer classifier is reflexive and symmetric wherever the required $\mathsf{Add}^{\uparrow}$ rows are displayed. Its transitive law is a full arithmetic obligation over additive associativity, commutativity, and cancellation on the unary continuation surface.*

Proof. Reflexivity compares $a+b$ with itself using an additive witness and hsame reflexivity. Symmetry reverses the displayed hsame witness in the cross-additive balance. Transitivity has the usual signed-pair shape: from $a + d = c + b$ and $c + f = e + d$, one composes additive rows, reorders by the commutative-associative $\mathsf{Add}^{\uparrow}$ certificate, and cancels the shared unary summand. The cancellation row is not a kernel rule; it is part of the L7 arithmetic certificate surface. □

Definition 9354.25 (IntUp naming certificate)**.** *The $\mathsf{Int}^{\uparrow}$ certificate has source signed unary pairs, pattern formal difference, classifier cross-additive balance, stability given by classifier equivalence, addition, negation, multiplication, and order transport where displayed, and ledger equal to the two unary histories together with normalization and cross-additive witnesses.*

Corollary 9354.26 (IntUp admission boundary)**.** *The interface $\mathsf{Int}^{\uparrow}$ is admitted as a signed-pair certificate over $\mathsf{Nat}^{\uparrow}$ and $\mathsf{Add}^{\uparrow}$. It does not import host integers, quotient integer equality, or ordered-ring structure without the corresponding displayed stability rows.*

9354.6 Rational Histories

Definition 9354.27 (Positive unary denominator)**.** *A positive unary denominator is*

$$\mathsf{PositiveUnary}(d) :\Longleftrightarrow \mathsf{Unary}(d) \wedge \neg\, \mathsf{hsame}(d, \mathsf{e}).$$

Theorem 9354.28 (Positive denominator has a one-extension tail)**.** *If $\mathsf{PositiveUnary}(d)$, then there exists t such that*

$$\mathsf{Unary}(t) \wedge \mathsf{hsame}(d, \mathsf{E1}(t)).$$

Proof. Invert the unary derivation of d. The empty case contradicts $\neg\, \mathsf{hsame}(d, \mathsf{e})$. The only remaining generated case is an E1-headed unary history, which supplies the displayed tail. □

Definition 9354.29 (Rational carrier and normalized classifier)**.** *The rational carrier consists of an $\mathsf{Int}^{\uparrow}$ numerator and a positive unary denominator:*

$$\mathsf{RatCarrier}(n, d) :\Longleftrightarrow \mathsf{IntCarrier}(n) \wedge \mathsf{PositiveUnary}(d).$$

The rational classifier is read through displayed normalization witnesses:

$$(n, d) \sim_{\mathsf{Rat}} (m, e)$$

only when there are normalized representatives (n', d') and (m', e') with displayed RatNorm ledgers, classified integer numerators, and classified unary denominators. It is not primitive quotient equality on unnormalized pairs.

Definition 9354.30 (RatUp naming certificate)**.** *The* $\mathsf{Rat}^{\uparrow}$ *certificate has source an* $\mathsf{Int}^{\uparrow}$ *numerator and a positive* $\mathsf{Nat}^{\uparrow}$ *denominator, pattern normalized rational representative, classifier normalized structural comparison, stability given by normalization uniqueness, arithmetic closure, denominator positivity, and order compatibility where supplied, and ledger equal to numerator history, denominator history, normalization trace, and coprimality evidence.*

Corollary 9354.31 (RatUp admission boundary)**.** *The interface* $\mathsf{Rat}^{\uparrow}$ *is admitted as a positive-denominator normalized history certificate. It does not import host rational numbers, quotient machinery, field order, or ordered-field structure unless those rows are displayed in the certificate.*

9354.7 Arithmetic Layer Boundary

Theorem 9354.32 (Arithmetic interface admission theorem)**.** *If the displayed certificates*

$$\mathsf{NameCert}_{\mathsf{Nat}^{\uparrow}},\quad \mathsf{NameCert}_{\mathsf{Add}^{\uparrow}},\quad \mathsf{NameCert}_{\mathsf{Mul}^{\uparrow}},\quad \mathsf{NameCert}_{\mathsf{Order}^{\uparrow}},\quad \mathsf{NameCert}_{\mathsf{Int}^{\uparrow}},\quad \mathsf{NameCert}_{\mathsf{Rat}^{\uparrow}}$$

provide their advertised carrier, classifier, stability, operation congruence, order, normalization, and ledger rows, then

$$\mathsf{Nat}^{\uparrow},\quad \mathsf{Add}^{\uparrow},\quad \mathsf{Mul}^{\uparrow},\quad \mathsf{Order}^{\uparrow},\quad \mathsf{Int}^{\uparrow},\quad \mathsf{Rat}^{\uparrow}$$

are admitted arithmetic interfaces.

Proof. $\mathsf{Nat}^{\uparrow}$ is licensed by unary histories and their induction spine. $\mathsf{Add}^{\uparrow}$ is licensed by unary continuation. $\mathsf{Mul}^{\uparrow}$ is licensed by repeated $\mathsf{Add}^{\uparrow}$ continuation. $\mathsf{Order}^{\uparrow}$ is licensed by finite unary prefix comparison. $\mathsf{Int}^{\uparrow}$ is licensed by signed unary pairs and cross-additive balance. $\mathsf{Rat}^{\uparrow}$ is licensed by signed numerators, positive unary denominators, and normalized comparison. Each case uses a $\mathsf{NameCert}$ surface with an explicit ledger, so none enters as a kernel primitive. □

Principle 9354.33 (Algebra boundary)**.** *Algebraic consumers may read arithmetic through these interfaces only as displayed certificate rows: unary histories, continuation ledgers, repeated-addition traces, prefix-comparison ledgers, signed-pair balances, and rational normalization traces. They may not replace those rows by host natural numbers, host integers, host rationals, quotient equality, or ambient ordered-field facts.*

Concretized in §28: The unary-history NatUp chapter realizes the first arithmetic-interface carrier of this spine.

Chapter 9355

Algebra Interface Spine

The arithmetic spine licenses unary counting, continuation addition, repeated addition, prefix comparison, signed pairs, and rational histories. The algebra layer reads those objects only through certificates. It does not insert host algebraic structures into the kernel. The layer indexed in section 9467.10 is the certificate chain

$$\mathsf{Magma}^{\uparrow} \to \mathsf{Semigroup}^{\uparrow} \to \mathsf{Monoid}^{\uparrow} \to \mathsf{Group}^{\uparrow} \to \mathsf{AbGroup}^{\uparrow} \to \mathsf{Ring}^{\uparrow} \to \mathsf{CommRing}^{\uparrow} \to \mathsf{Field}^{\uparrow} \to \mathsf{Module}^{\uparrow} \to \mathsf{VecSpa}$$

Each step keeps a carrier and classifier visible, adds only the operation or law rows named by that step, and records expression provenance in a ledger.

9355.1 Algebraic Certificate Template

Definition 9355.1 (Algebraic carrier)**.** *An algebraic carrier is a carrier-classifier pair*

$$(C, \sim_C)$$

where

$$C : \mathsf{Hist} \to \mathsf{Prop}$$

is the admitted carrier predicate and

$$\sim_C : \mathsf{Hist} \to \mathsf{Hist} \to \mathsf{Prop}$$

is the public classifier. The pair is usable by the algebra layer only after a displayed $\mathsf{NameCert}(C, \sim_C)$ *supplies carrier transport and classifier laws.*

Definition 9355.2 (Stable operations)**.** *A unary operation f on $(C, \sim_C)$ is stable when it supplies carrier closure, classifier congruence, and ledger rows:*

$$C(x) \Longrightarrow C(f(x)), \qquad x \sim_C y \Longrightarrow f(x) \sim_C f(y).$$

A binary operation μ is stable when it supplies

$$C(x) \wedge C(y) \Longrightarrow C(\mu(x, y)),$$

and

$$x \sim_C x' \wedge y \sim_C y' \Longrightarrow \mu(x, y) \sim_C \mu(x', y').$$

The operation ledger records the expression tree, the source histories, and the normalization or replay route hidden by the public operation symbol.

Definition 9355.3 (Algebraic interface certificate)**.** *An algebraic interface certificate is the packet*

$$\mathsf{AlgCert} = (C, \sim_C, \mathsf{Ops}, \mathsf{Laws}, \mathsf{Cong}, \mathsf{Ledger}, \mathsf{NameCert}).$$

The operation field records the displayed operation rows. The law field records the algebraic equations available at classifier resolution. The congruence field records transport of every operation through the classifier. The ledger field records finite expression provenance and normalization routes.

Principle 9355.4 (Algebra is certificate-facing)**.** *Every L8 interface is admitted only through an algebraic interface certificate. A familiar notation such as multiplication, inverse, scalar action, or vector addition is therefore a public name for displayed carrier, classifier, operation, law, congruence, and ledger rows.*

Concretized in §3341: The algebraic expression ledger realizes the operation-provenance rows of the algebra interface spine as finite NameCert data.

9355.2 Magma Through Monoid

Definition 9355.5 (Magma interface)**.** *A* $\mathsf{Magma}^{\uparrow}$ *interface is an admitted carrier-classifier pair* $(C, \sim_C)$ *with one stable binary operation* μ*. Its certificate records closure of* μ*, binary congruence of* μ*, and an operation ledger. It does not contain associativity, identity, inverse, or commutativity rows.*

Theorem 9355.6 (Magma operation descends to classifier classes)**.** *If* μ *satisfies binary congruence, then replacing either input by a classified input does not change the output classifier class.*

Proof. Given $x \sim_C x'$ and $y \sim_C y'$, binary congruence gives

$$\mu(x, y) \sim_C \mu(x', y').$$

This is exactly the descent condition for the public operation read. □

Definition 9355.7 (Semigroup interface)**.** *A* $\mathsf{Semigroup}^{\uparrow}$ *interface is a* $\mathsf{Magma}^{\uparrow}$ *interface with associativity:*

$$C(x) \wedge C(y) \wedge C(z) \Longrightarrow \mu(\mu(x, y), z) \sim_C \mu(x, \mu(y, z)).$$

Theorem 9355.8 (Fourfold rebracketing)**.** *In a* $\mathsf{Semigroup}^{\uparrow}$ *interface,*

$$\mu(\mu(\mu(a, b), c), d) \sim_C \mu(a, \mu(b, \mu(c, d))).$$

Proof. Apply associativity to the first three factors, then use binary congruence to move the rebracketing inside the outer product. Apply associativity once more to move the final factor into the right-nested expression. □

Definition 9355.9 (Monoid interface)**.** *A* $\mathsf{Monoid}^{\uparrow}$ *interface is a* $\mathsf{Semigroup}^{\uparrow}$ *interface with a displayed unit* e_C *satisfying*

$$C(e_C), \qquad \mu(e_C, x) \sim_C x, \qquad \mu(x, e_C) \sim_C x.$$

Theorem 9355.10 (Unit uniqueness)**.** *If* e *and* u *are both two-sided units for the same monoid operation, then* $e \sim_C u$*.*

Proof. Since u is a right unit, $\mu(e, u) \sim_C e$. Since e is a left unit, $\mu(e, u) \sim_C u$. Symmetry and transitivity of the classifier give $e \sim_C u$. □

Corollary 9355.11 (Unit normalization)**.** *Finite monoid expressions containing unit leaves normalize, at classifier resolution, to expressions in which those unit leaves have been removed.*

Proof. Induct on the expression tree. At a node $\mu(e_C, x)$ or $\mu(x, e_C)$, use the corresponding unit law. Binary congruence transports the substitution term through the enclosing expression contexts. □

9355.3 Groups

Definition 9355.12 (Group interface)**.** *A* $\mathsf{Group}^{\uparrow}$ *interface is a* $\mathsf{Monoid}^{\uparrow}$ *interface with a stable inverse operation* ι *satisfying*

$$C(x) \Longrightarrow C(\iota(x)), \qquad x \sim_C y \Longrightarrow \iota(x) \sim_C \iota(y),$$

and

$$\mu(\iota(x), x) \sim_C e_C, \qquad \mu(x, \iota(x)) \sim_C e_C.$$

Theorem 9355.13 (Group cancellation)**.** *In a* $\mathsf{Group}^{\uparrow}$ *interface, left and right multiplication by the same carried element are cancellable at classifier resolution.*

Proof. For left cancellation, assume $\mu(a, b) \sim_C \mu(a, c)$. Multiply both sides on the left by $\iota(a)$ and use binary congruence. Associativity rewrites the two sides as

$$\mu(\mu(\iota(a), a), b) \sim_C \mu(\mu(\iota(a), a), c).$$

The left inverse law turns the inner products into e_C, and the left unit law gives $b \sim_C c$. Right cancellation is the symmetric argument using right multiplication by $\iota(a)$. □

Theorem 9355.14 (Inverse uniqueness)**.** *If*

$$\mu(y, x) \sim_C e_C \qquad \textit{and} \qquad \mu(x, z) \sim_C e_C,$$

then $y \sim_C z$.

Proof. Use the chain

$$y \sim_C \mu(y, e_C) \sim_C \mu(y, \mu(x, z)) \sim_C \mu(\mu(y, x), z) \sim_C \mu(e_C, z) \sim_C z.$$

Each step is a unit law, associativity, the displayed inverse witness, or classifier transport through the operation. □

Definition 9355.15 (Abelian group interface)**.** *An* $\mathsf{AbGroup}^{\uparrow}$ *interface is a* $\mathsf{Group}^{\uparrow}$ *interface with commutativity:*

$$\mu(x, y) \sim_C \mu(y, x).$$

Theorem 9355.16 (Balanced cancellation)**.** *In an* $\mathsf{AbGroup}^{\uparrow}$ *interface, if*

$$\mu(a, b) \sim_C \mu(c, a),$$

then $b \sim_C c$.

Proof. Commutativity changes the right side to $\mu(a, c)$. Left cancellation in Definition 9355.13 then gives $b \sim_C c$. □

9355.4 Rings and Fields

Definition 9355.17 (Ring interface)**.** *A* $\mathsf{Ring}^{\uparrow}$ *interface is one carrier-classifier pair* $(C, \sim_C)$ *equipped with an additive* $\mathsf{AbGroup}^{\uparrow}$ *structure* $(+, 0, -)$*, a multiplicative* $\mathsf{Monoid}^{\uparrow}$ *structure* $(\cdot, 1)$*, and left and right distributivity:*

$$x \cdot (y + z) \sim_C x \cdot y + x \cdot z,$$

$$(x + y) \cdot z \sim_C x \cdot z + y \cdot z.$$

Its ledger records expression trees containing $0, 1, +, -, \cdot$ *together with the distributivity and sign-propagation rows used by normalization.*

Theorem 9355.18 (Zero multiplication)**.** *In a* $\mathsf{Ring}^{\uparrow}$ *interface,*

$$0 \cdot x \sim_C 0, \qquad x \cdot 0 \sim_C 0.$$

Proof. For the left zero law, use $0 + 0 \sim_C 0$ and multiply by x on the right. Right distributivity gives

$$(0 + 0) \cdot x \sim_C 0 \cdot x + 0 \cdot x.$$

The left side is classified with $0 \cdot x$, so additive cancellation in the underlying $\mathsf{AbGroup}^{\uparrow}$ gives $0 \cdot x \sim_C 0$. The right zero law is the same argument with left distributivity. □

Theorem 9355.19 (Negative products)**.** *In a* $\mathsf{Ring}^{\uparrow}$ *interface,*

$$(-x) \cdot y \sim_C -(x \cdot y), \qquad x \cdot (-y) \sim_C -(x \cdot y).$$

Proof. For the first identity, distribute $(-x + x) \cdot y$. The term $-x + x$ classifies with 0, and zero multiplication gives the zero endpoint. Thus $(-x) \cdot y + x \cdot y \sim_C 0$, so $(-x) \cdot y$ is an additive inverse of $x \cdot y$. Inverse uniqueness in the additive group gives the claim. The second identity is identical on the other side. □

Definition 9355.20 (Commutative ring interface)**.** *A* $\mathsf{CommRing}^{\uparrow}$ *interface is a* $\mathsf{Ring}^{\uparrow}$ *interface whose multiplication is commutative:*

$$x \cdot y \sim_C y \cdot x.$$

Theorem 9355.21 (Distributivity side transport)**.** *In a* $\mathsf{CommRing}^{\uparrow}$ *interface, either distributivity side implies the other.*

Proof. Assume left distributivity. Then

$$(x + y) \cdot z \sim_C z \cdot (x + y)$$

by multiplicative commutativity. Left distributivity gives $z \cdot x + z \cdot y$, and commutativity plus additive congruence transports that expression to $x \cdot z + y \cdot z$. The converse is symmetric. □

Definition 9355.22 (Field interface)**.** *A* $\mathsf{Field}^{\uparrow}$ *interface is a* $\mathsf{CommRing}^{\uparrow}$ *interface with an explicit apart-zero predicate* $\mathsf{NonZero}(x)$*, an inverse operation indexed by that witness,*

$$\mathrm{inv}(x, p) \qquad (p : \mathsf{NonZero}(x)),$$

inverse laws

$$x \cdot \mathrm{inv}(x, p) \sim_C 1, \qquad \mathrm{inv}(x, p) \cdot x \sim_C 1,$$

and nonzero transport along the classifier. The inverse is proof-indexed by apartness data, not by a host-level negated equality.

Theorem 9355.23 (Nonzero cancellation)**.** *If* $p : \mathsf{NonZero}(a)$ *and*

$$a \cdot x \sim_C a \cdot y,$$

then $x \sim_C y$*.*

Proof. Multiply both sides by $\mathrm{inv}(a, p)$ and use congruence. Associativity rewrites the two sides to

$$(\mathrm{inv}(a, p) \cdot a) \cdot x \sim_C (\mathrm{inv}(a, p) \cdot a) \cdot y.$$

The inverse law changes both left factors to 1, and the unit law gives $x \sim_C y$. □

Principle 9355.24 (Field boundary)**.** $\mathsf{Field}^{\uparrow}$ *is admitted only after the carrier, classifier, commutative-ring base, apart-zero predicate, proof-indexed inverse, inverse laws, transport, and ledger exactness rows are displayed. It is not a field primitive and it does not use excluded-middle reasoning to form inverses.*

9355.5 Modules and Vector Spaces

Definition 9355.25 (Module interface)**.** *Let* R *be a* $\mathsf{Ring}^{\uparrow}$ *scalar source and let* M *be an additive* $\mathsf{AbGroup}^{\uparrow}$ *carrier. A* $\mathsf{Module}^{\uparrow}$ *interface adds a stable scalar action*

$$R \times M \to M$$

with scalar-action congruence, scalar associativity,

$$(rs) \cdot m \sim_M r \cdot (s \cdot m),$$

distributivity over vector addition,

$$r \cdot (m + n) \sim_M r \cdot m + r \cdot n,$$

distributivity over scalar addition,

$$(r + s) \cdot m \sim_M r \cdot m + s \cdot m,$$

and scalar unit law $1 \cdot m \sim_M m$*.*

Theorem 9355.26 (Module zero and negative scalar laws)**.** *In a* $\mathsf{Module}^{\uparrow}$ *interface,*

$$0_R \cdot m \sim_M 0_M, \qquad (-r) \cdot m \sim_M -(r \cdot m).$$

Proof. For the zero scalar law, use $0_R + 0_R \sim_R 0_R$ and scalar distributivity over scalar addition:

$$(0_R + 0_R) \cdot m \sim_M 0_R \cdot m + 0_R \cdot m.$$

The left side is classified with $0_R \cdot m$, and additive cancellation in the module carrier gives $0_R \cdot m \sim_M 0_M$. For the negative scalar law, apply the same argument to $(-r+r) \cdot m$ and use inverse uniqueness in the additive group of M. □

Definition 9355.27 (Vector-space interface)**.** *A* $\mathsf{VecSpace}^{\uparrow}(F, V)$ *interface is a* $\mathsf{Module}^{\uparrow}(F, V)$ *interface whose scalar source is a* $\mathsf{Field}^{\uparrow}$ *interface. It requires no further operation field; the scalar source is strengthened from ring to field.*

Theorem 9355.28 (Nonzero scalar cancellation)**.** *If* $p : \mathsf{NonZero}(a)$ *and*

$$a \cdot v \sim_V a \cdot w,$$

then $v \sim_V w$*.*

Proof. Act on both sides by $\mathrm{inv}(a, p)$. Scalar associativity changes the two sides to

$$(\mathrm{inv}(a, p)a) \cdot v \sim_V (\mathrm{inv}(a, p)a) \cdot w.$$

The field inverse law identifies the scalar factor with 1, and scalar unit gives $v \sim_V w$. □

9355.6 Algebra Layer Boundary

Theorem 9355.29 (Algebra interface admission theorem)**.** *If the interfaces*

$\mathsf{Magma}^{\uparrow}$, $\mathsf{Semigroup}^{\uparrow}$, $\mathsf{Monoid}^{\uparrow}$, $\mathsf{Group}^{\uparrow}$, $\mathsf{AbGroup}^{\uparrow}$, $\mathsf{Ring}^{\uparrow}$, $\mathsf{CommRing}^{\uparrow}$, $\mathsf{Field}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{VecSpac}$

carry their advertised carrier, classifier, operation stability, congruence, law, ledger, and $\mathsf{NameCert}$ *rows, then the L8 algebra hierarchy is admitted. Each layer consumes only the rows exposed by the preceding layers and the additional rows named by its own certificate.*

Proof. $\mathsf{Magma}^{\uparrow}$ supplies one stable binary operation. $\mathsf{Semigroup}^{\uparrow}$ adds associativity. $\mathsf{Monoid}^{\uparrow}$ adds a unit. $\mathsf{Group}^{\uparrow}$ adds inverse rows. $\mathsf{AbGroup}^{\uparrow}$ adds commutativity. $\mathsf{Ring}^{\uparrow}$ combines an additive $\mathsf{AbGroup}^{\uparrow}$, a multiplicative $\mathsf{Monoid}^{\uparrow}$, and distributivity on the same carrier-classifier pair. $\mathsf{CommRing}^{\uparrow}$ adds multiplicative commutativity. $\mathsf{Field}^{\uparrow}$ adds apart-zero and proof-indexed inverse data. $\mathsf{Module}^{\uparrow}$ adds a scalar action over a ring and an additive abelian group. $\mathsf{VecSpace}^{\uparrow}$ specializes the scalar source to a field. All rows are certificate fields with ledgers, so no algebraic layer enters as a kernel primitive. □

Principle 9355.30 (Downstream algebra consumption)**.** *Later analytic, spectral, zeta-facing, and linear-algebraic packets may read L8 only through the displayed algebraic ledgers: expression trees, operation closure, congruence, normalization routes, inverse apartness witnesses, distributivity rows, and scalar-action rows. They may not replace these rows by host algebra, quotient equality, hidden inverses, or ambient vector-space facts.*

Chapter 9356

Order Set Type Interface Spine

The algebra spine exposes stable operations and their classifier-respecting laws. The next kernel-facing layer exposes stable comparison, membership, and transport. In the layer indexed by section 9467.11, the order–set–type surface is the certificate family

$$\mathsf{Preorder}^{\uparrow},\quad \mathsf{Poset}^{\uparrow},\quad \mathsf{TotalOrder}^{\uparrow},\quad \mathsf{Lattice}^{\uparrow},\quad \mathsf{SetLike}^{\uparrow},\quad \mathsf{TypeLike}^{\uparrow}.$$

The common rule is that no relation, membership predicate, subset relation, or typed family enters as an ambient object. Each is read through a carried source, a public classifier, stability rows, a ledger, and a local $\mathsf{NameCert}$.

Concretized in §8909: Finite membership classifier rows realize the order–set–type interface through displayed source, member, witness, stability, ledger, transport, replay, provenance, and NameCert rows.

9356.1 Relational Certificate Template

Definition 9356.1 (Relational interface)**.** *Let $(C, \sim_C)$ be an admitted carrier-classifier pair with*

$$C : \mathsf{Hist} \to \mathsf{Prop} \qquad \textit{and} \qquad \sim_C : \mathsf{Hist} \to \mathsf{Hist} \to \mathsf{Prop}.$$

A relational interface over this carrier is a packet

$$\mathcal{R} = (C, \sim_C, R, \mathsf{Stab}_R, \mathsf{Cong}_R, \mathsf{Ledger}_R, \mathsf{NameCert}_R),$$

where $R : \mathsf{Hist} \to \mathsf{Hist} \to \mathsf{Prop}$ is the displayed binary relation. The stability row records the law profile required by the interface name, the congruence row records classifier transport in both endpoints, and the ledger records the source of each comparison witness.

Definition 9356.2 (Relation congruence)**.** *The relation R respects the carrier classifier when*

$$C(x) \wedge C(y) \wedge C(x') \wedge C(y') \wedge x \sim_C x' \wedge y \sim_C y' \wedge R(x, y) \Longrightarrow R(x', y').$$

This row is part of the public relation interface, not an after-the-fact identification of representatives.

Principle 9356.3 (Relational primitive boundary)**.** *An L9 relation is admitted only through the displayed tuple*

$$C,\ \sim_C,\ R,\ \mathsf{Stab}_R,\ \mathsf{Cong}_R,\ \mathsf{Ledger}_R,\ \mathsf{NameCert}_R.$$

Order, elementhood, subset inclusion, and family transport are therefore licensed interface rows rather than kernel primitives.

9356.2 Preorders and Posets

Definition 9356.4 (Preorder interface)**.** *A* $\mathsf{Preorder}^{\uparrow}$ *interface is a relational interface* $(C, \sim_C, \leq_C)$ *with reflexivity and transitivity:*

$$C(x) \Longrightarrow x \leq_C x,$$

and

$$x \leq_C y \wedge y \leq_C z \Longrightarrow x \leq_C z.$$

It also carries relation congruence under $\sim_C$ *and a comparison ledger.*

Definition 9356.5 (Unary prefix preorder read)**.** *The concrete prefix read uses the unary-history carrier* $C(h) := \mathsf{Unary}(h)$*, the carrier-aware classifier*

$$h \sim_C k \Longleftrightarrow \mathsf{Unary}(h) \wedge \mathsf{Unary}(k) \wedge \mathsf{hsame}(h, k),$$

and the prefix relation

$$h \leq_C k \Longleftrightarrow \exists t \left(\mathsf{Unary}(t) \wedge \mathsf{Cont}(h, t, k)\right).$$

The comparison ledger records the tail t *and the continuation witness.*

Theorem 9356.6 (Prefix preorder laws)**.** *The unary prefix read supplies reflexivity, transitivity, and endpoint congruence for* $\mathsf{Preorder}^{\uparrow}$*.*

Proof. For reflexivity, take the empty unary tail and the right-unit continuation row. For transitivity, compose the two displayed continuation witnesses and use unary closure of the composed tail. For congruence, transport the source and endpoint histories along the two hsame rows in the carrier classifier; continuation stability supplies the transported comparison. □

Definition 9356.7 (Poset interface)**.** *A* $\mathsf{Poset}^{\uparrow}$ *interface is a* $\mathsf{Preorder}^{\uparrow}$ *interface with antisymmetry under the carrier classifier:*

$$x \leq_C y \wedge y \leq_C x \Longrightarrow x \sim_C y.$$

The existing concrete chapters also use the spelling $\mathsf{POSet}^{\uparrow}$ *for this partial-order surface; the present layer reads it through the public* $\mathsf{Poset}^{\uparrow}$ *macro.*

Theorem 9356.8 (Prefix antisymmetry)**.** *For the unary prefix carrier, opposing prefix comparisons classify the two endpoints:*

$$h \leq_C k \wedge k \leq_C h \Longrightarrow h \sim_C k.$$

Proof. The first comparison gives a unary tail t and a continuation $\mathsf{Cont}(h, t, k)$. The second gives a unary tail u and a continuation $\mathsf{Cont}(k, u, h)$. Composing the continuations yields a loop from h back to h through the combined tail. The append-empty inversion and right-unit uniqueness rows force the forward tail to be classified as empty, so the first comparison endpoint k is classified with h. This is exactly the carrier classifier conclusion $h \sim_C k$. □

Corollary 9356.9 (Poset exactness for prefix reads)**.** *On the unary prefix carrier,*

$$h \sim_C k \Longleftrightarrow (h \leq_C k \wedge k \leq_C h).$$

Proof. The forward direction transports reflexive prefix comparisons along the classifier row. The reverse direction is Definition 9356.8. □

9356.3 Total Orders and Lattices

Definition 9356.10 (Total-order interface)**.** *A* $\mathsf{TotalOrder}^{\uparrow}$ *interface is a* $\mathsf{Poset}^{\uparrow}$ *interface with explicit comparison data. For carried endpoints it supplies a displayed comparison branch, strict-to-apartness transport, classifier-stable comparison transport, and strict transitivity whenever the strict row is part of the packet. Its totality is data-bearing; it is not an excluded-middle assertion.*

Theorem 9356.11 (Unary comparison is certificate data)**.** *For unary prefix endpoints, a total-order read may be given by finite comparison data choosing one of the two prefix directions, with the equality branch read through the* $\mathsf{Poset}^{\uparrow}$ *exactness row.*

Proof. Unary histories are finite continuation spines. Compare the spines by structural inspection: the empty endpoint is a prefix of every unary endpoint, and equal leading unary extensions reduce the comparison to their tails. The selected branch is recorded as an explicit prefix witness. When both directions are present, Definition 9356.9 returns the classifier branch rather than a host equality. □

Definition 9356.12 (Lattice interface)**.** *A* $\mathsf{Lattice}^{\uparrow}$ *interface is a* $\mathsf{Poset}^{\uparrow}$ *interface with stable meet and join operations. For* $m = x \wedge y$*, the certificate records*

$$m \leq_C x, \qquad m \leq_C y,$$

and greatestness

$$z \leq_C x \wedge z \leq_C y \Longrightarrow z \leq_C m.$$

For $j = x \vee y$*, it records*

$$x \leq_C j, \qquad y \leq_C j,$$

and leastness

$$x \leq_C z \wedge y \leq_C z \Longrightarrow j \leq_C z.$$

Meet and join congruence, together with the bound-characterization ledger, complete the certificate.

Theorem 9356.13 (Meet and join uniqueness)**.** *In a* $\mathsf{Lattice}^{\uparrow}$ *interface, two displayed meets of the same pair are classified the same, and two displayed joins of the same pair are classified the same.*

Proof. If m and m' are both meets of x and y, then m is a lower bound, so greatestness of m' gives $m \leq_C m'$. Similarly m' is a lower bound, so greatestness of m gives $m' \leq_C m$. Poset antisymmetry gives $m \sim_C m'$. The join case is dual: upper-bound rows and leastness give the two comparisons, and antisymmetry gives the classifier conclusion. □

Theorem 9356.14 (Lattice laws from bounds)**.** *The idempotence, commutativity, and absorption laws for meet and join are classifier consequences of their bound-characterization rows.*

Proof. For idempotence, x is both a lower bound and an upper bound of the pair (x, x) by reflexivity. Greatestness and leastness supply the reverse comparisons against $x \wedge x$ and $x \vee x$, and antisymmetry gives the classifier equalities.

For commutativity, the lower-bound rows for $x \wedge y$ also make it a lower bound of (y, x), so greatestness gives $x \wedge y \leq_C y \wedge x$; the reverse comparison is identical with the operands exchanged. Joins are dual. For absorption, use the join upper-bound row $x \leq_C x \vee y$ to make x a lower bound of $(x, x \vee y)$; the meet lower-bound row supplies the opposite comparison. The second absorption law is dual. □

9356.4 Set-Like Membership

Definition 9356.15 (Set-like interface)**.** *For an element carrier $(E, \sim_E)$, a $\mathsf{SetLike}^{\uparrow}$ object is not an ambient set. It is a finite packet containing a generated membership predicate, membership stability under $\sim_E$, subset implication, restricted comprehension, an extensionality boundary, a ledger, and a local $\mathsf{NameCert}_{\mathsf{SetLike}^{\uparrow}}$ row.*

Definition 9356.16 (Membership stability and subset)**.** *Membership in a set-like object S is stable when*

$$x \sim_E y \wedge x \in_S \Longrightarrow y \in_S .$$

The subset relation is implication of membership:

$$S \subseteq T \Longleftrightarrow \prod_{x:E} (x \in_S \Longrightarrow x \in_T).$$

Both rows are read through the membership ledger; neither is a host powerset relation.

Definition 9356.17 (Restricted comprehension)**.** *A predicate family $P : E \to \mathsf{Prop}$ may define a set-like object only when it carries classifier stability,*

$$x \sim_E y \wedge P(x) \Longrightarrow P(y),$$

together with a predicate-generation ledger and a local name certificate. The comprehension row is therefore a bounded consumer of certified membership data.

Theorem 9356.18 (Subset preorder)**.** *For $\mathsf{SetLike}^{\uparrow}$ objects over the same element carrier, subset implication is reflexive and transitive.*

Proof. Reflexivity sends each membership witness $x \in_S$ to itself. For transitivity, compose the two displayed implication rows:

$$x \in_S \Longrightarrow x \in_T \Longrightarrow x \in_U .$$

The proof uses only the membership ledger and implication rows. □

Theorem 9356.19 (Set-like extensionality is a certificate field)**.** *If the extensionality boundary for S and T is available and*

$$S \subseteq T \qquad \text{and} \qquad T \subseteq S,$$

then S and T are classified as the same set-like object.

Proof. Apply the displayed extensionality boundary row to the two subset implications. The conclusion is the set-like classifier row recorded by the packet, not an ambient equality of host sets. □

Principle 9356.20 (Membership generation boundary)**.** *Every accepted membership read of a $\mathsf{SetLike}^{\uparrow}$ packet must expose the membership source, the classifier row, transport, replay, provenance, and the local name certificate. A downstream consumer may not replace this route by host elementhood, unrestricted separation, selected representatives, a powerset coordinate, or quotient equality of sets.*

9356.5 Type-Like Transport

Definition 9356.21 (Type-like interface)**.** *A* $\mathsf{TypeLike}^{\uparrow}$ *interface is a displayed family packet*

$$T = (B, F, Q, E, H, C, P, N).$$

Here B is the base classifier family, F is the indexed fiber-carrier row, Q is the family-compatible classifier, E is the endpoint-exactness ledger, H records componentwise hsame *transport, C records displayed* Cont *replay, P records provenance, and N is the local* $\mathsf{NameCert}_{\mathsf{TypeLike}^{\uparrow}}$ *row.*

Definition 9356.22 (Type-like transport)**.** *The transport row of a* $\mathsf{TypeLike}^{\uparrow}$ *packet has the form*

$$A(x) \wedge x \sim_A y \Longrightarrow A(y),$$

or, in displayed-family form, it preserves the base classifier, the indexed fiber carrier, the family-compatible classifier, and the endpoint-exactness ledger before any sibling consumer may read the endpoint.

Definition 9356.23 (Map-like object)**.** *For type-like interfaces A and B, a map-like object is an operation interface that sends carried A endpoints to carried B endpoints and respects classifiers:*

$$x \sim_A x' \Longrightarrow f(x) \sim_B f(x').$$

The operation is therefore a classifier-stable transport surface, not a bare host function.

Theorem 9356.24 (Transport core)**.** *If $A^{\uparrow}$ is a* $\mathsf{TypeLike}^{\uparrow}$ *interface, $A(x)$ holds, and $x \sim_A y$, then $A(y)$ holds.*

Proof. This is the transport row of the type-like certificate. The row preserves the carrier through the classifier and records the movement in the ledger. □

Principle 9356.25 (Type-like host boundary)**.** $\mathsf{TypeLike}^{\uparrow}$ *is not a host universe. Its public content is the displayed carrier, classifier, transport, endpoint-exactness, replay, provenance, and name-certificate route. It does not provide quotient type equality, impredicative comprehension, selected representatives, or an external category of all families.*

9356.6 L9 Boundary

Theorem 9356.26 (Order set type admission theorem)**.** *If*

$$\mathsf{Preorder}^{\uparrow}, \quad \mathsf{Poset}^{\uparrow}, \quad \mathsf{TotalOrder}^{\uparrow}, \quad \mathsf{Lattice}^{\uparrow}, \quad \mathsf{SetLike}^{\uparrow}, \quad \mathsf{TypeLike}^{\uparrow}$$

carry their advertised carrier, classifier, stability, congruence, membership-generation, transport, extensionality, ledger, and $\mathsf{NameCert}$ *rows, then the L9 order–set–type layer is admitted.*

Proof. $\mathsf{Preorder}^{\uparrow}$ supplies a reflexive and transitive relation over a carried classifier. $\mathsf{Poset}^{\uparrow}$ adds antisymmetry under that classifier. $\mathsf{TotalOrder}^{\uparrow}$ adds explicit comparison data and constructive apartness transport. $\mathsf{Lattice}^{\uparrow}$ adds meet and join operations through their bound characterizations. $\mathsf{SetLike}^{\uparrow}$ supplies generated membership, subset as membership implication, restricted comprehension, and an extensionality boundary. $\mathsf{TypeLike}^{\uparrow}$ supplies carrier-plus-classifier-plus-transport data for displayed families. Since each row is part of a finite certified route, no order, membership, set, or type interface is imported as a kernel primitive or host-level object. □

Principle 9356.27 (Downstream L9 consumption)**.** *Analytic, zeta-facing, completion, spectral, and model-theoretic packets may consume L9 only through its displayed rows: comparison ledgers, classifier transport, membership-generation ledgers, subset implications, restricted comprehension routes, extensionality boundaries, and type-like transport. They may not replace these rows by classical trichotomy, unrestricted membership, ambient powersets, quotient type equality, or host universes.*

Chapter 9357

Countable Completion Interface Spine

The order–set–type spine permits membership, comparison, and transport to be read through certified carriers. The completion layer crosses the boundary from finite history objects to certified countable names. A single finite Hist value does not encode an infinite object; it can only expose a finite observation, a replay route, and the certificate rows authorizing that observation. The L10 surface therefore factors through

$$\mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow},\quad \mathsf{Met}^{\uparrow},\quad \mathsf{Topology}^{\uparrow},\quad \mathsf{Completion}^{\uparrow},$$

together with $\mathsf{CompleteMetric}^{\uparrow}$, $\mathsf{CompactMetric}^{\uparrow}$, and $\mathsf{ContinuousMap}^{\uparrow}$ where the metric side is consumed. Each object is a visible countable-name or modulus-bearing interface, never a host quotient, selected limit, or ambient complete space.

9357.1 Countable Names

Definition 9357.1 (Finite-history object)**.** *An object is finite-history presented when every public row is ultimately read through finitely many constructor, continuation, signature, package, and name-certificate observations over* Hist*. Such a row may name a finite observation of an infinite process, but it is not itself the completed process.*

Definition 9357.2 (Countable name over a carrier)**.** *Let* $(X, \sim_X)$ *be a certified carrier-classifier pair. An* X*-countable name is an observation map* $s : \mathsf{Nat}^{\uparrow} \to X$ *with rows*

$$\forall n : \mathsf{Nat}^{\uparrow},\ X(s(n)),$$

and

$$n \sim_{\mathsf{Nat}^{\uparrow}} m \Longrightarrow s(n) \sim_X s(m).$$

Two such names classify together when all displayed observations classify pointwise:

$$s \sim_{\mathsf{stream}} t \Longleftrightarrow \forall n : \mathsf{Nat}^{\uparrow},\ s(n) \sim_X t(n).$$

Definition 9357.3 (StreamName carrier and classifier)**.** *The* $\mathsf{StreamName}^{\uparrow}$ *carrier over* X *is*

$$\mathsf{StreamCarrier}_X(s) \Longleftrightarrow \forall n : \mathsf{Nat}^{\uparrow},\ X(s(n)).$$

Its classifier is

$$\mathsf{StreamSame}_X(s,t) \Longleftrightarrow \forall n : \mathsf{Nat}^{\uparrow},\ s(n) \sim_X t(n).$$

The public ledger stores finite windows, pointwise classifier rows, reindexing routes, replay, provenance, and the local name certificate.

Theorem 9357.4 (Pointwise stream classifier)**.** *If $\sim_X$ is an equivalence classifier, then* $\mathsf{StreamSame}_X$ *is an equivalence classifier on stream names.*

Proof. Reflexivity is pointwise reflexivity of $\sim_X$. Symmetry sends each row $s(n) \sim_X t(n)$ to $t(n) \sim_X s(n)$. Transitivity composes the pointwise rows $s(n) \sim_X t(n)$ and $t(n) \sim_X u(n)$ to obtain $s(n) \sim_X u(n)$. The stream ledger records the same unary observation index in every step. □

Principle 9357.5 (Countable-name boundary)**.** *An infinite object in L10 is a certified countable name together with pointwise stability. It is not a single history, a host sequence, a quotient class, or a selected global limit.*

9357.2 Dyadic Rational Core

Definition 9357.6 (Dyadic rational code)**.** *A* $\mathsf{DyadicRatCore}^{\uparrow}$ *code is a signed integer mantissa with unary exponent, displayed as*

$$(a, n) \qquad a : \mathsf{Int}^{\uparrow}, \quad n : \mathsf{Nat}^{\uparrow},$$

and read as the dyadic value $a \cdot 2^{-n}$. The carrier is inherited from the signed-pair and unary-exponent spines.

Definition 9357.7 (Common-exponent dyadic classifier)**.** *Two dyadic codes classify together when they agree after scaling to a common unary exponent:*

$$(a, n) \sim_{\mathsf{dyad}} (b, m)$$

when there is k with $k \geq n$ and $k \geq m$ such that

$$a \cdot 2^{k-n} \sim_{\mathsf{Int}^{\uparrow}} b \cdot 2^{k-m}.$$

The witness is a comparison and scaling ledger, not a quotient representative.

Theorem 9357.8 (Dyadic classifier laws)**.** *The common-exponent classifier is reflexive, symmetric, and transitive.*

Proof. For reflexivity, use the same exponent $k = n$ and the multiplicative unit row on $\mathsf{Int}^{\uparrow}$. Symmetry reuses the same common exponent and reverses the $\mathsf{Int}^{\uparrow}$ classifier row. For transitivity, combine two common-exponent witnesses by taking a displayed exponent above both, scaling both equalities to that exponent, and composing the resulting $\mathsf{Int}^{\uparrow}$ classifier rows. □

Definition 9357.9 (Dyadic distance data)**.** *The dyadic absolute value and distance rows are*

$$|q|_{\mathsf{dyad}} \qquad \textit{and} \qquad d_{\mathsf{dyad}}(q, r) := |q - r|_{\mathsf{dyad}}.$$

Their certificate records arithmetic stability, order transport, monotone radii 2^{-n}, and classifier compatibility of subtraction and absolute value.

Principle 9357.10 (Dyadic core boundary)**.** $\mathsf{DyadicRatCore}^{\uparrow}$ *is the finite arithmetic substrate for L10 tolerances. It uses common-exponent predicates and integer arithmetic rows, not quotient types or host rational equality.*

9357.3 Regular Sequences and Real Names

Definition 9357.11 (Regular dyadic sequence)**.** *A regular dyadic sequence is a stream* $x : \mathsf{Nat}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow}$ *with regularity certificate*

$$\mathsf{Reg}(x) \iff \forall m\, n : \mathsf{Nat}^{\uparrow}, |x_m - x_n| \leq 2^{-m} + 2^{-n}.$$

Thus a $\mathsf{RegSeqRat}^{\uparrow}$ *carrier is a* $\mathsf{StreamName}^{\uparrow}$ *over* $\mathsf{DyadicRatCore}^{\uparrow}$ *together with this displayed Cauchy bound.*

Definition 9357.12 (Regular-sequence classifier)**.** *Two regular dyadic sequences classify together when every requested dyadic tolerance is met by a displayed tail comparison. Equivalently, in a fixed regular scale one may read rows of the form*

$$\forall n : \mathsf{Nat}^{\uparrow},\ |x_n - y_n| \leq 2^{-n},$$

with the ledger allowing reindexing, halving, and tail transport.

Theorem 9357.13 (Regular-sequence classifier laws)**.** *The regular-sequence classifier is reflexive, symmetric, and transitive when dyadic absolute value, order transport, and halving rows are available.*

Proof. Reflexivity uses $|x_n - x_n| = 0$ and $0 \leq 2^{-n}$. Symmetry uses absolute-value symmetry. For transitivity at tolerance ε, read the two comparison rows at $\varepsilon/2$ and apply the triangle inequality:

$$|x_n - z_n| \leq |x_n - y_n| + |y_n - z_n| \leq \varepsilon.$$

The halving row is explicit dyadic data, so no classical choice is used. □

Definition 9357.14 (Real carrier and classifier)**.** *A* $\mathsf{Real}^{\uparrow}$ *carrier is a sealed regular-sequence name*

$$r = \mathsf{Seal}(x, \mathsf{Reg}(x)).$$

Two sealed real names classify together when their exposed $\mathsf{RegSeqRat}^{\uparrow}$ *representatives classify:*

$$r \sim_{\mathsf{Real}^{\uparrow}} s \iff x \sim_{\mathsf{reg}} y.$$

The seal ledger controls which representative rows are visible to a consumer.

Definition 9357.15 (Constant real embedding)**.** *A certified dyadic or rational point* d *embeds as the sealed constant stream*

$$\iota(d) := \mathsf{Seal}(\lambda n.\, d, \mathsf{constant_regularity}).$$

On the history surface, the constant-real carrier is the row saying that the history is classified with an E_1*-seal of a certified rational endpoint.*

Theorem 9357.16 (Constant real seal boundary)**.** *The* E_1 *constant seal exposes exactly the carried rational endpoint, and an* E_0 *seal cannot expose a constant real endpoint.*

Proof. For an E_1 seal, constructor injectivity transports the rational carrier between the displayed endpoint and the endpoint named by the seal. For an E_0 seal, the assumed constant-real row would contain an hsame witness between an E_0 constructor and an E_1 constructor, contradicting constructor no-confusion. □

Theorem 9357.17 (Real classifier transfer)**.** *If the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier is an equivalence classifier, then the* $\mathsf{Real}^{\uparrow}$ *classifier is an equivalence classifier.*

Proof. Unseal a real name only through the displayed seal ledger. Reflexivity, symmetry, and transitivity are exactly the corresponding regular-sequence classifier rows transported through that ledger. □

Principle 9357.18 (Real primitive boundary)**.** $\mathsf{Real}^{\uparrow}$ *is a sealed regular Cauchy name. It is not a quotient set of sequences, not a Dedekind cut imported from a host universe, and not a completed scalar field until the relevant algebra, order, apartness, and operation-closure rows are supplied.*

9357.4 Completion

Definition 9357.19 (Regular Cauchy sequence with modulus)**.** *For a metric or regular-sequence carrier, a completion input is a sequence* $X : \mathsf{Nat}^{\uparrow} \to A$ *with an explicit modulus*

$$\mu : \mathbb{Q}^{\uparrow}_{>0} \to \mathsf{Nat}^{\uparrow}$$

such that, whenever $m, n \geq \mu(\varepsilon)$*, the distance between* X_m *and* X_n *lies inside the displayed* ε*-ball at zero.*

Definition 9357.20 (Diagonal representative)**.** *For a regular Cauchy sequence of regular dyadic names, the diagonal representative is*

$$L_n := X_{\mu(1/(n+1))}\big(\mu(1/(n+1)) + n + 1\big).$$

The ledger records the modulus request, the selected sequence member, the internal observation index, and the dyadic value returned by that observation.

Theorem 9357.21 (Diagonal regularity)**.** *The diagonal representative is regular when the constituent regularity rows, the Cauchy modulus, dyadic halving, and triangle inequality are available.*

Proof. Compare L_m and L_n by inserting a common observation scale. The difference splits into three displayed parts: movement inside the first regular sequence member, movement between the two sequence members controlled by the Cauchy modulus, and movement inside the second regular sequence member. The constituent regularity rows control the outer parts, the modulus controls the middle part, and the triangle inequality combines the dyadic budgets. □

Theorem 9357.22 (Completion limit and uniqueness)**.** *When the diagonal representative is sealed as a real name, it is a limit candidate for the regular Cauchy input; any other candidate satisfying the same modulus constraints classifies with it under the separated real classifier.*

Proof. The modulus brings X_n close to the selected member used in the diagonal representative, and the regularity of that member brings the selected observation close to the diagonal value. Combining these estimates gives the limit comparison. If L' is another candidate, compare L and L' through X_n:

$$d(L, L') \leq d(L, X_n) + d(X_n, L').$$

The two terms can be made smaller than any displayed tolerance, so the classifier identifies the two candidates. □

Principle 9357.23 (Completion boundary)**.** $\mathsf{Completion}^{\uparrow}$ *is explicit modulus data plus diagonal extraction plus classifier uniqueness. It is not an external existence theorem, not a quotient construction, and not a use of a selected representative outside the ledger.*

9357.5 Metric and Topology

Definition 9357.24 (Metric interface)**.** *For a point carrier* $(C, \sim_C)$ *with apartness boundary, a* $\mathsf{Met}^{\uparrow}$ *interface provides a distance*

$$d : C \times C \to \mathsf{Real}^{\uparrow}$$

with nonnegativity, identity of indiscernibles through the carrier classifier, symmetry, triangle inequality, endpoint congruence, and explicit real moduli for inequality transport. The ledger records the point witnesses and the real distance witness for each comparison.

Theorem 9357.25 (Metric empty distance exactness)**.** *A concrete empty distance witness classifies exactly the two endpoints with the empty history:*

$$\mathsf{MetricDistanceWitness}(x, y, \mathsf{e}) \iff \mathsf{hsame}(x, \mathsf{e}) \wedge \mathsf{hsame}(y, \mathsf{e}).$$

Proof. Unfold the concrete distance witness. In the forward direction its continuation row has empty result, so continuation inversion forces both endpoints to be empty up to hsame. Conversely, transport the reflexive empty distance witness along the two endpoint hsame rows. □

Theorem 9357.26 (Metric symmetry ledger)**.** *For unary endpoint histories, forward and reversed concrete distance ledgers classify their distance histories together.*

Proof. The two witnesses are the forward and reversed unary continuation ledgers. Unary continuation commutativity supplies the hsame classifier row between the two distance histories. □

Definition 9357.27 (Metric-generated topology)**.** *For a* $\mathsf{Met}^{\uparrow}$ *carrier, the open ball centered at* x *with positive radius* $r : \mathsf{Real}^{\uparrow}$ *is*

$$B(x, r) = \{y : C \mid d(x, y) < r\}.$$

A $\mathsf{Topology}^{\uparrow}$ *surface generated by these balls records open-set membership, neighbourhood witnesses, finite intersection closure, certified union closure, membership stability, and a local name certificate.*

Theorem 9357.28 (Metric balls are open)**.** *Every metric ball with positive radius is open in the generated topology.*

Proof. Let $y \in B(x, r)$, so $d(x, y) < r$. The positive remainder $r - d(x, y)$ supplies a displayed radius budget. Take a certified half of that budget. If $d(y, z)$ is below the half-budget, then the triangle inequality gives

$$d(x, z) \leq d(x, y) + d(y, z) < r.$$

Thus z remains in the ball. The proof uses real apartness and modulus rows, not classical trichotomy. □

Principle 9357.29 (Topology boundary)**.** $\mathsf{Topology}^{\uparrow}$ *is an open-set classifier and neighbourhood interface with certified closure rows. Metric topology is generated from distance and positive-radius data; it does not provide arbitrary powersets, open-cover compactness, or an ambient point-set topology.*

9357.6 Metric Completion and Maps

Definition 9357.30 (Regular Cauchy point name)**.** *In a* $\mathsf{Met}^{\uparrow}$ *space* X*, a regular Cauchy point name is a stream* $x : \mathsf{Nat}^{\uparrow} \to X$ *satisfying*

$$\forall m\, n : \mathsf{Nat}^{\uparrow},\ d(x_m, x_n) \leq 2^{-m} + 2^{-n}.$$

Convergence to $a : X$ *is recorded by an explicit modulus* $N : \mathbb{Q}^{\uparrow}_{>0} \to \mathsf{Nat}^{\uparrow}$ *such that*

$$n \geq N(\varepsilon) \Longrightarrow d(x_n, a) < \varepsilon.$$

Definition 9357.31 (Complete and compact metric carriers)**.** *A* $\mathsf{CompleteMetric}^{\uparrow}$ *carrier is a* $\mathsf{Met}^{\uparrow}$ *carrier in which each regular Cauchy point name has an explicit limit and convergence modulus, with uniqueness under separatedness. A* $\mathsf{CompactMetric}^{\uparrow}$ *carrier is the product of metric, complete-metric, and totally-bounded rows:*

$$\mathsf{CompactMetricCarrier}(X) \Longleftrightarrow \mathsf{MetricCarrier}(X) \wedge \mathsf{CompleteMetricCarrier}(X) \wedge \mathsf{TotallyBoundedCarrier}(X).$$

The totally-bounded row supplies finite ε*-nets as* $\mathsf{List}^{\uparrow}$*-certified data.*

Theorem 9357.32 (Limit uniqueness under separatedness)**.** *If a regular Cauchy point name converges to* a *and to* b*, and the metric space is separated, then* $a \sim_X b$*.*

Proof. For any positive tolerance ε, choose one displayed index beyond the two convergence moduli at $\varepsilon/2$. The triangle inequality gives

$$d(a, b) \leq d(a, x_n) + d(x_n, b) < \varepsilon.$$

Since the distance is below every displayed tolerance, the zero-distance classifier applies; separatedness then gives $a \sim_X b$. □

Definition 9357.33 (Continuous map interface)**.** *For metric carriers* X *and* Y*, a* $\mathsf{ContinuousMap}^{\uparrow}$ *interface for* $f : X \to Y$ *contains classifier respect and a uniform modulus*

$$\omega : \mathbb{Q}^{\uparrow}_{>0} \to \mathbb{Q}^{\uparrow}_{>0}$$

such that

$$d_X(x, x') < \omega(\varepsilon) \Longrightarrow d_Y(f(x), f(x')) < \varepsilon.$$

Theorem 9357.34 (Identity and composition of continuous maps)**.** *Identity maps are continuous with identity modulus, and continuous maps compose with composed modulus.*

Proof. For the identity, take $\omega(\varepsilon) = \varepsilon$. For composition, if f has modulus ω_f and g has modulus ω_g, use

$$\omega_{g \circ f}(\varepsilon) := \omega_f(\omega_g(\varepsilon)).$$

The f row sends a source comparison below $\omega_f(\omega_g(\varepsilon))$ to a target comparison below $\omega_g(\varepsilon)$, and the g row sends that comparison below ε. Classifier respect is the composition of the two classifier-respect rows. □

9357.7 L10 Boundary

Theorem 9357.35 (Countable completion admission theorem)**.** *If the carrier, classifier, stability, modulus, ledger, and* NameCert *rows are supplied for*

$$\mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{StreamName}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{Real}^{\uparrow},\quad \mathsf{Met}^{\uparrow},\quad \mathsf{Topology}^{\uparrow},\quad \mathsf{Completion}^{\uparrow},\quad \mathsf{CompleteMetric}^{\uparrow},$$

then the L10 countable-completion layer is admitted.

Proof. $\mathsf{DyadicRatCore}^{\uparrow}$ supplies finite dyadic tolerance arithmetic. $\mathsf{StreamName}^{\uparrow}$ supplies countable observation names with pointwise classifier stability. $\mathsf{RegSeqRat}^{\uparrow}$ adds regular Cauchy bounds over dyadic streams. $\mathsf{Real}^{\uparrow}$ seals regular names and exposes only classifier-stable real observations. $\mathsf{Completion}^{\uparrow}$ adds explicit modulus data, diagonal representatives, and uniqueness through the classifier. $\mathsf{Met}^{\uparrow}$ supplies real-valued distance ledgers. $\mathsf{Topology}^{\uparrow}$ supplies generated open-set and neighbourhood classifiers. $\mathsf{CompleteMetric}^{\uparrow}$, $\mathsf{CompactMetric}^{\uparrow}$, and $\mathsf{ContinuousMap}^{\uparrow}$ add explicit limit, finite-net, and modulus-of-continuity rows. Since every row is routed through displayed carriers and ledgers, none of these interfaces imports quotient equality, selected limits, host sequences, open-cover compactness, or classical trichotomy. □

Principle 9357.36 (Downstream analytic consumption)**.** *Analytic and zeta-facing packets may consume L10 only through certified countable names, regularity witnesses, explicit moduli, real seals, metric distance ledgers, topology classifiers, and completion uniqueness rows. They may not replace those rows by host real numbers, bare limits, quotient classes, selected representatives, or ambient complete metric spaces.*

Concretized in §8758: Regular-sequence window coherence is realized as finite StreamName windows, dyadic tolerance rows, RegSeqRat readback, Real seal, transport, replay, provenance, and local NameCert data.

Concretized in §6041: The Real completion universal-property packet realizes dense-source, StreamName, RegSeqRat, Bishop regular Cauchy completion, extension, uniqueness, and Real-seal rows as finite NameCert data.

Concretized in §8759: Located metric reflection realizes the countable-completion interface as a located metric packet before completion reads.

Concretized in §8925: The dyadic located-modulus packet realizes finite tolerance-to-window data for the countable completion spine.

Concretized in §8746: Regular Cauchy modulus-of-convergence packets realize finite tolerance-to-window schedules for the countable-completion spine.

Concretized in §9052: The diagonal representative route is realized as finite regular-Cauchy family, selector, dyadic tolerance, RegSeqRat readback, Real seal, transport, replay, provenance, and local NameCert rows.

Concretized in §9178: Compact Real interval modulus windows realize the countable-completion spine through finite interval, StreamName, RegSeqRat, DyadicRatCore tolerance, compact finite-cover, and RealUp seal rows.

Chapter 9358

Analysis Interface Spine

The countable-completion spine supplies certified streams, regular Cauchy names, real seals, metric ledgers, topology classifiers, and completion moduli. L11 consumes those rows as the substrate for analysis:

$$\mathsf{Calculus}^{\uparrow},\quad \mathsf{RealAnalytic}^{\uparrow},\quad \mathsf{CplxAnalytic}^{\uparrow},\quad \mathsf{Measure}^{\uparrow},\quad \mathsf{FunctionalAnalysis}^{\uparrow}.$$

The same layer also exposes the $\mathsf{Gamma}^{\uparrow}$ bridge used by later zeta-facing certificates. In all cases an analytic object is a packet of finite approximations, completion routes, classifier transport, explicit moduli, and ledger rows. It is not a host analytic function, a bare limit, a hidden operator norm, or an imported spectral theorem.

9358.1 Analytic Certificate Template

Definition 9358.1 (Analytic interface)**.** *An analytic interface over a carrier-classifier pair* $(C, \sim_C)$ *is a packet*

$$\mathsf{AnalyticInterface}^{\uparrow} = (C, \sim_C, \mathsf{Ops}, \mathsf{Approx}, \mathsf{Limit}, \mathsf{Stab}, \mathsf{Ledger}, \mathsf{NameCert}).$$

Here Ops *records the permitted analytic operations, such as derivative, integral, series, limit, or operator formation. The* Approx *row records finite approximants. The* Limit *row is a reference to the L10 completion route that turns the approximants into a public value. The stability row records classifier congruence, operation descent, modulus transport, and uniqueness through the target classifier.*

Definition 9358.2 (Analytic ledger)**.** *The analytic ledger records the data that make an analytic read finite: Cauchy moduli, input bounds, finite partitions, partial sums, tail estimates, positive apartness witnesses, branch witnesses, operator bounds, and the completion or metric route through which the output is accepted.*

Principle 9358.3 (Analysis is certificate-facing)**.** *An analytic name is admitted only when the finite approximation surface, the completion or measure route, the classifier transport, the stability rows, and the local* NameCert *are visible. The public surface cannot be replaced by a host function space, an external limit operator, a quotient of functions, or a choice-selected representative.*

9358.2 Calculus

Definition 9358.4 (Derivative witness)**.** *Let X and Y be normed vector carriers and let $f : X \to Y$ be a continuous map in the classifier-respecting sense. A derivative witness for f at $a : X$ is a bounded linear map $L : X \to Y$ together with a remainder row*

$$R_a(h) := f(a + h) - f(a) - L(h)$$

and a local modulus:

$$\forall \varepsilon > 0\ \exists \delta > 0, \quad 0 < \|h\| < \delta \Longrightarrow \|R_a(h)\| \le \varepsilon \|h\|.$$

The witness records the local linear approximation and its explicit error budget.

Definition 9358.5 (Derivative classifier)**.** *Two derivative witnesses L and M for the same input data classify together when they agree pointwise through the codomain classifier:*

$$L \sim_{\mathsf{Deriv}} M \Longleftrightarrow \forall h : X,\ L(h) \sim_Y M(h).$$

Theorem 9358.6 (Derivative uniqueness)**.** *If L and M are derivative witnesses for the same map at the same point, then $L \sim_{\mathsf{Deriv}} M$.*

Proof. Fix $h : X$. For $h = 0$, linearity gives $L(0) \sim_Y 0 \sim_Y M(0)$. For a displayed nonzero h, compare the two remainder rows at th with positive t tending to zero through the L10 countable-name route. Subtracting the two estimates gives

$$(L - M)(th) = o(\|th\|).$$

Linearity rewrites the left side as $t(L - M)(h)$ and the norm row rewrites the scale as $t\|h\|$. Cancelling the positive scalar in the displayed apartness field gives

$$\|(L - M)(h)\| \le \varepsilon \|h\|$$

for every displayed positive ε. The separated norm classifier therefore gives $(L - M)(h) \sim_Y 0$, hence $L(h) \sim_Y M(h)$. □

Definition 9358.7 (Finite-sum integral seed)**.** *For a continuous real-valued map on a compact interval, a calculus integral seed is a directed finite-sum system. A tagged partition*

$$P = (a = x_0 < x_1 < \cdots < x_n = b,\ \xi_i \in [x_i, x_{i+1}])$$

has finite sum

$$S(P, f) := \sum_{i=0}^{n-1} f(\xi_i)(x_{i+1} - x_i).$$

An integral witness for value $I : \mathsf{Real}^{\uparrow}$ is a regular Cauchy completion row for these sums with explicit refinement modulus and endpoint transport.

Definition 9358.8 (Measure-facing integral seed)**.** *When a $\mathsf{Measure}^{\uparrow}$ interface is available, the integral may instead be read through simple-function approximation and a completion row. The ledger records the simple functions, measurable partitions, coefficient rows, dominance or monotonicity evidence, and the completion route to the final value.*

Theorem 9358.9 (Integral uniqueness)**.** *Two integral witnesses built from the same directed finite-sum system and compatible moduli classify to the same real value.*

Proof. Both witnesses are L10 completion limits of the same directed finite-sum name. The completion uniqueness row transports the shared regular Cauchy classifier to the $\mathsf{Real}^{\uparrow}$ classifier, giving the desired equality at the real-history surface. □

Principle 9358.10 (Calculus boundary)**.** $\mathsf{Calculus}^{\uparrow}$ *consumes* $\mathsf{Real}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, *and normed vector data. The fundamental theorem belongs only after the interval or measure interface supplies stable integration and differentiation routes; it is not part of the root calculus name.*

9358.3 Real Analytic Functions

Definition 9358.11 (Real-analytic package)**.** *The* $\mathsf{RealAnalytic}^{\uparrow}$ *package contains the real-history rows for*

$$\pi, \quad \exp, \quad \log, \quad \sin, \quad \cos.$$

Each row is generated from unary-indexed rational or dyadic approximants with an explicit Cauchy modulus, then sealed through $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$.

Definition 9358.12 (Leibniz partial sums and π)**.** *For unary index n, the Leibniz partial sum row is*

$$S_n = \sum_{k=0}^{n} \frac{(-1)^k}{2k+1}.$$

The real name π is the sealed completion of the rescaled stream $(4S_n)_n$ with its alternating-series modulus.

Theorem 9358.13 (Leibniz modulus)**.** *For $N(k) = 2^{k+1}$, if $m, n \geq N(k)$, then*

$$|4S_m - 4S_n| < 2^{-k}.$$

Proof. The alternating-series tail is bounded by the first omitted term. Hence

$$|S_m - S_n| \leq \frac{1}{2N(k)+1}.$$

Multiplying by 4 and using $N(k) = 2^{k+1}$ gives

$$|4S_m - 4S_n| \leq \frac{4}{2N(k)+1} < 2^{-k}.$$

The comparison is recorded in the dyadic tolerance ledger. □

Definition 9358.14 (Exponential partial sums)**.** *For $x : \mathsf{Real}^{\uparrow}$, the exponential partial-sum row is*

$$E_n(x) = \sum_{k=0}^{n} \frac{x^k}{k!}.$$

Powers use iterated real multiplication, factorials use unary recursion, and division is read through a positive denominator and inverse certificate.

Theorem 9358.15 (Exponential modulus on bounded input)**.** *If $\|x\| \leq B$, then the exponential partial sums are regular Cauchy with a displayed modulus of the form $N(k) = 2B + k$.*

Proof. For $n \geq 2B$, the ratio of successive tail terms is at most $1/2$:

$$\frac{\|x\|}{n+1} \leq \frac{1}{2}.$$

The remaining tail is bounded by a geometric series. Taking $n \geq 2B + k$ makes the tail smaller than 2^{-k}, producing the displayed modulus. □

Theorem 9358.16 (Exponential additivity)**.** *If the three exponential rows for x, y, and $x+y$ are supplied, then*

$$\exp(x+y) \sim_{\mathsf{Real}^{\uparrow}} \exp(x)\exp(y).$$

Proof. At the finite layer, compare the partial sums for $\exp(x+y)$ with the Cauchy product of the partial sums for $\exp(x)$ and $\exp(y)$. The binomial identity matches equal-degree terms, while the exponential moduli control the tails. Passing through the $\mathsf{Real}^{\uparrow}$ completion uniqueness row yields the classifier equality. □

Definition 9358.17 (Logarithm by bisection)**.** *For a positive real input x with apartness from zero, the logarithm row is generated by dyadic bisection. At precision k it records a dyadic interval*

$$[y_k, y_k + 2^{-k}]$$

such that

$$\exp(y_k) \leq x < \exp(y_k + 2^{-k}).$$

The sequence $(y_k)_k$ is a regular Cauchy name whose seal is $\log(x)$.

Theorem 9358.18 (Logarithm inverse row)**.** *Concretized in §1817: The logarithm-by-bisection inverse route is realized as finite exponential, dyadic bracket, StreamName, RegSeqRat, and Real seal NameCert data.*

Concretized in §9119: The analytic tail-budget route is realized as finite dyadic tolerance, StreamName, RegSeqRat, Real seal, and completion-facing tail NameCert data.

For positive x, if $\log(x)$ is produced by the bisection row, then

$$\exp(\log(x)) \sim_{\mathsf{Real}^{\uparrow}} x.$$

If $\exp(z)$ is positive and a logarithm row for it is supplied, then the logarithm classifies with z.

Proof. The bisection ledger forces $\exp(y_k)$ to converge to x at every displayed precision. Completion uniqueness gives $\exp(\log(x)) \sim_{\mathsf{Real}^{\uparrow}} x$. For an input already known as $\exp(z)$, the same monotone inverse ledger and completion uniqueness identify the bisection limit with z. □

Definition 9358.19 (Trigonometric partial sums)**.** *The sine and cosine partial sums are*

$$S_n(x) = \sum_{k=0}^{n} (-1)^k \frac{x^{2k+1}}{(2k+1)!},$$

and

$$C_n(x) = \sum_{k=0}^{n} (-1)^k \frac{x^{2k}}{(2k)!}.$$

Their real-history values are sealed regular Cauchy limits with explicit input bounds and alternating-tail ledgers.

Theorem 9358.20 (Trigonometric modulus and identities)**.** *For bounded input, sine and cosine partial sums have explicit Cauchy moduli. Their sealed limits satisfy*

$$\sin(x)^2 + \cos(x)^2 \sim_{\mathsf{Real}^\uparrow} 1,$$

and signed unary integer multiples of π are zeros of sine.

Proof. The factorial denominator forces the tail terms to decrease once the displayed index dominates the input bound. Alternating-tail estimates give the Cauchy moduli. The Pythagorean identity is obtained by multiplying finite partial sums, grouping the Cauchy-product terms, and sending the remaining tail through the same modulus. The integer-multiple zero row is proved by induction using the addition formula and the base $\sin(\pi)$ row. □

Principle 9358.21 (Real-analytic boundary)**.** $\mathsf{RealAnalytic}^\uparrow$ *licenses* π, exp, log, sin, *and* cos *only as regular Cauchy constructions over rational or dyadic finite approximants. They are not primitive constants or host functions.*

9358.4 Complex Analytic Functions

Definition 9358.22 (Complex exponential)**.** *For a complex history $z = x + iy$, the complex exponential row is*

$$\exp_{\mathbb{C}}(z) = \big(\exp(x)\cos(y),\ \exp(x)\sin(y)\big).$$

The classifier is componentwise through the $\mathsf{Real}^\uparrow$ *classifier.*

Theorem 9358.23 (Complex exponential stability)**.** *The complex exponential is stable under the* $\mathsf{Complex}^\uparrow$ *classifier and has a unique output class for each accepted input class.*

Proof. The $\mathsf{Complex}^\uparrow$ classifier is componentwise. The real rows exp, sin, and cos are stable under $\mathsf{Real}^\uparrow$ classifier transport. Thus both components of the complex exponential output transport through the same real classifier rows, giving a unique complex classifier result. □

Theorem 9358.24 (Complex exponential additivity and Euler row)**.** *The complex exponential satisfies*

$$\exp_{\mathbb{C}}(z + z') \sim_{\mathsf{Complex}^\uparrow} \exp_{\mathbb{C}}(z)\exp_{\mathbb{C}}(z'),$$

and for pure imaginary input $i\theta$,

$$\exp_{\mathbb{C}}(i\theta) \sim_{\mathsf{Complex}^\uparrow} (\cos\theta, \sin\theta).$$

Proof. Write $z = x + iy$ and $z' = x' + iy'$. The real part uses real exponential additivity and the cosine addition formula; the imaginary part uses real exponential additivity and the sine addition formula. For $i\theta$, the real part of the input is zero, so $\exp(0) \sim_{\mathsf{Real}^\uparrow} 1$, leaving the components $(\cos\theta, \sin\theta)$. □

Principle 9358.25 (Complex-analytic boundary)**.** $\mathsf{CplxAnalytic}^\uparrow$ *is componentwise over* $\mathsf{Complex}^\uparrow$ *and* $\mathsf{RealAnalytic}^\uparrow$*, with branch and apartness ledgers for logarithm and power operations. It does not import a host holomorphic calculus or an untracked principal branch.*

9358.5 Measure and Integration

Definition 9358.26 (Measurable carrier)**.** *A measurable carrier is a tuple* $(X, \sim_X, \mathcal{A})$ *where* $\mathcal{A}$ *is a* $\mathsf{SetLike}^{\uparrow}$ *family of event rows over* X*. The family contains empty and total events, is closed under complement and finite unions, and is closed under certified countable unions supplied as* $\mathsf{StreamName}^{\uparrow}$ *families.*

Definition 9358.27 (Measure interface)**.** *A* $\mathsf{Measure}^{\uparrow}$ *interface is a nonnegative real-valued map on event rows:*

$$\mu : \mathcal{A} \to \mathsf{Real}^{\uparrow}_{\geq 0}.$$

Its certificate records the null empty event, finite additivity on disjoint events, certified countable additivity on disjoint event streams, monotonicity, and stability under $\mathsf{SetLike}^{\uparrow}$ *extensional classification.*

Theorem 9358.28 (Monotonicity from finite additivity)**.** *If* $A \subseteq B$ *and the decomposition*

$$B = A \sqcup (B \setminus A)$$

is certified, then $\mu(A) \leq \mu(B)$*.*

Proof. Finite additivity gives

$$\mu(B) = \mu(A) + \mu(B \setminus A).$$

Nonnegativity gives $\mu(B \setminus A) \geq 0$, so the real order row yields $\mu(A) \leq \mu(B)$. □

Definition 9358.29 (Simple integral and nonnegative integral)**.** *A simple function is a finite partition expression*

$$s = \sum_{i=1}^{n} a_i \mathbf{1}_{A_i}$$

with $a_i : \mathsf{Real}^{\uparrow}$ *and* $A_i \in \mathcal{A}$*. Its integral is*

$$\int s \, d\mu := \sum_{i=1}^{n} a_i \mu(A_i).$$

For nonnegative measurable f*, the integral is read as a directed completion of simple functions below* f*, with an approximation ledger.*

Definition 9358.30 (L^p seed)**.** *For* $1 \leq p < \infty$*, the* L^p *seed carrier records functions with finite value*

$$\int |f|^p \, d\mu.$$

The classifier is almost-everywhere equality through the measure ledger:

$$f \sim g \iff \mu(\{x : f(x) \not\sim g(x)\}) = 0.$$

The zero-event and equality rows are measure certificates, not host quotient classes.

Principle 9358.31 (Measure boundary)**.** $\mathsf{Measure}^{\uparrow}$ *requires* $\mathsf{SetLike}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Topology}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, *and certified countable families. Countable operations are stream-name data; they are not host countable choice.*

9358.6 Functional Analysis

Definition 9358.32 (Normed vector carrier)**.** *A* $\mathsf{Norm}^{\uparrow}$ *row over a* $\mathsf{VecSpace}^{\uparrow}$ *carrier* V *is a map*

$$\|-\| : V \to \mathsf{Real}^{\uparrow}_{\geq 0}$$

with positivity, definiteness, scalar homogeneity, triangle inequality, and classifier congruence. It induces the metric used by Banach and Hilbert completion rows.

Definition 9358.33 (Banach and Hilbert carriers)**.** *A* $\mathsf{Banach}^{\uparrow}$ *carrier is a normed vector carrier with a regular Cauchy completeness witness in the norm-induced metric. A* $\mathsf{Hilbert}^{\uparrow}$ *carrier is a Banach carrier with an inner product*

$$\langle -, - \rangle : V \times V \to F$$

whose induced norm satisfies

$$\|v\|^2 \sim \langle v, v \rangle.$$

The inner product row records linearity, conjugate symmetry when needed, positivity, definiteness, and classifier congruence.

Theorem 9358.34 (Parallelogram row)**.** *In an inner-product carrier,*

$$\|v + w\|^2 + \|v - w\|^2 \sim 2\|v\|^2 + 2\|w\|^2.$$

Proof. Use $\|x\|^2 \sim \langle x, x \rangle$. Expanding $\langle v + w, v + w \rangle$ gives the two diagonal terms and the two cross terms. Expanding $\langle v - w, v - w \rangle$ gives the same diagonal terms and the negative cross terms. Addition cancels the cross terms by the additive classifier and leaves twice the two diagonal rows. □

Definition 9358.35 (Bounded linear operator)**.** *For normed vector carriers* V *and* W*, a bounded linear operator row for* $T : V \to W$ *consists of linearity plus a bound* $M : \mathsf{Real}^{\uparrow}_{\geq 0}$ *satisfying*

$$\|Tv\| \leq M\|v\|$$

for every carried v*. Operator classification is pointwise:*

$$T \sim_{\mathsf{op}} S \iff \forall v,\ T(v) \sim_W S(v).$$

Theorem 9358.36 (Bounded operators form a vector-space carrier)**.** *Bounded linear maps from* V *to* W *are closed under pointwise addition and scalar multiplication.*

Proof. If T and S have bounds M and N, then

$$\|(T + S)v\| \leq \|Tv\| + \|Sv\| \leq (M + N)\|v\|.$$

If λ is a scalar, then

$$\|(\lambda T)v\| \sim |\lambda|\|Tv\| \leq |\lambda|M\|v\|.$$

The vector-space laws descend pointwise from W through the operator classifier. □

Definition 9358.37 (Spectrum and compact operator rows)**.** *For a bounded operator* $T : V \to V$*, the resolvent row at* λ *is a bounded inverse certificate for* $T - \lambda I$*. The spectrum row records failure of that inverse package through a certified non-invertibility or apartness witness, not bare undecidable negation. A compact-operator row records either total-bounded image data or a subsequence-with-modulus witness for bounded sequences.*

Principle 9358.38 (Functional-analysis boundary)**.** $\mathsf{FunctionalAnalysis}^{\uparrow}$ *collects Banach, Hilbert, bounded-operator, dual, adjoint, compactness, and spectral-substrate rows. The spectral theorem is a major target over those rows, not part of the root functional-analysis certificate.*

9358.7 Gamma Bridge

Definition 9358.39 (Gamma pole and domain)**.** *The* $\mathsf{Gamma}^{\uparrow}$ *pole locus is the complex-history row saying that* s *is a non-positive integer:*

$$\mathsf{GammaPole}(s) \iff \exists n : \mathsf{Nat}^{\uparrow},\ s \sim_{\mathsf{Complex}^{\uparrow}} -n.$$

The domain row $\mathsf{GammaDom}(s)$ *contains a* $\mathsf{Complex}^{\uparrow}$ *carrier and an explicit apartness witness from that pole locus.*

Definition 9358.40 (Gamma by product and recurrence)**.** *The gamma row is built from the integer factorial identity*

$$\Gamma(n+1) = n!,$$

a Weierstrass-product extension on $\mathsf{GammaDom}$ *with unary Cauchy modulus, and the recurrence*

$$\Gamma(s+1) = s\Gamma(s).$$

The construction consumes $\mathsf{RealAnalytic}^{\uparrow}$ *exponent and logarithm rows,* $\mathsf{Complex}^{\uparrow}$ *arithmetic, and the pole-apartness ledger.*

Theorem 9358.41 (Gamma uniqueness)**.** *If two* $\mathsf{Gamma}^{\uparrow}$ *rows evaluate the same domain point through compatible product moduli, their outputs classify together in* $\mathsf{Complex}^{\uparrow}$*.*

Proof. Both outputs are limits of the same unary-indexed product stream on the same domain row. The complex limit uniqueness row transports the shared product classifier to the $\mathsf{Complex}^{\uparrow}$ classifier. □

Principle 9358.42 (Gamma boundary)**.** $\mathsf{Gamma}^{\uparrow}$ *is an analytic bridge over* $\mathsf{Complex}^{\uparrow}$ *and* $\mathsf{RealAnalytic}^{\uparrow}$*. It is not a meromorphic black box; the public row must expose pole apartness, product modulus, recurrence, transport, replay, and local naming.*

Concretized in §8843: The Mellin transform packet realizes the Gamma-facing transform branch as finite positive-real source, integrand-window, Gamma handoff, Real-seal, transport, replay, provenance, and NameCert rows.

9358.8 L11 Boundary

Theorem 9358.43 (Analysis admission theorem)**.** *If*

$$\mathsf{Calculus}^{\uparrow},\quad \mathsf{RealAnalytic}^{\uparrow},\quad \mathsf{CplxAnalytic}^{\uparrow},\quad \mathsf{Measure}^{\uparrow},\quad \mathsf{FunctionalAnalysis}^{\uparrow},\quad \mathsf{Gamma}^{\uparrow}$$

carry their advertised carrier, classifier, finite approximation, completion, modulus, stability, ledger, and $\mathsf{NameCert}$ *rows, then the L11 analysis layer is admitted.*

Proof. $\mathsf{Calculus}^{\uparrow}$ supplies local linear approximation and finite-sum or measure-facing integration through L10 completion. $\mathsf{RealAnalytic}^{\uparrow}$ supplies π, exponential, logarithm, sine, and cosine through explicit series or bisection moduli. $\mathsf{CplxAnalytic}^{\uparrow}$ composes those real rows componentwise over $\mathsf{Complex}^{\uparrow}$ and records Euler and exponential-additivity rows. $\mathsf{Measure}^{\uparrow}$ supplies stable event algebras, certified countable additivity, integration, and L^p seeds. $\mathsf{FunctionalAnalysis}^{\uparrow}$ supplies normed, Banach, Hilbert, bounded-operator, compactness, and spectral-substrate rows. $\mathsf{Gamma}^{\uparrow}$ supplies the analytic bridge needed for zeta-facing functional-equation packets. Each row is a certified finite-approximation or modulus-bearing route, so no host analytic object enters as a primitive. □

Principle 9358.44 (Downstream zeta consumption)**.** *Zeta-facing packets may consume L11 only through the real and complex analytic rows, measure or contour-integral ledgers when present, gamma-domain and gamma-product rows, and functional-analysis operator rows when a spectral route is chosen. They may not replace these rows by host exponentials, untracked logarithm branches, classical nonzero predicates, or black-box meromorphic functions.*

Chapter 9359

Geometry, Category, and Homology Interface Spine

Concretized in §8931: Finite cover incidence realizers instantiate the geometry/category/homology spine as cover membership, overlap, simplicial face, homology handoff, transport, replay, provenance, and local NameCert rows.

The analysis layer supplies real and complex analytic rows, measure-facing integration, functional-analysis carriers, and gamma bridges. L12 reads those rows together with the earlier type, set, topology, continuous-map, and abelian-group interfaces as a geometry layer:

$$\mathsf{Cat}^{\uparrow},\quad \mathsf{Functor}^{\uparrow},\quad \mathsf{NatTrans}^{\uparrow},\quad \mathsf{CatLimit}^{\uparrow},\quad \mathsf{Manifold}^{\uparrow},\quad \mathsf{Bundle}^{\uparrow},\quad \mathsf{Homology}^{\uparrow}.$$

The role of this layer is not to add a point-set universe. It turns certified carriers into local data, transition data, gluing data, classifier-stable maps, and obstruction ledgers.

9359.1 Geometry Certificate Template

Definition 9359.1 (Geometry interface)**.** *A geometry interface over a carrier-classifier pair* $(C, \sim_C)$ *is a packet*

$$\mathsf{GeomInterface}^{\uparrow} = (C, \sim_C, \mathsf{LocalData}, \mathsf{Gluing}, \mathsf{Transition}, \mathsf{Stab}, \mathsf{Ledger}, \mathsf{NameCert}).$$

The local-data row may contain charts, local trivialisations, simplices, chains, cone components, morphisms, or sections. The gluing row records how local presentations assemble. The transition row records overlap maps, change-of-chart maps, functorial transport, boundary maps, or comparison morphisms. The stability row states that all of those rows descend through the relevant classifiers.

Principle 9359.2 (Geometry is not a point set)**.** *A L12 object is admitted only as carrier, classifier, local data, transition or gluing data, ledger, and local* NameCert*. A host set of points, a quotient of representatives, an extensional equality of objects, or a selected global representative is never the public surface.*

9359.2 Categories, Functors, and Natural Transformations

Definition 9359.3 (Category carrier)**.** *A* $\mathsf{Cat}^{\uparrow}$ *carrier is a multisorted certificate*

$$\mathcal{C} = (\mathsf{Obj}, \sim_{\mathsf{Obj}}, \mathsf{Hom}, \sim_{\mathsf{Hom}}, \mathsf{id}, \mathsf{comp}, \mathsf{Law}, \mathsf{Ledger}, \mathsf{NameCert}).$$

Objects are certified carriers. For certified objects A, B, the hom row $\mathsf{Hom}_{\mathcal{C}}(A, B)$ is a certified morphism carrier with its own parallel-morphism classifier. Identity and composition are operations on those hom rows, and the unit, associativity, and congruence laws are stated up to the displayed morphism classifiers.

Definition 9359.4 (Isomorphism record)**.** *Object comparison in a $\mathsf{Cat}^{\uparrow}$ carrier is never inferred from host extensionality. An isomorphism between A and B is a record*

$$(f : A \to B,\ g : B \to A,\ g \circ f \sim \mathsf{id}_A,\ f \circ g \sim \mathsf{id}_B)$$

with both triangle rows living in the relevant morphism classifiers. Subcategory inclusion is likewise data: an object row, a hom-row inclusion, and stability under identity and composition.

Theorem 9359.5 (Identity uniqueness)**.** *If $e_A : A \to A$ is both a left and right unit for every parallel hom row at A, then $e_A \sim \mathsf{id}_A$ in $\mathsf{Hom}_{\mathcal{C}}(A, A)$.*

Proof. Apply the unit property of e_A to id_A. One unit row gives $e_A \circ \mathsf{id}_A \sim \mathsf{id}_A$, while the unit row for id_A gives $e_A \circ \mathsf{id}_A \sim e_A$. Symmetry and transitivity of the morphism classifier identify e_A with id_A. □

Definition 9359.6 (Functor certificate)**.** *A $\mathsf{Functor}^{\uparrow}$ certificate $F : \mathcal{C} \to \mathcal{D}$ consists of an object map F_0, endpoint-indexed morphism maps $F_{A,B}$, classifier-respect rows for objects and morphisms, and preservation rows*

$$F(\mathsf{id}_A) \sim \mathsf{id}_{F(A)}, \qquad F(g \circ f) \sim F(g) \circ F(f).$$

The codomain of a morphism image is the hom carrier at the image endpoints; raw preservation of unclassified composites is not enough.

Theorem 9359.7 (Functor composition)**.** *Certified functors compose, and the identity functor is certified.*

Proof. For $F : \mathcal{C} \to \mathcal{D}$ and $G : \mathcal{D} \to \mathcal{E}$, define the composite on objects by $G_0(F_0(A))$ and on morphisms by $G(F(f))$. Classifier respect is the composite of the two classifier-respect rows. Identity preservation follows from

$$G(F(\mathsf{id}_A)) \sim G(\mathsf{id}_{F(A)}) \sim \mathsf{id}_{G(F(A))}.$$

Composition preservation follows in the same way:

$$G(F(g \circ f)) \sim G(F(g) \circ F(f)) \sim G(F(g)) \circ G(F(f)).$$

The identity functor uses the identity object and morphism maps, with all rows supplied by reflexivity. □

Definition 9359.8 (Natural transformation certificate)**.** *For functors $F, G : \mathcal{C} \to \mathcal{D}$, a $\mathsf{NatTrans}^{\uparrow}$ certificate $\eta : F \Rightarrow G$ is an object-indexed family of component morphisms*

$$\eta_A : F(A) \to G(A)$$

such that every $f : A \to B$ satisfies the naturality classifier row

$$G(f) \circ \eta_A \sim \eta_B \circ F(f).$$

Theorem 9359.9 (Vertical natural-transformation composition)**.** *If $\eta : F \Rightarrow G$ and $\theta : G \Rightarrow H$ are certified natural transformations, then the family $(\theta_A \circ \eta_A)_A$ is a certified natural transformation $F \Rightarrow H$.*

Proof. For $f : A \to B$, reassociate $H(f) \circ (\theta_A \circ \eta_A)$. Naturality of θ rewrites $H(f) \circ \theta_A$ as $\theta_B \circ G(f)$, and naturality of η rewrites $G(f) \circ \eta_A$ as $\eta_B \circ F(f)$. Associativity in $\mathcal{D}$ gives $(\theta_B \circ \eta_B) \circ F(f)$. □

Remark 9359.10 (Kernel category boundary)**.** *chapter 9363 records the checked unary-continuation category over* BHist *and the bounded* $\mathsf{Functor}^{\uparrow}$ *and* $\mathsf{NatTrans}^{\uparrow}$ *bridges available at the paper-Lean surface. The present spine uses that result as the kernel-facing instance and keeps the general L12 interface at the certificate level.*

9359.3 Categorical Limits

Definition 9359.11 (Diagram, cone, and limit)**.** *For certified categories J and $\mathcal{C}$, a diagram is a certified functor $D : J \to \mathcal{C}$. A cone over D is an apex object L together with components*

$$\lambda_j : L \to D(j)$$

such that every arrow $u : j \to k$ in J satisfies

$$D(u) \circ \lambda_j \sim \lambda_k.$$

A $\mathsf{CatLimit}^{\uparrow}$ *row is a cone (L, λ) that is universal among cones: for every cone (X, ξ) there is a morphism $u : X \to L$, unique up to the morphism classifier, such that $\lambda_j \circ u \sim \xi_j$ for all j.*

Theorem 9359.12 (Limit comparison isomorphism)**.** *Two* $\mathsf{CatLimit}^{\uparrow}$ *cones over the same certified diagram are connected by an isomorphism record whose composites classify with the two identity morphisms.*

Proof. Let (L, λ) and (M, μ) be limiting cones. Apply the universal property of M to the cone L to obtain $f : L \to M$ with $\mu_j \circ f \sim \lambda_j$. Apply the universal property of L to the cone M to obtain $g : M \to L$ with $\lambda_j \circ g \sim \mu_j$. The composite $g \circ f$ is a cone endomorphism of (L, λ), since

$$\lambda_j \circ (g \circ f) \sim (\lambda_j \circ g) \circ f \sim \mu_j \circ f \sim \lambda_j.$$

The identity of L satisfies the same component equations, so uniqueness gives $g \circ f \sim \mathsf{id}_L$. The other composite is identical by symmetry with L and M interchanged. □

9359.4 Manifolds and Bundles

Definition 9359.13 (Charted manifold)**.** *A* $\mathsf{Manifold}^{\uparrow}$ *certificate is a topological carrier equipped with a finite atlas. Each chart has an open domain U_i, a finite coordinate row into* $(\mathsf{Real}^{\uparrow})^{n_i}$*, and a classifier-stable coordinate map. Each overlap row $U_i \cap U_j$ carries a transition ledger from the i-coordinates to the j-coordinates, certified by the available real-analytic and calculus interfaces.*

Theorem 9359.14 (Chart-change classifier stability)**.** *On an overlap $U_i \cap U_j$, the chart-change expression $\varphi_j(\varphi_i^{-1}(\varphi_i(x)))$ classifies with $\varphi_j(x)$.*

Proof. The inverse row for the i-chart gives $\varphi_i^{-1}(\varphi_i(x)) \sim x$ in the manifold carrier classifier. Classifier congruence for the j-chart transports this comparison to the coordinate row, yielding the displayed chart-change stability. □

Theorem 9359.15 (Transition cocycle)**.** *On a triple overlap $U_i \cap U_j \cap U_k$, the transition from chart i to chart k classifies with the composite of the transitions from i to j and from j to k.*

Proof. The composite transition expands as

$$\varphi_k \circ \varphi_j^{-1} \circ \varphi_j \circ \varphi_i^{-1}.$$

The middle inverse row classifies $\varphi_j^{-1} \circ \varphi_j$ with the identity on the shared coordinate window. Composition congruence then reduces the composite to $\varphi_k \circ \varphi_i^{-1}$. □

Definition 9359.16 (Bundle certificate)**.** *A* $\mathsf{Bundle}^{\uparrow}$ *certificate over a base* $\mathsf{Manifold}^{\uparrow}$ *row is a fibred carrier $p : E \to B$ with model fibre F, local trivialisations*

$$\tau_i : p^{-1}(U_i) \to U_i \times F,$$

transition functions on overlaps, cocycle rows on triple overlaps, and a ledger for section, connection, and curvature-facing consumers when those interfaces are present. The projection, local trivialisation, and transition rows are all classifier-stable.

Theorem 9359.17 (Bundle transition identity and cocycle)**.** *For a* $\mathsf{Bundle}^{\uparrow}$ *certificate, g_{ii} classifies with the identity on the model fibre, and on triple overlaps g_{ik} classifies with $g_{jk} \circ g_{ij}$.*

Proof. The identity row follows from $\tau_i \circ \tau_i^{-1}$ on $U_i \times F$. For the triple-overlap row, compare $\tau_k \circ \tau_i^{-1}$ with $(\tau_k \circ \tau_j^{-1}) \circ (\tau_j \circ \tau_i^{-1})$. The shared j-trivialisation cancels by the inverse law, and the fibre components read as g_{ik} and $g_{jk} \circ g_{ij}$. □

9359.5 Homology and Cohomology

Definition 9359.18 (Chain complex and homology)**.** *A* $\mathsf{Homology}^{\uparrow}$ *certificate starts with a degree-indexed family of* $\mathsf{AbGroup}^{\uparrow}$ *carriers C_n and boundary maps $\partial_n : C_n \to C_{n-1}$ satisfying the square-zero row*

$$\partial_{n-1} \circ \partial_n \sim 0.$$

The cycle carrier is $\mathsf{Ker}(\partial_n)$*, the boundary carrier is* $\mathsf{Im}(\partial_{n+1})$*, and the homology object is the* $\mathsf{QuotientGroup}^{\uparrow}$ *row Z_n/B_n with its carrier, classifier, projection, soundness, completeness, and ledger.*

Theorem 9359.19 (Boundaries are cycles)**.** *For every degree n, the boundary carrier B_n is contained in the cycle carrier Z_n.*

Proof. If $c \in B_n$, then some $d \in C_{n+1}$ satisfies $c \sim \partial_{n+1}(d)$. Applying ∂_n gives

$$\partial_n(c) \sim \partial_n(\partial_{n+1}(d)) \sim (\partial_n \circ \partial_{n+1})(d) \sim 0.$$

Thus c is a cycle. □

Definition 9359.20 (Chain-map transport)**.** *A chain map $f : C \to D$ is a family of homomorphism rows $f_n : C_n \to D_n$ satisfying*

$$\partial_n^D \circ f_n \sim f_{n-1} \circ \partial_n^C.$$

It sends cycles to cycles and boundaries to boundaries, so it induces a classifier-stable map on the quotient rows $H_n(C) \to H_n(D)$.

Definition 9359.21 (Cohomology row)**.** *A* $\mathsf{Cohomology}^{\uparrow}$ *certificate is the dual cochain interface: groups C^n, coboundary maps $d^n : C^n \to C^{n+1}$, a square-zero row $d^{n+1} \circ d^n \sim 0$, cocycles* $\mathsf{Ker}(d^n)$*, coboundaries* $\mathsf{Im}(d^{n-1})$*, and quotient-group rows $H^n(C)$.*

9359.6 L12 Boundary

Theorem 9359.22 (Geometry-category-homology admission)**.** *If the advertised category, functor, natural-transformation, categorical-limit, manifold, bundle, homology, and cohomology rows carry their carrier, classifier, local-data, transition, gluing, stability, ledger, and* NameCert *fields, then the L12 layer is admitted as a BEDC interface.*

Proof. $\mathsf{Cat}^{\uparrow}$ supplies certified object and morphism carriers with laws up to the morphism classifier. $\mathsf{Functor}^{\uparrow}$ and $\mathsf{NatTrans}^{\uparrow}$ add only classifier-respecting transport between those carriers. $\mathsf{CatLimit}^{\uparrow}$ packages the universal cone surface over certified diagrams. $\mathsf{Manifold}^{\uparrow}$ turns topological and real-analytic rows into finite chart atlases with overlap ledgers. $\mathsf{Bundle}^{\uparrow}$ adds fibred carriers, local trivialisations, and cocycle rows over the manifold substrate. $\mathsf{Homology}^{\uparrow}$ and $\mathsf{Cohomology}^{\uparrow}$ read square-zero chain or cochain data through kernel, image, and quotient carriers over $\mathsf{AbGroup}^{\uparrow}$. Each item is a certificate over earlier rows, so no host geometry, quotient, or global representative is introduced. □

Principle 9359.23 (Zeta-facing geometric consumption)**.** *Zeta-facing packets may use L12 only through certified categorical limits, bundle and section ledgers, manifold-coordinate rows, and homology or cohomology obstruction rows. A boundary-bulk-fibre-section reading is therefore a certificate route through* $\mathsf{CatLimit}^{\uparrow}$*,* $\mathsf{Manifold}^{\uparrow}$*,* $\mathsf{Bundle}^{\uparrow}$*, and* $\mathsf{Homology}^{\uparrow}$*, not an external geometric oracle.*

Chapter 9360

Number Theory and Zeta Interface Spine

The geometry layer exposes category, gluing, bundle, and homology rows. L13 uses the arithmetic, completion, analysis, and geometry interfaces to reach the zeta-facing surface:

$$\mathsf{Prime}^{\uparrow},\quad \mathsf{Padic}^{\uparrow},\quad \mathsf{Adele}^{\uparrow},\quad \mathsf{Dirichlet}^{\uparrow},\quad \mathsf{Zeta}^{\uparrow},\quad \mathsf{CritStrip}^{\uparrow},\quad \mathsf{ZetaZeros}^{\uparrow}.$$

The governing boundary is strict: Riemann-hypothesis-shaped statements are theorem targets. They are not naming-seed assertions, not zero-enumeration procedures, and not consequences of merely licensing $\mathsf{ZetaZeros}^{\uparrow}$.

9360.1 Prime Axis

Definition 9360.1 (Divisibility and primality)**.** *For unary histories d, n, divisibility is the displayed quotient predicate*

$$\mathsf{NatDivides}(d, n) \iff \exists q,\ \mathsf{NatMul}(d, q, n).$$

The quotient q is part of the witness. A prime row $\mathsf{NatPrime}(p)$ requires unary membership, strict inequality $p > 1$ through the unary strict-prefix relation, and the divisor condition that every divisor of p classifies with the unit or with p.

Theorem 9360.2 (Unit exclusion)**.** *The unary unit is not prime.*

Proof. If the unit were prime, the strict inequality field in the prime predicate would give a strict unary prefix from the unit to itself. Strict prefix is irreflexive, so the prime witness cannot exist. □

Definition 9360.3 (Trial division and factorization ledger)**.** *The $\mathsf{Prime}^{\uparrow}$ certificate records bounded trial division over finite unary segments, factorization lists*

$$[p_1, \ldots, p_k]$$

whose entries are nondecreasing unary primes and whose iterated product classifies with the target history, and the Euclid-lemma ledger used to compare two such lists.

Theorem 9360.4 (Prime factorization uniqueness)**.** *Two prime factorization lists of the same positive unary history have the same length and pointwise* hsame*-classified entries.*

Proof. The first prime in one list divides the product of the other list. Euclid's lemma moves that divisibility to one factor. Since that factor is prime, the two primes classify together. The nondecreasing ledger aligns the matching entries, cancels them from the two products, and the argument recurses on the remaining lists. □

Definition 9360.5 (Prime-coordinate readout)**.** *For a positive unary history n and a prime row p, the exponent $v_p(n) = k$ means that n classifies with $p^k m$ for some unary m not divisible by p. The prime-coordinate readout is the finite-support family*

$$\Phi(n) = (v_p(n))_{p:\mathsf{Prime}^{\uparrow}}.$$

The finite support is read from the factorization list.

Theorem 9360.6 (Multiplication is coordinate addition)**.** *For positive unary histories m, n,*

$$\Phi(mn) = \Phi(m) + \Phi(n).$$

Proof. Factorization gives $m = \prod_p p^{v_p(m)}$ and $n = \prod_p p^{v_p(n)}$ with finite support. Multiplying the two products adds exponents prime by prime. Factorization uniqueness identifies those exponents with the coordinates of mn. □

Concretized in §64: PrimeUp realizes the Prime Axis divisibility, primality, bounded trial-division, and factorization-ledger rows as finite NameCert data.

9360.2 p-Adic and Adele Rows

Definition 9360.7 (Prime scale and valuation)**.** *For histories p, e, r, the predicate* $\mathsf{PadicPrimeScale}(p, e, r)$ *holds when p is a* $\mathsf{Prime}^{\uparrow}$ *prime and r is the unary multiplication result of p by exponent e. For a nonzero rational history $x = a/b$, the valuation row is*

$$v_p(x) = v_p(a) - v_p(b),$$

with well-definedness supplied by the rational-normalisation ledger.

Theorem 9360.8 (Prime scale totality)**.** *If p is prime and e is unary, then some r satisfies* $\mathsf{PadicPrimeScale}(p, e, r)$*.*

Proof. The prime witness supplies unary membership for p. Unary multiplication totality applied to p and e gives a result r and a $\mathsf{NatMul}(p, e, r)$ witness. Pairing this multiplication row with the prime row is exactly the prime-scale packet. □

Definition 9360.9 (p-adic carrier)**.** *For a prime row p, the* $\mathsf{Padic}^{\uparrow}(p)$ *carrier is the regular Cauchy completion of* $\mathsf{Rat}^{\uparrow}$ *under*

$$d_p(x, y) = |x - y|_p, \qquad |x|_p = p^{-v_p(x)}.$$

The classifier is zero p-adic distance, and the ledger records the prime index, valuation decomposition, ultrametric estimate, Cauchy modulus, and completion seal.

Theorem 9360.10 (Ultrametric estimate)**.** *The p-adic metric satisfies*

$$d_p(x, z) \leq \max(d_p(x, y), d_p(y, z)).$$

Proof. Write $x - z = (x - y) + (y - z)$. The valuation ledger gives $v_p(a + b) \geq \min(v_p(a), v_p(b))$. Applying $p^{-(-)}$ reverses this minimum into the displayed maximum bound for the absolute values. □

Definition 9360.11 (Adele carrier)**.** *An* $\mathsf{Adele}^{\uparrow}$ *row is a restricted product packet*

$$x = (x_\infty, (x_p)_{p:\mathsf{Prime}^{\uparrow}})$$

with $x_\infty : \mathsf{Real}^{\uparrow}$*,* $x_p : \mathsf{Padic}^{\uparrow}(p)$*, and a finite exception list of primes outside which* $|x_p|_p \leq 1$*. The classifier is componentwise, together with classification of the restricted-product exception ledgers.*

Theorem 9360.12 (Diagonal rationals are restricted)**.** *The diagonal embedding* $\Delta : \mathsf{Rat}^{\uparrow} \to \mathsf{Adele}^{\uparrow}$ *lands in the restricted product carrier.*

Proof. For a normalized rational $q = a/b$, only the primes occurring in the factorization lists of a and b can have nonzero $v_p(q)$. That finite union is the exception ledger. For all other primes, $v_p(q) = 0$, so $|q|_p = 1$ and the restricted-product bound holds. □

9360.3 Dirichlet Series and Zeta

Definition 9360.13 (Dirichlet series row)**.** *A* $\mathsf{Dirichlet}^{\uparrow}$ *row consists of coefficient histories* $a : \mathsf{Nat}^{\uparrow}_{>0} \to \mathsf{Complex}^{\uparrow}$*, a complex input* s*, Dirichlet terms*

$$T_n(a, s) = a_n n^{-s}, \qquad n^{-s} := \exp(-s \log n),$$

an absolute-convergence half-plane ledger, regular Cauchy partial sums, and a classifier-stable limit value.

Definition 9360.14 (Completely multiplicative coefficients)**.** *A coefficient row is completely multiplicative when* a_1 *is the unit and*

$$a_{mn} \sim a_m a_n$$

for all positive unary m, n*. This is the coefficient condition that permits Euler-product regrouping through* $\mathsf{Prime}^{\uparrow}$ *factorization.*

Theorem 9360.15 (Euler product for Dirichlet rows)**.** *For completely multiplicative coefficients in the absolute-convergence half-plane,*

$$\sum_{n \geq 1} a_n n^{-s} \sim \prod_p (1 - a_p p^{-s})^{-1}.$$

Proof. Every positive unary n has a unique finite-support prime factorization $n = \prod_p p^{k_p}$. Complete multiplicativity gives $a_n \sim \prod_p a_p^{k_p}$, while the complex analytic term row gives $n^{-s} \sim \prod_p p^{-sk_p}$. The term indexed by n therefore matches a finite-support exponent tuple. Absolute convergence supplies the modulus that permits regrouping into the product of geometric series. □

Definition 9360.16 (Zeta rows)**.** $\mathsf{ZetaBasic}^{\uparrow}$ *is the specialization of* $\mathsf{Dirichlet}^{\uparrow}$ *at the constant unit coefficient row on the half-plane* $\Re(s) > 1$*. It has both the Dirichlet-sum face and the Euler-product face*

$$\zeta(s) \sim \prod_p (1 - p^{-s})^{-1}.$$

The $\mathsf{ZetaCont}^{\uparrow}$ *row extends this carrier to* $\mathsf{Complex}^{\uparrow} \setminus \{1\}$ *by a continuation ledger with pole, functional-equation, trivial-zero, and* $\mathsf{Gamma}^{\uparrow}$ *horizon rows.*

Theorem 9360.17 (Zeta non-vanishing in the Euler-product half-plane)**.** *For $\Re(s) > 1$, the* $\mathsf{ZetaBasic}^{\uparrow}$ *value is apart from zero.*

Proof. The Euler-product row gives factors $(1 - p^{-s})^{-1}$. Their denominators have lower bound $1 - p^{-\Re(s)}$, and the product convergence ledger gives an explicit positive bound for the finite products and their limit. Thus the limit value is apart from the zero complex history. □

9360.4 Critical Strip and Zeta Zeros

Definition 9360.18 (Critical strip and line)**.** *For a complex history s with real component σ, the critical strip row is*

$$\mathsf{InCritStrip}(s) \iff 0 < \sigma < 1$$

through strict order and apartness witnesses. The critical line row is

$$\mathsf{OnCritLine}(s) \iff \sigma \sim_{\mathsf{Real}^{\uparrow}} \frac{1}{2}.$$

The mirror involution is $J(s) = 1 - \overline{s}$, whose fixed points are exactly the critical-line rows.

Definition 9360.19 (Zeta zero ledger)**.** *A* $\mathsf{ZetaZeros}^{\uparrow}$ *row contains a source s, a value row* $\mathsf{ZetaVal}(s, z)$ *read through* $\mathsf{ZetaCont}^{\uparrow}$*, and a zero-pattern row $z \sim_{\mathsf{Complex}^{\uparrow}} 0$. A nontrivial zero row is a zeta-zero row together with the displayed* $\mathsf{InCritStrip}(s)$ *row.*

Theorem 9360.20 (Nontrivial zero is strip-bound)**.** *Every nontrivial-zero row carries its critical-strip row.*

Proof. This is projection from the nontrivial-zero packet: it is a pair consisting of the zero row and the strip row. □

Theorem 9360.21 (Conjugate zero symmetry)**.** *If s is a zeta-zero row, then $\overline{s}$ is a zeta-zero row.*

Proof. The Dirichlet sum and continuation ledgers respect complex conjugation, so $\zeta(\overline{s}) \sim \overline{\zeta(s)}$. The conjugate of the zero complex history is classified with zero, hence the zero row transports to $\overline{s}$. □

Principle 9360.22 (Zero enumeration boundary)**.** $\mathsf{ZetaZeros}^{\uparrow}$ *defines the zero predicate and its classifier-stable ledger. It does not constructively enumerate all nontrivial zeros, decide exact zerohood from finite precision, or prove the critical-line conclusion.*

9360.5 RH Target Surface

Definition 9360.23 (RH predicate)**.** *The RH-facing statement is the dependent target*

$$\mathsf{RH} := \prod_{s:\mathsf{Complex}^{\uparrow}} \left(\mathsf{InCritStrip}(s) \times \mathsf{ZetaZero}(s) \to \mathsf{OnCritLine}(s)\right).$$

A constructive counterexample surface is a complex history together with a critical-strip row, a zeta-zero row, and a displayed apartness witness from the mirror fixed locus.

Definition 9360.24 (Finite prime-window defect)**.** *For a nonempty finite prime window S, define the defect expression*

$$D_S(s) := \sum_{p \in S} \log |p^{1/2-s}|.$$

If $s = 1/2 + \delta + i\tau$, then the modulus ledger reads

$$|D_S(s)| = |\delta| \sum_{p \in S} \log p.$$

Principle 9360.25 (Defect-zero incompatibility target)**.** *The central RH-facing target is the theorem schema*

$$\mathsf{DefectZeroIncompatibility}.$$

It says that a nonempty finite prime-window defect inside the completed zeta carrier forces apartness of the zeta value from zero. This is not supplied by licensing $\mathsf{ZetaZeros}^{\uparrow}$*; it is the remaining rigidity target.*

Theorem 9360.26 (Defect incompatibility implies RH)**.** *Assume defect-zero incompatibility, zero-ledger soundness, a route from off-fixed critical-strip sources to a nonempty finite prime-window defect, and located-real collapse from absence of off-fixed apartness to the critical-line row. Then* RH *follows.*

Proof. Let s carry $\mathsf{InCritStrip}(s)$ and $\mathsf{ZetaZero}(s)$. If s is apart from the critical line, the off-fixed-to-defect route supplies a nonempty finite prime window S with $|D_S(s)| > 0$. Defect-zero incompatibility then gives apartness of $\zeta(s)$ from zero. Zero-ledger soundness gives the zero value, a contradiction. Hence no off-fixed apartness remains, and located-real collapse supplies $\mathsf{OnCritLine}(s)$. □

9360.6 L13 Boundary

Theorem 9360.27 (Number-theory and zeta admission)**.** *If the prime, prime-coordinate, p-adic, adele, Dirichlet-series, zeta-basic, critical-strip, zeta-continuation, and zeta-zero rows carry their advertised carrier, classifier, stability, ledger, and* $\mathsf{NameCert}$ *fields, then the L13 number-theory and zeta layer is admitted.*

Proof. $\mathsf{Prime}^{\uparrow}$ supplies divisibility, primality, trial division, Euclid rows, and factorization uniqueness. Prime-coordinate rows turn multiplication into finite-support exponent addition. $\mathsf{Padic}^{\uparrow}$ reads those axes as valuations, non-archimedean metrics, and completions of $\mathsf{Rat}^{\uparrow}$. $\mathsf{Adele}^{\uparrow}$ packages the archimedean and p-adic components with a finite restricted-product exception ledger. $\mathsf{Dirichlet}^{\uparrow}$ supplies regular Cauchy sums, convergence half-planes, holomorphicity, and Euler products. $\mathsf{ZetaBasic}^{\uparrow}$ specializes that interface to unit coefficients, while $\mathsf{ZetaCont}^{\uparrow}$ supplies continuation with pole, functional-equation, trivial-zero, and $\mathsf{Gamma}^{\uparrow}$ ledgers. $\mathsf{CritStrip}^{\uparrow}$ and $\mathsf{ZetaZeros}^{\uparrow}$ expose the zero-facing predicate and its boundary rows. Each row is a certificate over earlier layers, so no RH claim, zero enumeration, or ambient analytic oracle is introduced. □

Principle 9360.28 (Omega and zeta readout)**.** *At L13, prime factorization supplies the multiplicative coordinate axes, Dirichlet rows apply the exponential kernel to those axes, zeta rows recover the Euler-product carrier, continuation extends the carrier away from the pole, and zero rows expose ledgered zero atoms. This is the zeta-facing readout route; RH remains a rigidity theorem over that route.*

Chapter 9361

Omega Generation Structure Interface

chapter 9351 supplies the generated history carrier and continuation relation, while chapter 9353 licenses finite displays such as sums, products, and lists through certificates and ledgers. The present chapter records the structural interface needed before the Ω-tower of chapter 9362 is read as a single generated body: encoded display, pairing by involution, and the asymmetric time arrow. These rows do not add primitive objects. They state how already licensed interfaces may be displayed, paired, and ordered by generation.

9361.1 Licensed Generation Category

Definition 9361.1 (Licensed interface object)**.** *A licensed interface object is a packet*

$$A = (|A|, \sim_A, \Lambda_A, \mathsf{NameCert}_A)$$

where $|A|$ is a carrier predicate over admitted histories or packets, $\sim_A$ is its public classifier, Λ_A is its ledger, and $\mathsf{NameCert}_A$ is the displayed naming certificate. The certificate fields are the source specification, pattern specification, classifier specification, stability certificate, and ledger policy.

Definition 9361.2 (Licensed morphism)**.** *A licensed morphism $f : A \to B$ is a carrier map that preserves classifiers, ledgers, and continuation transport:*

$$x \sim_A y \to f(x) \sim_B f(y),$$

$$\Lambda_A(x) \to \Lambda_B(f(x)),$$

and, whenever the source interface exposes a continuation row,

$$\mathsf{Cont}_A(x, m, x') \to \mathsf{Cont}_B(f(x), m', f(x')).$$

The category of such packets and morphisms is denoted Lic_Ω.

Principle 9361.3 (No unlicensed tower coordinates)**.** *Every coordinate used by an Ω-diagram must be an object of Lic_Ω. A host carrier, informal pairing, or external encoding is invisible to the tower until it is represented by carrier, classifier, stability, ledger, and $\mathsf{NameCert}$ rows.*

Definition 9361.4 (Generation diagram)**.** *An Ω generation diagram is a directed diagram*

$$\mathcal{D}_\Omega : I \to \mathsf{Lic}_\Omega, \qquad i \mapsto R_i,$$

with readback morphisms

$$\rho_{ji} : R_j \to R_i \qquad (j \geq i).$$

Its compatible body is the carrier

$$T_\Omega := \sum_{(x_i) \in \prod_{i \in I} R_i} \prod_{j \geq i} \rho_{ji}(x_j) \sim_i x_i,$$

together with the induced body ledger assembled from the coordinate ledgers and readback witnesses.

9361.2 Encoded Display

Definition 9361.5 (Legal stream display)**.** *A legal stream display for T_Ω is a licensed interface $\mathsf{LegalStream}^\uparrow$ equipped with a stream classifier $\sim_{\mathsf{Code}}$, a stream ledger Λ_{Code}, and a decode relation*

$$\mathsf{Decode}_\Omega : \mathsf{LegalStream}^\uparrow \to T_\Omega \to \mathsf{Prop}.$$

The stream interface is not a raw bit string. It is a certified public display whose suppressed source rows remain available through the ledger.

Definition 9361.6 (Omega code morphism)**.** *An Ω code morphism is a licensed morphism*

$$\mathsf{Code}_\Omega : T_\Omega \to \mathsf{LegalStream}^\uparrow$$

such that

$$x \sim_\Omega y \to \mathsf{Code}_\Omega(x) \sim_{\mathsf{Code}} \mathsf{Code}_\Omega(y),$$

and the body ledger maps into the stream ledger:

$$\Lambda_\Omega(x) \to \Lambda_{\mathsf{Code}}(\mathsf{Code}_\Omega(x)).$$

Definition 9361.7 (Faithful and readable code)**.** *The code morphism is faithful when*

$$\mathsf{Code}_\Omega(x) \sim_{\mathsf{Code}} \mathsf{Code}_\Omega(y) \to x \sim_\Omega y.$$

It is readable when every encoded body row has a displayed readback:

$$\prod_{x : T_\Omega} \mathsf{Decode}_\Omega(\mathsf{Code}_\Omega(x), x).$$

Theorem 9361.8 (Faithful readable code excludes hidden body rows)**.** *If Code_Ω is faithful and readable, then two Ω-body rows with the same code are classified as the same body row.*

Proof. Assume

$$\mathsf{Code}_\Omega(x) \sim_{\mathsf{Code}} \mathsf{Code}_\Omega(y).$$

Faithfulness gives $x \sim_\Omega y$. Readability records that the public code is not a one-way compression: its source row is accompanied by a decode witness and a ledger route. Thus no further body distinction remains behind the displayed code. □

Corollary 9361.9 (Compiler display boundary)**.** *Compiler-style display is a faithful readable interface over licensed rows, not a hand table of external encodings. Its correctness claim is the preservation and reflection of classifiers together with the ledger route needed for readback.*

9361.3 Pairing by Involution

Definition 9361.10 (Pairing involution)**.** *For a licensed interface A, a pairing involution is a licensed endomorphism*

$$J_A : A \to A$$

with the classifier laws

$$x \sim_A y \to J_A(x) \sim_A J_A(y),$$

and

$$J_A(J_A(x)) \sim_A x.$$

Its fixed predicate is

$$\mathsf{Fix}_{J_A}(x) := J_A(x) \sim_A x,$$

and its apart-pair predicate is

$$\mathsf{ApartPair}_{J_A}(x) := J_A(x) \#_A x.$$

Theorem 9361.11 (Pairing orbits are typed)**.** *If J_A is a pairing involution, then every displayed row is either read through the fixed predicate or through a nontrivial two-step orbit whenever an apart-pair witness is supplied.*

Proof. If $\mathsf{Fix}_{J_A}(x)$ holds, the row is fixed by definition. If $\mathsf{ApartPair}_{J_A}(x)$ holds, then the first step $x \mapsto J_A(x)$ is classifier-apart from x, while the second step satisfies $J_A(J_A(x)) \sim_A x$. Thus the displayed orbit returns after two applications and is nontrivial at the first step. □

Principle 9361.12 (Pairing requires an involution)**.** *Pairing is not a global axiom over all generated objects. A layer supports pairing only after it exposes a licensed involution. Without such a morphism, the statement that rows occur in pairs has no typed BEDC meaning.*

Definition 9361.13 (Mirror row as pairing instance)**.** *At the complex zeta layer the mirror row*

$$J_\zeta(s) := 1 - \overline{s}$$

is a pairing involution on the displayed critical-strip carrier. Its fixed predicate is the critical-line row:

$$J_\zeta(s) \sim s \quad \Longleftrightarrow \quad \mathsf{OnCritLine}(s).$$

Theorem 9361.14 (Pairing-compatible generation preserves fixed rows)**.** *Let J_A be a pairing involution and let $\alpha_A : A \to A$ be a licensed generation morphism. If*

$$J_A(\alpha_A(x)) \sim_A \alpha_A(J_A(x))$$

for all x, then α_A sends fixed rows to fixed rows and sends a nontrivial paired orbit to a paired orbit or to a fixed row.

Proof. If $J_A(x) \sim_A x$, classifier preservation by α_A gives $\alpha_A(J_A(x)) \sim_A \alpha_A(x)$. The displayed commutation row then gives $J_A(\alpha_A(x)) \sim_A \alpha_A(x)$, so the image is fixed. For a nontrivial orbit, the partner of $\alpha_A(x)$ is classified with $\alpha_A(J_A(x))$. If the two images are apart, the orbit remains nontrivial; if they are classified together, it has collapsed to a fixed row. □

9361.4 Time as Generated Direction

Definition 9361.15 (One-step time row)**.** *The one-step time row on histories is the relation*

$$\mathsf{TimeStep}(h, h') := \mathsf{Ext}(h, \mathsf{b0}, h') \vee \mathsf{Ext}(h, \mathsf{b1}, h').$$

Its finite transitive closure is denoted

$$h \prec h'.$$

This is a generation order over BHist*, not an ambient clock.*

Definition 9361.16 (Local time stream)**.** *A local time stream for h is a finite chain*

$$\mathsf{Empty} = h_0 \prec h_1 \prec \cdots \prec h_n = h$$

whose adjacent rows are one-step time rows. It is a ledger of how a history is generated from the empty history.

Theorem 9361.17 (Time has forward determinacy by displayed mark)**.** *For a fixed source history h and fixed mark m, if*

$$\mathsf{Ext}(h, m, h_1), \qquad \mathsf{Ext}(h, m, h_2),$$

then $\mathsf{hsame}(h_1, h_2)$*.*

Proof. By Definition 9351.10, an Ext row with mark $\mathsf{b0}$ has result classified with the same $\mathsf{e0}$ extension of the source, and an Ext row with mark $\mathsf{b1}$ has result classified with the same $\mathsf{e1}$ extension of the source. Since the mark is fixed, both target rows lie in the same constructor class, hence are hsame. □

Theorem 9361.18 (Time direction is not pairing)**.** *The time relation $\prec$ is not a pairing involution.*

Proof. A pairing involution requires an endomorphism J with $J(J(h)) \sim h$. The time relation is generated by extension from a source history to a longer history, and Definition 9351.7 separates an empty history from its extensions and separates the two extension heads. Thus the one-step time row supplies forward generation data but does not supply a global constructive inverse endomorphism satisfying the involution law. □

Principle 9361.19 (Pairing and time have different sources)**.** *Rows may be paired only where an involution is licensed. Time is instead the finite generation direction exposed by* Ext *and accumulated by* Cont*. It is therefore not a failure of pairing, but a different structural interface over the same generated histories.*

9361.5 Interface Assembly

Theorem 9361.20 (Omega generation structure package)**.** *Assume an Ω generation diagram in* Lic_Ω*, a faithful readable code morphism, pairing involutions on the layers that claim paired behavior, and the history time row of Definition 9361.15. Then:*

encoded sameness reflects body sameness,

paired behavior is available exactly on involutive layers,

and

time is the generated continuation direction rather than an involution.

Proof. Encoded reflection is Definition 9361.8. Typed pairing is Definition 9361.11 together with Definition 9361.12. The time claim is Definition 9361.18. These three interfaces are compatible because they all live over licensed carrier, classifier, ledger, and NameCert rows. □

Principle 9361.21 (Connection to prime-shadow rigidity)**.** *The structural package does not prove any zero-rigidity theorem. It only ensures that the* Ω *body has a faithful display, that mirror fixedness is typed by an involution where available, and that the generated history direction is not confused with pairing. The RH-facing rigidity claim remains the prime-shadow and defect-zero interface of chapter 9332.*

Concretized in §8983: Omega generation boundary packets realize licensed interface, morphism, legal display, pairing, time-row, transport, replay, provenance, and local NameCert rows.

Chapter 9362

Mature Bridge and Omega Rigidity Interface Spine

L14 does not introduce another mathematical carrier beside the L0–L13 construction sequence. Its external-facing role is conservative bridge and audit:

$\mathsf{MatureSystemBridge}^{\uparrow}$, $\mathsf{StdModel}^{\uparrow}$, $\mathsf{MathlibBridge}^{\uparrow}$, $\mathsf{ConservativityReport}^{\uparrow}$, $\mathsf{VerificationReport}^{\uparrow}$.

Its internal-facing consequence is a disciplined synthesis surface: once the lower rows exist, one may package their compatible readouts as an Ω-tower and state the remaining RH rigidity target. The bridge layer interprets; the certificate layer admits.

9362.1 Conservative Bridge Boundary

Definition 9362.1 (Mature system)**.** *A mature system is an external reference environment, such as a set-theoretic presentation, a category-theory library, a homotopy-type-theory library, or a Lean/mathlib development. It is not part of the BEDC finite kernel and is not available as a source of BEDC constructors, classifiers, or theorem inhabitants.*

Definition 9362.2 (Conservative bridge)**.** *For a licensed BEDC object $A^{\uparrow}$ and a mature reference object A^{std}, a conservative bridge is a packet*

$$\mathsf{Bridge}(A^{\uparrow}, A^{\mathrm{std}}) = (F, G, \eta, \epsilon, \mathsf{LawPres}, \mathsf{NoReplace}, \mathsf{Ledger}).$$

Here F interprets BEDC rows externally, G is a partial reconstruction or decode route on a declared subdomain, η and ϵ are the displayed return witnesses, $\mathsf{LawPres}$ *records preservation of listed operations and relations,* $\mathsf{NoReplace}$ *states that the bridge does not replace internal proof obligations, and* Ledger *records unsupported fields and external dependencies.*

Theorem 9362.3 (Bridge does not generate)**.** *An external object and a bridge packet do not license $A^{\uparrow}$ unless the internal* $\mathsf{NameCert}(A^{\uparrow})$ *is already present.*

Proof. BEDC admits objects through internal carrier, classifier, stability, ledger, and naming rows. The mature object lies outside that generative surface. A bridge can interpret a licensed BEDC row, but if the internal $\mathsf{NameCert}$ is absent there is no BEDC carrier for the bridge to interpret. Therefore the external object cannot substitute for internal admission. □

Principle 9362.4 (Bridge interpretation boundary)**.** *Standard models may read out BEDC objects, and bridge packets may compare finite theorem lists. They do not authorize additional BEDC objects, additional BEDC classifiers, or additional BEDC proof terms.*

9362.2 Standard and Mathlib Bridges

Definition 9362.5 (Standard interpretation)**.** *A standard interpretation for $A^{\uparrow}$ is a map*

$$\mathsf{Interp}_A(-) : A^{\uparrow} \to A^{\mathrm{std}}$$

that respects the BEDC classifier and the listed operations. Exactness in the reverse direction is a separate field and is usually restricted to normalized or otherwise decoded subcarriers.

Theorem 9362.6 (Standard preservation)**.** *If a licensed BEDC object carries a theorem expressed by its classifier, and the bridge supplies the listed law-preservation rows, then the interpreted statement holds in the mature reference object.*

Proof. Apply the interpretation to both sides of the BEDC classifier theorem. Classifier preservation identifies the interpreted endpoints. Operation preservation rewrites the interpreted BEDC operations into the corresponding mature operations. The resulting equality is the mature-side statement named by the bridge ledger. □

Definition 9362.7 (Mathlib bridge)**.** *A mathlib bridge for $A^{\uparrow}$ is an external interoperability packet*

$$(\mathsf{TargetType}, \mathsf{Encode}, \mathsf{Decode}, \mathsf{Sound}, \mathsf{Complete}, \mathsf{LawMap}, \mathsf{AxiomAudit}).$$

The target type belongs to mathlib, the encode and decode rows are bridge-layer maps, soundness and completeness are scoped to the declared domain, LawMap *lists theorem correspondences, and* AxiomAudit *records use of host axioms and unsupported features.*

Theorem 9362.8 (Mathlib bridge conservativity)**.** *If $A^{\uparrow}$ already has a BEDC* NameCert*, the mathlib bridge is used only after internal construction, and no mathlib target type flows into the BEDC carrier, classifier, or proof term, then the bridge is conservative over the BEDC theorem surface.*

Proof. The internal proof DAG for a BEDC theorem contains only BEDC rows. The bridge is applied after the theorem is generated, as an interpretation layer. Removing the bridge leaves the same internal proof DAG and the same public theorem. Thus the bridge adds interoperability but not internal proof strength. □

9362.3 Conservativity and Verification Reports

Definition 9362.9 (Conservativity report)**.** *A conservativity report for a module M records*

$$(\mathsf{InternalDeps}, \mathsf{ExternalDeps}, \mathsf{AxiomUse}, \mathsf{HostLeakage}, \mathsf{BridgeOnly}, \mathsf{SubstitutionCheck}, \mathsf{Verdict}).$$

The verdict is conservative only when external references are bridge-only, host primitives do not appear on the public BEDC surface, forbidden axiom use is absent, and no mature object substitutes for an internal proof obligation.

Theorem 9362.10 (Bridge-only external references are conservative)**.** *If every external reference in M is bridge-only and the substitution check does not fail, then those references do not add internal BEDC theorem content.*

Proof. Bridge-only means the external system interprets already generated rows. The substitution check rules out using the external object as the source of a BEDC carrier, classifier, or proof. Deleting the external bridge therefore leaves the internal dependencies and proof obligations unchanged. □

Definition 9362.11 (Verification report)**.** *A verification report records the checker version, command, external imports, checked theorem names, admitted or pending statements, public API audit, and axiom audit. Its strict pass condition requires no admitted statements, no forbidden axiom dependencies, no public host leakage, marker resolution for every checked paper target, and a reproducible command line.*

Theorem 9362.12 (Strict pass yields checked certificate status)**.** *If a module's verification report has strict pass, then its checked markers may be used as checked certificate rows for the corresponding paper sites.*

Proof. Strict pass states that every checked marker resolves to a real declaration, no pending or admitted statement is being used as a proof, the axiom audit is clean, and the public API does not expose host primitives. Those are exactly the conditions needed for the checked marker to harden the corresponding certificate row. □

9362.4 Phase Discipline and Refutation Boundary

Definition 9362.13 (Development phase)**.** *A development phase is a packet*

$$(\mathsf{Name}, \mathsf{Scope}, \mathsf{ExitCriterion}, \mathsf{AllowedTargets}).$$

The phase controls which layer may be hardened and which higher-layer targets may appear only as scaffolds or consumers of the current closure work.

Principle 9362.14 (Lowest open layer priority)**.** *If a lower layer has an unmet exit criterion, work in a higher layer does not close that lower layer. Higher-layer rows may be written as scaffold or route targets only when their purpose is to expose the lower-layer obligation.*

Theorem 9362.15 (Higher rows do not close lower obligations)**.** *Let L_k have an unmet carrier, classifier, stability, ledger, or* $\mathsf{NameCert}$ *obligation. A checked row in a layer L_j with $j > k$ does not by itself close the missing L_k obligation.*

Proof. The dependency direction runs from lower layers to higher layers. A higher row may consume lower rows, but it does not provide the missing lower carrier, classifier, stability, ledger, or naming field unless it is explicitly a proof of that lower obligation. Therefore higher-layer success does not imply lower closure. □

Definition 9362.16 (Refutation boundary)**.** *BEDC accepts a displayed route $P \to \bot$ as a refutation of P. It does not accept a witness-free move from $\neg P \to \bot$ to P when P is an existential or otherwise witness-bearing claim outside a decidable fragment.*

Principle 9362.17 (RH contradiction discipline)**.** *An RH argument translated into BEDC must produce the proof function*

$$\prod_s (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{OnCritLine}(s))$$

or explicitly mark the step that leaves the constructive fragment.

9362.5 Omega Tower

Definition 9362.18 (Full constraint diagram)**.** *The Ω diagram is a family*

$$\mathcal{D}_\Omega = (R_i, \sim_i, C_i, \rho_{ji}, \alpha_i, \Lambda_i)_{i\in I}$$

where R_i is a layer carrier, $\sim_i$ its classifier, C_i its constraint predicate, $\rho_{ji} : R_j \to R_i$ a readback map, $\alpha_i : R_i \to R_i$ a self-similar operation at that layer, and Λ_i the local ledger.

Definition 9362.19 (Omega tower carrier)**.** *The tower carrier is the compatible family packet*

$$T_\Omega := \sum_{(r_i)\in\prod_i R_i} \left[\prod_i C_i(r_i)\right] \times \left[\prod_{j\to i} \rho_{ji}(r_j) \sim_i r_i\right] \times \Lambda_\Omega.$$

It is the $\mathsf{CatLimit}^\uparrow$ *reading of all layer readouts, constraints, readbacks, and ledgers at once.*

Definition 9362.20 (Mother operation)**.** *If the operations α_i commute with readback,*

$$\rho_{ji}(\alpha_j(r_j)) \sim_i \alpha_i(\rho_{ji}(r_j)),$$

then $\Omega_\infty : T_\Omega \to T_\Omega$ is defined by acting componentwise:

$$\Omega_\infty((r_i)_i) = (\alpha_i(r_i))_i.$$

Theorem 9362.21 (Projection law)**.** *For every layer projection $\pi_i : T_\Omega \to R_i$,*

$$\pi_i \circ \Omega_\infty \sim \alpha_i \circ \pi_i.$$

Proof. For $x = (r_i)_i$, the left side reads the i-component of $(\alpha_j(r_j))_j$, namely $\alpha_i(r_i)$. The right side first reads r_i and then applies α_i. The two displayed histories are the same component row, so the layer classifier identifies them. □

Principle 9362.22 (Boundary and fibre reading)**.** *Each projection $\pi_i : T_\Omega \to R_i$ is a boundary readout, and the fibre over r is the compatible bulk packet*

$$\mathrm{Fib}_i(r) := \sum_{x:T_\Omega} \pi_i(x) \sim_i r.$$

Thus the tower is a boundary, bulk, fibre, and readback geometry over the previously licensed layers.

9362.6 Omega-RH Rigidity

Definition 9362.23 (Zeta projection and zero atom)**.** *Let $\pi_\zeta : T_\Omega \to R_\zeta$ be the projection to the* $\mathsf{ZetaCont}^\uparrow$ *and* $\mathsf{ZetaZeros}^\uparrow$ *layer. The tower zero atom predicate is*

$$\mathsf{ZeroAtom}_\Omega(x) := \mathsf{ZetaZero}(\pi_\zeta(x)).$$

Definition 9362.24 (Omega counterexample surface)**.** *The tower counterexample surface is*

$$\mathsf{CounterRH}_\Omega := \sum_{x:T_\Omega} \left(\mathsf{ZeroAtom}_\Omega(x) \times \mathsf{InCritStrip}(\pi_\zeta(x)) \times \mathsf{ApartNonFix}(\pi_\zeta(x))\right).$$

It is a witness-bearing surface, not a decision procedure over all zeros.

Definition 9362.25 (Omega zero rigidity)**.** *The tower rigidity target is*

$$\mathsf{ZeroRigidity}_\Omega := \prod_{x:T_\Omega} (\mathsf{ZeroAtom}_\Omega(x) \times \mathsf{InCritStrip}(\pi_\zeta(x)) \to \mathsf{OnCritLine}(\pi_\zeta(x)))\,.$$

Theorem 9362.26 (Tower rigidity implies RH)**.** *If every legal zeta-zero packet is the π_ζ projection of some tower point and* $\mathsf{ZeroRigidity}_\Omega$ *holds, then the RH predicate holds.*

Proof. Let s carry $\mathsf{ZetaZero}(s)$ and $\mathsf{InCritStrip}(s)$. By the same-source projection hypothesis, choose $x : T_\Omega$ with $\pi_\zeta(x) \sim s$. Transport the zero and strip rows along this classifier comparison. Tower rigidity gives $\mathsf{OnCritLine}(\pi_\zeta(x))$, and classifier transport gives $\mathsf{OnCritLine}(s)$. □

Theorem 9362.27 (Defect incompatibility gives tower rigidity)**.** *Assume* $\mathsf{DefectZeroIncompatibility}$*, zero-ledger soundness, off-fixed-to-defect, and located-real collapse. Then* $\mathsf{ZeroRigidity}_\Omega$ *holds.*

Proof. Take $x : T_\Omega$ with a zero atom and critical-strip row, and write $s := \pi_\zeta(x)$. If s is apart from the critical line, the off-fixed-to-defect route supplies a nonempty finite prime-window defect. Defect-zero incompatibility makes $\zeta(s)$ apart from zero. Zero-ledger soundness from the zero atom gives the zero value, a contradiction. Hence there is no off-fixed apartness, and located-real collapse gives $\mathsf{OnCritLine}(s)$. □

9362.7 L14 Boundary

Theorem 9362.28 (Mature bridge and omega synthesis admission)**.** *If mature-system bridge, standard-model bridge, mathlib bridge, conservativity-report, and verification-report packets carry their declared fields, and if the Ω tower is given as the internal compatible* $\mathsf{CatLimit}^\uparrow$ *packet over L0–L13 readouts, then L14 is admitted as a bridge and audit layer, while* $\mathsf{ZeroRigidity}_\Omega$ *remains the internal RH-facing rigidity target.*

Proof. The bridge packets interpret licensed objects and carry no substitution route for internal certificates. Conservativity and verification reports audit external dependencies, host leakage, checked markers, and axiom use. Phase discipline prevents higher bridge rows from closing lower layer obligations. The Ω tower is internal because it is a compatible $\mathsf{CatLimit}^\uparrow$ packet over the already declared lower readouts. The projection law supplies the componentwise mother-operation readout, and the RH-facing theorems reduce RH to tower zero rigidity, with defect-zero incompatibility identified as the remaining rigidity target. □

Principle 9362.29 (Final boundary)**.** *At this surface the tower from b_0, b_1 through* $\mathsf{ZetaZeros}^\uparrow$ *and Ω_∞ can state RH as a rigidity theorem. The work is no longer a claim that the bridge proves RH; it is the explicit target that off-fixed zero atoms in the tower must be incompatible with the zeta zero ledger.*

Concretized in §8829: The Omega-rigidity ledger is realized as finite bridge-report, standard-readout, lower-layer NameCert, compatibility, audit, and no-replacement rows.

Chapter 9363

The Finite Kernel Is Already a Category

The checked categorical interface for BEDC is the unary-continuation $\mathsf{Cat}^{\uparrow}$ package over BHist. Its objects are unary histories, its displayed hom-carriers are histories f equipped with a continuation ledger from a to b, and morphism equality is the endpoint-stable classifier hsame on displayed hom histories. The prior capstone Computation as Continuation (chapter 9365) reads Cont as a small-step relation; the present chapter records the checked categorical reading available to the paper-Lean interface.

9363.1 Hom as unary continuation

Theorem 9363.1 (Unary-continuation category realizes the continuation interface)**.** *For unary histories $a, b, f : \mathsf{BHist}$, the checked hom-carrier $\mathsf{CategoryHomCarrier}(a, b, f)$ is equivalent to unary endpoints and a continuation morphism whose tail is classified as f:*

$$\mathsf{CategoryHomCarrier}(a, b, f) \iff \mathsf{UnaryHistory}(a) \wedge \mathsf{UnaryHistory}(b) \wedge \mathsf{UnaryHistory}(f) \wedge \exists m : \mathsf{ContinuationMorphis}$$

With this hom-carrier, the unary-continuation $\mathsf{Cat}^{\uparrow}$ package satisfies identity, binary composition closure, associativity of displayed composition, left and right unit laws, and endpoint-transport stability under hsame.

Proof. The equivalence is exactly Definition 61.317. Its forward direction unpacks a displayed hom-carrier into unary source, target, and morphism histories, then packages the continuation ledger as a $\mathsf{ContinuationMorphism}$ whose displayed tail is classified by hsame. Its reverse direction transports the continuation ledger carried by the morphism tail across the supplied hsame classifier and repacks the four fields of $\mathsf{CategoryHomCarrier}$.

The categorical law package is Definition 61.325. It supplies the empty hom-carrier identities, closure under displayed binary composition, associativity for the two displayed composites of a threefold composition, the left and right empty-composition laws, and preservation of hom-carriers after endpoint transport along hsame. □

Theorem 9363.2 (Category hom-carrier morphism induction)**.** *For fixed unary-continuation endpoints $a, b : \mathsf{BHist}$, any predicate on displayed morphism histories holds for every $\mathsf{CategoryHomCarrier}(a, b, f)$ if it holds at e and is preserved by one-step unary extension of the morphism history.*

Proof. Unpack $\mathsf{CategoryHomCarrier}(a, b, f)$. Its morphism field is exactly the unary-history witness for f, so unary-history induction over f proves the displayed predicate. □

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier morphism induction`

9363.2 Derived presentations over the unary category

Remark 9363.3 (FunctorUp and NatTransUp as bounded bridges)**.** $\mathsf{NameCert}_{\mathsf{Functor}^{\uparrow}}$ *(chapter 62) and* $\mathsf{NameCert}_{\mathsf{NatTrans}^{\uparrow}}$ *(chapter 63) are prefix and component presentations over the checked unary-continuation category. They use the same BEDC carriers, classifiers, and continuation stability obligations at their own certificate sites. A standard category interface or mathlib bridge is not asserted here; that bridge remains governed by the roadmap bridge phase.*

Capstone

Theorem 9363.4 (Prefix functor identity naturality bridge)**.** *For histories* $p, a, b, f, left, right$: BHist*, assume* $\mathsf{UnaryHistory}(p)$*,* $\mathsf{CategoryHomCarrier}(a, b, f)$*,* $\mathsf{Cont}(\mathsf{e}, f, left)$*, and* $\mathsf{Cont}(f, \mathsf{e}, right)$*. Then the checked* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, and* $\mathsf{NatTrans}^{\uparrow}$ *facts compose into the concrete identity-naturality bridge:*

1. *$left$ and $right$ are hom-carriers from* $\mathsf{append}(p, a)$ *to* $\mathsf{append}(p, b)$*.*
2. $\mathsf{hsame}(left, right)$*.*
3. *each displayed hom-carrier reflects through the unary context exactness theorem to the original unprefixed hom carrier* $\mathsf{CategoryHomCarrier}(a, b, f)$*, with the left and right unit continuations identifying the displayed morphism with f.*
4. *for every unary object x :* BHist *and every empty identity continuation id with* $\mathsf{Cont}(\mathsf{e}, \mathsf{e}, id)$*, the empty component supplied by the prefix functor identity law is a hom-carrier from* $\mathsf{append}(p, x)$ *to* $\mathsf{append}(p, x)$*.*

Proof. Apply Definition 63.47 to the unary prefix, the displayed hom-carrier $f : a \to b$, and the two empty-composite continuations. It gives the two displayed hom-carriers after prefixing by p and the classifier equality $\mathsf{hsame}(left, right)$.

Next apply Definition 61.51 to each displayed carrier. The same unary prefix p is already part of the hypotheses, so the readback is the corresponding unprefixed hom-carrier; the empty left and right unit continuations identify those displayed morphisms with the original carrier f.

Finally, apply Definition 62.36 at any unary object x. Its identity-closure statement supplies the empty component carrier over $\mathsf{append}(p, x)$, giving the component data used by the identity natural transformation. □

Remark 9363.5 (No new axioms)**.** *Definition 9363.1 introduces no kernel-level definition not already present in the checked* $\mathsf{Cat}^{\uparrow}$ *continuation bridge. The categorical reading is obtained by unfolding* $\mathsf{CategoryHomCarrier}$*,* $\mathsf{ContinuationMorphism}$*, and* hsame *transport, then applying the already checked stability package.*

Concretized in §471: Unary-continuation category packet over BHist, Cont, hsame, Pkg, and NameCert.

Concretized in §488: The unary-continuation category is realized as a concrete NameCert over BHist hom rows, hsame transport, Cont routes, and package provenance.

Concretized in §484: Finite kernel category carrier and NameCert packet.

Concretized in §480: The unary-continuation categorical reading is realized as a concrete NameCert surface over BHist, Cont, hsame, CategoryHomCarrier, Pkg, and local naming rows.

Concretized in §675: Prefix functor identity-naturality bridges are realized as finite BHist, CategoryHomCarrier, Cont, hsame, FunctorUp, NatTransUp, Pkg, and NameCert packets.

Concretized in §835: Finite-support packets over unary-continuation hom rows, Cont routes, hsame transport, Pkg provenance, and NameCert ledger rows.

Concretized in §1111: Unary-continuation endofunctors are realized as finite BHist packets preserving object rows, hom rows, identities, composition, hsame transport, Cont routes, Pkg provenance, and local NameCert data.

Concretized in §1179: Slice-category packets over a fixed unary-continuation base object are realized as finite BHist, CategoryHomCarrier, hsame, Cont, Pkg, and NameCert fibers.

Concretized in §7158: Kernel-category functorial transport is realized as a finite NameCert packet.

Chapter 9364

Lean Kernel Acceptance as the Canonical BEDC Audit Witness

BEDC repeatedly speaks of audit gates, generator-closure classifiers, NameCert verification, and executable ledgers. This chapter identifies the concrete mechanism underneath those phrases. Lean 4 kernel acceptance is the canonical audit witness for BEDC. It is not a metaphor for audit. It is the mechanism by which a proposed definition, theorem, inductive carrier, recursor use, and proof object enters the BEDC ledger as checked content.

The claim is intentionally strict. A BEDC audit unit has a generator, a classifier, a stamp, and a ledger position. At the Lean boundary, the generator is the term-building process that produces an elaborated term. The classifier is the kernel type-checking predicate, including definitional reduction and the side conditions for accepted recursion and inductive declarations. The stamp is kernel acceptance. The ledger position is the declaration entered into the environment and later visible to dependency queries such as `#print axioms`.

9364.1 The setup

The paper-side vocabulary is abstract because it must apply across many surfaces. A NameCert says that a public name is not decorative: it has a source, a classifier, a stability route, and a ledger row. A generator-closure classifier says which outputs remain inside the closure of the generator that licensed them. An audit gate is the executable refusal rule that rejects a record whose source, classifier, or dependency ancestry does not match the claim.

Lean kernel acceptance is the place where these abstract units become one machine event. When Lean accepts `def f := t`, the environment does not merely store text. It stores a name whose type has been checked against an elaborated term. When Lean accepts `theorem T : P := p`, the environment stores a name whose proof term has been checked as an inhabitant of P. When Lean accepts an `inductive` declaration, it stores a closed constructor signature and emits the eliminators permitted by that signature. When Lean accepts a structurally recursive definition, it has checked the recursion discipline that allows the definition to compute inside the accepted closure.

Thus the BEDC audit unit at the Lean boundary is:

$$\begin{aligned}\text{term builder} &\xrightarrow{\text{elaboration}} \text{kernel candidate}\\ &\xrightarrow{\text{type checking}} \text{accepted declaration}\\ &\xrightarrow{\text{environment entry}} \text{ledger row.}\end{aligned}$$

The same event has the BEDC reading:

$$\begin{aligned}\text{generator} &\xrightarrow{\text{classifier}} \text{stamped name}\\ &\xrightarrow{\text{ledger}} \mathsf{NameCert}\text{-visible content.}\end{aligned}$$

There is no second certification channel behind this map. The kernel event is the certification channel used by the Lean side of BEDC.

9364.2 What the Lean kernel does at acceptance

At acceptance time the kernel checks an elaborated object against its claimed type. This check includes substitution under binders, universe and type compatibility checks, definitional reduction, and the de Bruijn shifting that keeps binder structure coherent. For recursive definitions, Lean also requires an accepted recursion or termination account. For inductive declarations, Lean checks the constructor signature and its positivity discipline before the carrier and eliminators enter the environment.

The important feature for BEDC is that the kernel checks a generated object, not a prose intention. The object may have been produced by a tactic, by a direct term, by a recursive definition, or by elaboration of ordinary syntax. Those routes matter as generators, but the acceptance event is the kernel's judgment that the generated object has the claimed type inside the current environment.

If the check fails, there is no BEDC stamp at that name. If the check succeeds, the declaration is entered. This is the exact operational meaning of a checked Lean target in the manuscript. The paper marker is not a promise that the prose is convincing. It is a pointer to a declaration whose proof term or definition has passed kernel acceptance.

9364.3 NameCert stamping

Each kernel-acceptance event is one $\mathsf{NameCert}$ stamping at the relevant Lean name. The statement is definitional at the BEDC reading layer:

$$\begin{aligned}\text{classifier} &:= \text{kernel type-checking predicate,}\\ \text{generator} &:= \text{term builder that produced the candidate,}\\ \text{stamp} &:= \text{kernel acceptance of the candidate,}\\ \text{ledger} &:= \text{environment entry under the accepted name.}\end{aligned}$$

Thus a checked theorem name is not a theorem plus a separate certificate. Its checkedness is the certificate surface. A checked definition name is not a definition plus a separate permission slip. Its accepted type and body are the permission event. A checked inductive carrier is not a carrier plus an external authorization story. Its accepted constructor signature and emitted eliminator are the authorization.

BEDC uses NameCert vocabulary because it needs a uniform language for these events across paper-side certificates, recognized event flows, concrete instances, and Lean declarations. At the Lean boundary, the uniform language is realized by kernel acceptance. NameCert is the BEDC name for that accepted name-bearing closure event.

9364.4 `#print axioms` as audit ledger closure

A local kernel stamp is necessary, but BEDC also asks whether the accepted object imports any forbidden source through its ancestry. Lean exposes this by the command `#print axioms`. For a theorem, the command reports the transitive axiom dependencies of the declaration. This is not a philosophical summary. It is a dependency-ledger query over the checked environment.

BEDC's strict purity audit uses that query as a gate. The command `python3 lean4/scripts/bedc_ci.py axiom-purity -strict` builds the relevant Lean-side query surface, runs `#print axioms` over BEDC declarations, and rejects forbidden dependencies. The target report for a BEDC theorem is that the transitive axiom set is empty. The project-level witness is:

$$\texttt{\#print axioms}\, T = \texttt{(no axioms)}.$$

This is the strongest audit witness in the project because it does not stop at the local declaration surface. It asks whether the whole transitive closure of the theorem's proof ancestry contains an ungenerated commitment. A proof that looks structurally acceptable locally but depends on `Classical.choice`, `Quot.sound`, or `propext` fails this ledger reading. The problem is not that Lean cannot accept such a proof in a broader environment. The problem is that BEDC does not classify such ancestry as BEDC-internal closure.

9364.5 `lake build` as ledger instantiation

The command `cd lean4 && lake build` instantiates the Lean ledger as a single execution. Lean loads the project modules in dependency order, elaborates the declarations, invokes the kernel, checks recursion and inductive authorization at the appropriate sites, and enters accepted declarations into the environment. A successful build means the project has replayed the kernel-acceptance events required by the Lean modules.

In BEDC terms:

$$\begin{aligned} \texttt{lake build} &= \text{execution of all Lean-side classifier checks,} \\ \text{successful build} &= \text{all required kernel stamps obtained,} \\ \text{strict purity pass} &= \text{accepted stamps have clean transitive ancestry.} \end{aligned}$$

This is why build success is more than compilation hygiene for BEDC. It is the act by which the audit ledger is populated in a reproducible run. The manuscript can cite a Lean target only because the target is replayable through this mechanism and its dependency row can be queried afterward.

Concretized in §549: Kernel acceptance witness packets realize the Lean boundary as a finite NameCert surface over generated candidates, accepted declarations, environment ledger rows, axiom-query purity, and refusal boundaries.

9364.6 Closed-term substitution cross-link

chapter 9372 reads closed-term substitution as a self-compilation step. The local classifier is `ClosedAt`. The generator is `substitute`. The closure witness is that substitution at the closed boundary is inert:

$$\mathsf{ClosedAt}(d, t) \Rightarrow \mathsf{substitute}(d, v, t) = t.$$

The corresponding Lean target is

↪ variant `BEDC.MetaCIC.substitute closed`

with the companion shifting witness

↪ variant `BEDC.MetaCIC.shift closed`

The generator-closure classifier abstraction over both is

↪ variant `BEDC.MetaCIC.GeneratorClosureClassifier`

with concrete instances

↪ variant `BEDC.MetaCIC.closed under substitute classifier`

and

↪ variant `BEDC.MetaCIC.closed under shift classifier`

; each instance is a single kernel-accepted closure proof, and the audit witness reading of this chapter applies pointwise to every such instance.

The present chapter adds the outer audit fact. The theorem can function as a BEDC certificate only because the Lean kernel accepts its proof term. The paper-side reading says that `substitute` preserves the closed-term classifier on the relevant slice. The kernel-side event says that the proof term inhabiting that statement has been checked and entered into the ledger.

The layers are not competitors. The substitution theorem describes a generator-closure classifier instance inside MetaCIC. Kernel acceptance is the audit instrument that lets that description become checked BEDC content.

Concretized in §711: GeneratorAuditClosureUp realizes generator-closure classifier proofs as finite audit packets over generator rows, accepted closure witnesses, audit-query ledgers, hsame transport, Cont replay, Pkg provenance, and local NameCert naming.

9364.7 Recursor cross-link

chapter 9373 reads the recursor emitted for an accepted `inductive` declaration as an authorized generator. The present chapter pins down when that authorization occurs. It occurs at kernel time.

For an `inductive` declaration I, Lean checks the constructor signature and its positivity discipline. Only after that acceptance does the carrier enter the environment and only then are the eliminators associated with I available as legal generators. A later use of I.`rec` is checked again through its motive, branch package, and recursive structure. There is no kernel-external licensing authority that blesses the recursor after the fact.

The authorization map is:

$$\begin{aligned} \text{strictly positive accepted signature} &\Longrightarrow \text{closed carrier}, \\ \text{closed carrier} &\Longrightarrow \text{emitted recursor}, \\ \text{accepted recursor use} &\Longrightarrow \text{checked generator output}. \end{aligned}$$

This is precisely the NameCert stamping pattern. Constructor signature, eliminator generation, branch checking, and output type checking are not separate metaphors for BEDC authorization. They are the kernel events whose BEDC name is authorization.

9364.8 Why this is not an infinite regress

The kernel itself is not audited by another BEDC kernel inside the project. It is the project trust boundary. BEDC treats the Lean 4 kernel as its minimal trusted base, or MTB, for mechanized checking. This is an explicit commitment, not an epistemic gap hidden behind the paper vocabulary.

The same boundary appears in Lean projects generally and in neighboring proof assistant traditions such as Coq and Agda. A formal development trusts a small kernel to check proof objects, then audits what enters through that kernel. BEDC's difference is not that it has no trust boundary. The difference is that it names the boundary and refuses to let forbidden dependencies cross it silently into BEDC theorem content.

Thus the audit story stops at the kernel because the kernel is the instrument, not because BEDC has forgotten to audit one more layer. Below that boundary lie the implementation language, compiler, runtime, hardware, and human operational discipline. Those are real dependencies, but they are outside the BEDC theorem-content classifier. Their position is the MTB socket, not an unmarked Lean theorem.

9364.9 Kernel boundary as apophatic socket

Kernel acceptance is apophatic in the precise BEDC sense. The kernel does not give a positive philosophical interpretation of the generator output. It checks whether the generated object fits the claimed type under the accepted rules and environment. It certifies closure without explaining the content as a human meaning.

This is exactly why the kernel is the deepest BEDC socket. Downstream audit can ask whether a name resolves, whether a theorem builds, whether `#print axioms` is clean, whether a paper marker points to an existing target, and whether an inductive generator was accepted. All those questions delegate to the kernel boundary. The boundary says yes or no to a generated object. It does not convert that yes into a complete positive interpretation of the object.

The apophatic discipline is therefore not outside the engineering. The kernel is the last-resort socket through which BEDC receives checked formal content. It is a socket because BEDC does not internalize the kernel's own correctness as a BEDC theorem. It is apophatic because the acceptance event supplies the audit stamp while remaining silent about any interpretation not expressed in the checked type.

9364.10 Boundary: what kernel acceptance does not certify

Kernel acceptance is necessary for Lean-side BEDC content, but it is not sufficient for every paper-side interpretation. The kernel can accept:

```
theorem T : True := True.intro.
```

That declaration is a legal Lean theorem. The kernel has checked that `True.intro` inhabits `True`. It has not checked that the name `T` carries a deeper intended claim, nor that the surrounding

prose has earned a strong interpretation. This is the root of the placeholder pattern: a theorem with a weak statement can be fully accepted by the kernel while carrying little mathematical content.

BEDC therefore uses kernel acceptance as the canonical audit witness, while also keeping paper-side closure status, marker discipline, NameCert rows, and purity gates separate. The kernel tells the project that the generated Lean object is well typed and ledgered. The strict dependency audit tells the project whether the object imports forbidden ancestry. The manuscript must still state the scope of the claim accurately.

The final equation is:

$$\text{Lean kernel acceptance} = \text{canonical BEDC audit witness},$$
$$\text{canonical audit witness} \neq \text{unlimited semantic certification}.$$

The first line is the mechanism. The second line is the boundary that keeps the mechanism honest.

Concretized in §547: Lean kernel acceptance is realized as a finite audit-witness NameCert packet over generated candidate, accepted declaration, environment ledger, axiom-query, build replay, and non-escape rows.

Concretized in §742: Build replay is realized as a finite NameCert packet over generated candidate, accepted declaration, build command, replay result, axiom-query handoff, route, provenance, and non-escape rows.

Concretized in §557: Kernel acceptance traces are realized as finite NameCert packets over generated candidates, kernel classifier stamps, environment ledger rows, axiom-dependency reports, hsame transport, Cont replay, Pkg provenance, and local naming.

Concretized in §915: Kernel inductive acceptance is realized as finite carrier, constructor, audit-witness, transport, replay, provenance, and NameCert rows.

Concretized in §1096: Kernel inductive eliminator packets realize the emitted case-analysis rule surface as finite NameCert data.

Concretized in §654: Axiom query ledgers realize strict proof-ancestry audit as finite BHist rows for accepted declarations, axiom-query output, forbidden-dependency refusal, replay provenance, and local NameCert naming.

Concretized in §671: KernelSourceChannelLedgerUp realizes the source-channel audit ledger separating generated candidates, kernel stamps, accepted declarations, environment ancestry, and axiom-query refusal boundaries.

Concretized in §709: Closed generator audit packets realize kernel acceptance, authorized recursor output, and closed-term substitution as one finite MetaCIC NameCert audit surface.

Concretized in §1029: Kernel-normalization audit joins realize kernel acceptance, axiom-query ledger, normalization audit replay, and subject-reduction boundary rows as one finite NameCert packet.

Concretized in §6007: Kernel acceptance boundary packets realize generated candidates, kernel classifier stamps, ledger rows, purity queries, and refusal boundaries as finite NameCert data.

Concretized in §6356: Finite kernel budget flow is realized as BMark, BHist, Cont, Pkg, Gap, ledger, and NameCert rows.

Chapter 9365

Computation as Continuation: BEDC's Operational Semantics

Concretized in §469: Packages the continuation-as-small-step reading as a finite BHist trace certificate with readback and non-escape boundaries.

Concretized in §657: Continuation big-step packets realize terminal-read computation as a finite BHist NameCert surface over small-step traces, Cont replay, hsame transport, Pkg provenance, and local naming.

Concretized in §683: Continuation trace normal forms realize terminal Cont-replay computation as a finite NameCert packet with no host conversion or normalization oracle.

Concretized in §931: Unary Cont monoid packets realize the continuation-as-computation vision as a finite NameCert carrier over UnaryHistory, Cont composition, Empty unit, hsame transport, and non-escape ledger rows.

Concretized in §1026: Kleisli trace packets realize continuation computation as a finite BHist trace surface over ContinuationMonad, trace normal form, Category hom rows, hsame transport, Cont replay, Pkg provenance, and local naming.

The continuation primitive Cont of chapter 4 carries the formal content of a small-step transition relation. Reading $\mathsf{Cont}\, h\, m\, h'$ as "the history h steps via mark m to history h'" makes Cont a Plotkin-style structural operational semantics over the BEDC primitive layer. The chapter records the structural isomorphism between Cont and the small-step relations of standard programming-language semantics, and locates termination, big-step semantics, and behavioural equivalence as classifier-level notions already present in the kernel.

Concretized in §482: Continuation automata realize the Cont-as-small-step vision as a finite NameCert carrier with behaviour classifiers.

Concretized in §1016: Finite prefix automata realize bounded continuation-recognizer runs as finite BHist transition, prefix, endpoint, acceptance, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1030: Finite prefix machines realize machine-specific bounded continuation prefixes as displayed BHist, Cont, Pkg, and NameCert rows.

Concretized in §597: Continuation termination packets realize the termination and behaviour-classifier reading of Cont traces as finite BHist, hsame, Pkg, and NameCert rows.

9365.1 Continuation as small-step transition

Theorem 9365.1 (Continuation-SOS correspondence)**.** *Let* Terminates *be a history carrier equipped with a naming certificate whose classifier is* Behavior*. If a small-step predicate* Step *is exactly the relation "there exists a continuation tail", then every step exposes such a tail and every continuation-tail witness reconstructs a step. The naming certificate transports termination along behaviour, each terminating history is behaviour-related to itself, and internal sameness from a terminating history supplies the canonical behaviour witness on the carrier.*

Lean4 ✓ `BEDC.Reflection.computation as continuation correspondence proof`

↪ variant `BEDC.Reflection.computation as continuation correspondence`

Capstone. The same continuation ledger has three concrete readings: as categorical hom-carrier data, as a unary prefix preorder witness, and as monoid append of continuation tails.

Theorem 9365.2 (Unary prefix category correspondence)**.** *For unary histories a, b, f, the displayed ledger* $\mathsf{CategoryHomCarrier}(a, b, f)$ *is exactly the datum that f is the unary continuation tail witnessing the concrete prefix comparison from a to b:* $\mathsf{UnaryHistory}(a)$*,* $\mathsf{UnaryHistory}(f)$*, and* $\mathsf{Cont}(a, f, b)$*. Under this correspondence,* e *is the identity tail, categorical composition is BEDC monoid append of tails, and* PreorderPrefixLE *transitivity is composition closure up to* hsame*.*

Proof. Unfold CategoryHomCarrier. A hom-carrier ledger already contains the unary source and morphism witnesses together with the continuation $\mathsf{Cont}(a, f, b)$, so the prefix witness is obtained by reading f as the displayed tail from a to b.

Conversely, the prefix tail data supplies the source and morphism witnesses directly, and unary continuation closure supplies the target witness. The continuation field is the displayed $\mathsf{Cont}(a, f, b)$, so the hom-carrier ledger is rebuilt. The concrete preorder form is the same tail display, with Definition 52.18 giving the canonical append presentation.

The identity case is Definition 61.2: the empty tail witnesses the identity continuation at every unary object. Composition uses Definition 61.19, while the preorder side uses Definition 52.28. The agreement of these two composites is the unit and associativity content of Definition 40.22, with comparison of resulting tails taken through hsame. □

Theorem 9365.3 (Suffixed composite middle object determinacy)**.** *If two composable unary hom-carrier ledgers display the middle object through the same right suffix q,*

$$\mathsf{CategoryHomCarrier}(a \cdot q, b \cdot q, f) \quad \textit{and} \quad \mathsf{CategoryHomCarrier}(b' \cdot q, c \cdot q, g),$$

and the displayed composite ledger has target $c \cdot q$, then the unsuffixed middle objects satisfy $\mathsf{hsame}(b, b')$*.*

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier append suffix comp middle object deterministic`

Proof. Apply middle-object determinacy to the suffixed composite ledgers. The result identifies $b \cdot q$ with $b' \cdot q$, and right cancellation of the common suffix gives $\mathsf{hsame}(b, b')$. □

Concretized in §485: Continuation monad packages the continuation-as-small-step reading as a certified Kleisli interface.

Theorem 9365.4 (Category hom-carrier empty morphism endpoint iff)**.** *For histories a, b, f : BHist, a hom-carrier ledger from a to b identifies the displayed morphism with the empty tail exactly when the two endpoints are internally the same:*

$$\mathsf{CategoryHomCarrier}(a, b, f) \Longrightarrow (f\mathsf{hsamee} \Longleftrightarrow a\mathsf{hsame}b).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier morphism empty endpoint iff`

Proof. Unfold the hom-carrier ledger to its continuation field $\mathsf{Cont}(a, f, b)$. If $f\mathsf{hsamee}$, determinacy against the right-unit continuation identifies b with a. Conversely, if $a\mathsf{hsame}b$, compare the displayed continuation with the endpoint equality and cancel the common left endpoint to obtain $f\mathsf{hsamee}$. □

Theorem 9365.5 (Cyclic continuation morphisms have empty tails)**.** *If the opposite continuation morphism records*

$$left : \mathsf{ContinuationMorphism}(a, b) \quad \textit{and} \quad right : \mathsf{ContinuationMorphism}(b, a)$$

both hold, then the endpoints are internally the same and both displayed tails are empty:

$$\mathsf{hsame}(a, b) \wedge \mathsf{hsame}(\mathsf{tail}(left), \mathsf{e}) \wedge \mathsf{hsame}(\mathsf{tail}(right), \mathsf{e}).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.ContinuationMorphism cycle tails empty`

Proof. Unpack the two continuation morphism records. The two exposed continuation ledgers form mutual extensions, one from a to b and one from b back to a. Kernel mutual-extension cancellation identifies the endpoints and forces both displayed tails to be the empty history. □

Theorem 9365.6 (Prefixed cyclic continuation morphisms have empty tails)**.** *If a prefixed continuation morphism and an opposite base continuation morphism record*

$$left : \mathsf{ContinuationMorphism}(\mathsf{append}(p, a), \mathsf{append}(p, b))$$

and

$$right : \mathsf{ContinuationMorphism}(b, a),$$

then the base endpoints are internally the same and both displayed tails are empty:

$$\mathsf{hsame}(a, b) \wedge \mathsf{hsame}(\mathsf{tail}(left), \mathsf{e}) \wedge \mathsf{hsame}(\mathsf{tail}(right), \mathsf{e}).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.ContinuationMorphism prefix cycle tails empty`

Proof. Unpack the prefixed morphism and cancel the common left continuation prefix in its exposed ledger. The resulting base continuation from a to b and the opposite continuation from b to a form mutual extensions, so kernel cancellation identifies the base endpoints and empties both tails. □

Theorem 9365.7 (Unary-suffix cyclic continuation morphisms have empty tails)**.** *If a unary suffix q is shared by the source and target of the forward continuation morphism, and the displayed forward tail is unary,*

$$left : \mathsf{ContinuationMorphism}(\mathsf{append}(a, q), \mathsf{append}(b, q))$$

and

$$right : \mathsf{ContinuationMorphism}(b, a),$$

then the base endpoints are internally the same and both displayed tails are empty:

$$\mathsf{hsame}(a, b) \wedge \mathsf{hsame}(\mathsf{tail}(left), \mathsf{e}) \wedge \mathsf{hsame}(\mathsf{tail}(right), \mathsf{e}).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.ContinuationMorphism unary suffix cycle tails empty`

Proof. Unpack the suffixed morphism. Unary commutation moves the shared suffix past the unary displayed tail, and suffix cancellation exposes a base continuation from a to b. This base continuation and the opposite continuation from b to a form mutual extensions, so kernel cancellation identifies the base endpoints and forces both displayed tails to be empty. □

Theorem 9365.8 (Zero-headed to one-headed continuation morphisms have no opposite cycle)**.** *For histories $a, r : \mathsf{BHist}$, no opposite pair can run from $\mathsf{E0}(a)$ to $\mathsf{E1}(r)$ and back:*

$$\mathsf{ContinuationMorphism}(\mathsf{E0}(a), \mathsf{E1}(r)) \to \mathsf{ContinuationMorphism}(\mathsf{E1}(r), \mathsf{E0}(a)) \to \bot.$$

Lean4 ✓ `BEDC.Derived.CategoryUp.ContinuationMorphism e0 e1 cycle absurd`

Proof. Cyclic continuation cancellation forces the forward displayed tail to be classified with e. The visible boundary theorem for a zero-headed source and one-headed target forces that same tail to be one-headed, hence not empty. The two conclusions contradict the generated-history separation theorem. □

Theorem 9365.9 (Triangular cyclic continuation morphisms have empty tails)**.** *If composable continuation morphisms record*

$$left : \mathsf{ContinuationMorphism}(a, b),$$

$$right : \mathsf{ContinuationMorphism}(b, c),$$

$$back : \mathsf{ContinuationMorphism}(c, a),$$

then all three displayed tails are empty and the adjacent endpoints collapse:

$$\mathsf{hsame}(\mathsf{tail}(left), \mathsf{e}) \wedge \mathsf{hsame}(\mathsf{tail}(right), \mathsf{e}) \wedge \mathsf{hsame}(\mathsf{tail}(back), \mathsf{e}) \wedge \mathsf{hsame}(a, b) \wedge \mathsf{hsame}(b, c).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.ContinuationMorphism triangle cycle tails empty`

Proof. Compose the first two continuation morphisms. The composite morphism from a to c and the displayed return morphism from c to a form a mutual extension cycle. Kernel cancellation forces the composite tail and the return tail to be empty. Empty append inversion splits the composite tail into empty left and right component tails. Comparing the component continuation ledgers with the right-unit continuations at a and b identifies the adjacent endpoints. □

Theorem 9365.10 (Prefixed triangular cyclic continuation morphisms have empty tails)**.** *If continuation morphisms record*

$$left : \mathsf{ContinuationMorphism}(\mathsf{append}(p, a), \mathsf{append}(p, b)),$$

$$middle : \mathsf{ContinuationMorphism}(b, c),$$

and

$$back : \mathsf{ContinuationMorphism}(c, a),$$

then all three displayed tails are empty and the adjacent base endpoints collapse:

$$\mathsf{hsame}(\mathsf{tail}(left), \mathsf{e}) \wedge \mathsf{hsame}(\mathsf{tail}(middle), \mathsf{e}) \wedge \mathsf{hsame}(\mathsf{tail}(back), \mathsf{e}) \wedge \mathsf{hsame}(a, b) \wedge \mathsf{hsame}(b, c).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.ContinuationMorphism prefix triangle cycle tails empty`

Proof. Cancel the common prefix in the first continuation ledger, then compose the base left ledger with the middle ledger. The composite and the back ledger form a mutual-extension cycle, so the composite tail and the back tail are empty. Empty append inversion splits the composite tail into the left and middle tails, and deterministic comparison with right-unit ledgers identifies the adjacent endpoints. □

Theorem 9365.11 (Visible e1 continuation morphism tail cases)**.** *If a continuation morphism runs from* $\mathsf{E1}(a)$ *to* $\mathsf{E1}(r)$*, then its tail is either empty and the payload endpoints satisfy* $a\mathsf{hsame}r$*, or the tail itself has visible one-headed form* $\mathsf{E1}(k)$ *and exposes a continuation* $\mathsf{Cont}(\mathsf{E1}(a), k, r)$*.*

Lean4 ✓ `BEDC.Derived.CategoryUp.ContinuationMorphism e1 source e1 target tail cases`

Proof. Apply the one-headed source tail split for continuation morphisms. The empty-tail branch identifies $\mathsf{E1}(r)$ with $\mathsf{E1}(a)$, and constructor injectivity gives $a\mathsf{hsame}r$. The zero-headed tail branch would identify an $\mathsf{E1}$ target with an $\mathsf{E0}$ target, contradicting kernel no-confusion. In the one-headed branch, constructor injectivity reindexes the displayed target payload, leaving the tail equality and the continuation witness $\mathsf{Cont}(\mathsf{E1}(a), k, r)$. □

Theorem 9365.12 (Visible e1 continuation morphism nonempty tail extraction)**.** *If a continuation morphism runs from* $\mathsf{E1}(a)$ *to* $\mathsf{E1}(r)$ *and its displayed tail is not* e*, then the tail has one-headed form* $\mathsf{E1}(k)$ *and exposes a continuation witness* $\mathsf{Cont}(\mathsf{E1}(a), k, r)$*.*

Lean4 ✓ `BEDC.Derived.CategoryUp.ContinuationMorphism e1 source e1 target nonempty tail cases`

Proof. Inspect the concrete tail of the continuation morphism. The empty branch is excluded by the nonempty hypothesis. A zero-headed tail would force the one-headed target to coincide with a zero-headed result of the step inversion, contradicting kernel no-confusion. The remaining one-headed tail branch gives the displayed core continuation after constructor injectivity on the target. □

Theorem 9365.13 (Visible e1 continuation morphism tail core deterministic)**.** *For two continuation morphisms from* $\mathsf{E1}(a)$ *to* $\mathsf{E1}(r)$*, if their displayed tails are respectively* $\mathsf{E1}(k)$ *and* $\mathsf{E1}(l)$ *up to* hsame*, then the tail cores satisfy* $k\mathsf{hsame}l$*.*

Lean4 ✓ `BEDC.Derived.CategoryUp.ContinuationMorphism e1 source e1 target tail core deterministic`

Proof. Continuation morphism tail determinacy compares the two displayed tails. Compose that comparison with the two one-headed tail identifications, then use constructor injectivity for $\mathsf{E1}$ to obtain the core comparison. □

Theorem 9365.14 (Cyclic hom-carriers have empty tails)**.** *If the opposite hom-carrier ledgers*

$$\mathsf{CategoryHomCarrier}(a, b, f) \quad \textit{and} \quad \mathsf{CategoryHomCarrier}(b, a, g)$$

both hold, then the endpoints are internally the same and both morphism tails are empty:

$$\mathsf{hsame}(a, b) \wedge \mathsf{hsame}(f, \mathsf{e}) \wedge \mathsf{hsame}(g, \mathsf{e}).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier cycle tails empty`

Proof. Each hom-carrier exposes a concrete continuation ledger, one from a to b through f and one from b back to a through g. Mutual continuation cancellation identifies the endpoints and forces both tails to be the empty history. □

Theorem 9365.15 (Cyclic hom-carrier composites have empty result)**.** *If the opposite hom-carrier ledgers*

$$\mathsf{CategoryHomCarrier}(a, b, f) \quad \textit{and} \quad \mathsf{CategoryHomCarrier}(b, a, g)$$

both hold, then every displayed continuation composite

$$\mathsf{Cont}(f, g, fg)$$

has empty result:

$$\mathsf{hsame}(fg, \mathsf{e}).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier comp cycle result empty`

Proof. The two hom-carrier ledgers expose reciprocal continuations $\mathsf{Cont}(a, f, b)$ and $\mathsf{Cont}(b, g, a)$. Mutual continuation cancellation forces $f\mathsf{hsamee}$ and $g\mathsf{hsamee}$. Transport the displayed composite $\mathsf{Cont}(f, g, fg)$ across these two tail equalities to a continuation $\mathsf{Cont}(\mathsf{e}, \mathsf{e}, fg)$, then read back the empty result by the continuation left-unit law. □

Theorem 9365.16 (Cyclic hom-carriers expose identity carriers)**.** *If the opposite hom-carrier ledgers*

$$\mathsf{CategoryHomCarrier}(a, b, f) \quad \textit{and} \quad \mathsf{CategoryHomCarrier}(b, a, g)$$

both hold, then the two endpoints carry empty-tail identities and the endpoints are internally the same:

$$\mathsf{CategoryHomCarrier}(a, a, \mathsf{e}) \wedge \mathsf{CategoryHomCarrier}(b, b, \mathsf{e}) \wedge \mathsf{hsame}(a, b).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier cycle identity carriers`

Proof. Apply the cyclic tail theorem to obtain $\mathsf{hsame}(a, b)$ together with $f\mathsf{hsamee}$ and $g\mathsf{hsamee}$. Transport the two displayed hom-carriers along these endpoint and tail equalities. The forward carrier becomes the empty-tail identity carrier at a, and the reverse carrier becomes the empty-tail identity carrier at b. □

Theorem 9365.17 (Split-mono witnesses have empty cyclic boundary)**.** *If $f : a \to b$ and $g : b \to a$ are category hom-carriers, $i : a \to a$ is an identity hom-carrier, $\mathsf{Cont}(f, g, c)$ displays the composite, and $c : a \to a$ is also a category hom-carrier, then the whole cyclic boundary collapses:*

$$f\mathsf{hsamee} \wedge g\mathsf{hsamee} \wedge i\mathsf{hsamee} \wedge c\mathsf{hsamee} \wedge a\mathsf{hsame}b.$$

Proof. The two opposite hom-carriers give the cyclic tail theorem, so $a\mathsf{hsame}b$ and both displayed tails are empty. Transport the forward hom-carrier across the endpoint and tail comparisons to obtain the empty identity carrier at a. Category hom-carrier determinacy compares the displayed identity with that empty carrier. The composite continuation transports across the empty tail comparisons to a continuation from e by e, while the supplied endomorphism carrier identifies this composite with the category composition carrier; continuation determinacy reads the composite as empty. □

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier split mono witness empty boundary`

Theorem 9365.18 (Triangular cyclic hom-carriers have empty tails)**.** *If the hom-carrier ledgers*

$$\mathsf{CategoryHomCarrier}(a, b, f),$$

$$\mathsf{CategoryHomCarrier}(b, c, g),$$

$$\mathsf{CategoryHomCarrier}(c, a, h)$$

all hold, then all three morphism tails are empty and the adjacent endpoints collapse:

$$\mathsf{hsame}(f, \mathsf{e}) \wedge \mathsf{hsame}(g, \mathsf{e}) \wedge \mathsf{hsame}(h, \mathsf{e}) \wedge \mathsf{hsame}(a, b) \wedge \mathsf{hsame}(b, c).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier triangle cycle tails empty`

Proof. The first two hom-carriers expose continuation ledgers $\mathsf{Cont}(a, f, b)$ and $\mathsf{Cont}(b, g, c)$. Compose them into a single continuation $\mathsf{Cont}(a, \mathsf{append}(f, g), c)$. This composite continuation and the return ledger $\mathsf{Cont}(c, h, a)$ form a mutual extension cycle, so kernel cancellation forces $\mathsf{append}(f, g)\mathsf{hsame}\mathsf{e}$ and $h\mathsf{hsame}\mathsf{e}$. Empty append inversion splits the composite tail into $f\mathsf{hsame}\mathsf{e}$ and $g\mathsf{hsame}\mathsf{e}$. Comparing the original component ledgers with the right-unit continuations at a and b gives $a\mathsf{hsame}b$ and $b\mathsf{hsame}c$. □

Theorem 9365.19 (Triangular cyclic hom-carriers have empty hom exactness)**.** *If the hom-carrier ledgers*

$$\mathsf{CategoryHomCarrier}(a, b, f),$$

$$\mathsf{CategoryHomCarrier}(b, c, g),$$

$$\mathsf{CategoryHomCarrier}(c, a, h)$$

all hold, then the empty morphism itself is displayed on each side of the triangle, and the adjacent endpoints collapse:

$$\mathsf{CategoryHomCarrier}(a, b, \mathsf{e}) \wedge \mathsf{CategoryHomCarrier}(b, c, \mathsf{e}) \wedge \mathsf{CategoryHomCarrier}(c, a, \mathsf{e}) \wedge \mathsf{hsame}(a, b) \wedge \mathsf{hsame}(b, c).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier triangle cycle empty hom exactness`

Proof. The triangular tail theorem gives $f\mathsf{hsame}\mathsf{e}$, $g\mathsf{hsame}\mathsf{e}$, and $h\mathsf{hsame}\mathsf{e}$, together with the adjacent endpoint equalities. Hom-carrier transport moves the three displayed carriers across those tail equalities, yielding empty hom-carriers on the original triangle edges. □

Theorem 9365.20 (Visible one-step morphisms have no triangular cycle)**.** *If the first hom-carrier in a triangular cycle has visible one-headed morphism tail* $\mathsf{e}_1(k)$*,*

$$\mathsf{CategoryHomCarrier}(a, b, \mathsf{e}_1(k)),$$

and the remaining hom-carriers run from b *to* c *and from* c *back to* a*, then the three ledgers are contradictory:*

$$\mathsf{CategoryHomCarrier}(a, b, \mathsf{e}_1(k)) \to \mathsf{CategoryHomCarrier}(b, c, g) \to \mathsf{CategoryHomCarrier}(c, a, h) \to \bot.$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier e1 morphism triangle cycle absurd`

Proof. Each hom-carrier exposes its underlying continuation ledger. The first two continuations compose into a tail $\mathsf{append}(\mathsf{e}_1(k), g)$, and the third continuation returns to the source. The kernel triangular continuation exclusion says this visible left component cannot be part of such a cycle. □

Theorem 9365.21 (Triangular cyclic hom-carriers expose identity carriers)**.** *If the hom-carrier ledgers*

$$\mathsf{CategoryHomCarrier}(a, b, f),$$

$$\mathsf{CategoryHomCarrier}(b, c, g),$$

$$\mathsf{CategoryHomCarrier}(c, a, h)$$

all hold, then the three objects carry empty-tail identities and the adjacent endpoints collapse:

$$\mathsf{CategoryHomCarrier}(a, a, \mathsf{e}) \wedge \mathsf{CategoryHomCarrier}(b, b, \mathsf{e}) \wedge \mathsf{CategoryHomCarrier}(c, c, \mathsf{e}) \wedge \mathsf{hsame}(a, b) \wedge \mathsf{hsame}(b, c).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier triangle cycle identity carriers`

Proof. Apply the triangular cyclic tail theorem. The first carrier is transported along $b\mathsf{hsame}a$ and $f\mathsf{hsame}\mathsf{e}$ to become the empty identity carrier at a. The second is transported along $c\mathsf{hsame}b$ and $g\mathsf{hsame}\mathsf{e}$ to become the empty identity carrier at b. The return carrier is transported along the composite endpoint equality $a\mathsf{hsame}c$ and $h\mathsf{hsame}\mathsf{e}$ to become the empty identity carrier at c. □

Theorem 9365.22 (Unary-prefix triangle cyclic hom-carriers expose identity carriers)**.** *If the first hom-carrier has a shared unary prefix,*

$$\mathsf{CategoryHomCarrier}(\mathsf{append}(p, a), \mathsf{append}(p, b), f),$$

and the remaining two hom-carriers close the triangle,

$$\mathsf{CategoryHomCarrier}(b, c, g) \quad \textit{and} \quad \mathsf{CategoryHomCarrier}(c, a, h),$$

then the base endpoints carry empty-tail identities and adjacent endpoints are internally the same:

$$\mathsf{CategoryHomCarrier}(a, a, \mathsf{e}) \wedge \mathsf{CategoryHomCarrier}(b, b, \mathsf{e}) \wedge \mathsf{CategoryHomCarrier}(c, c, \mathsf{e}) \wedge \mathsf{hsame}(a, b) \wedge \mathsf{hsame}(b, c).$$

Proof. Prefix exactness strips the shared unary prefix from the first hom-carrier, leaving a base carrier from a to b. The ordinary triangular cyclic identity-carrier theorem applies to this base carrier and the two remaining hom-carriers. □

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier unary prefix triangle cycle identity carriers`

Theorem 9365.23 (Unary prefix category isomorphism collapse)**.** *If the opposite unary hom-carrier ledgers*

$$\mathsf{CategoryHomCarrier}(a, b, f) \quad \textit{and} \quad \mathsf{CategoryHomCarrier}(b, a, g)$$

both hold, then they expose bidirectional prefix comparison,

$$\mathsf{PreorderPrefixLE}(a, b) \quad \textit{and} \quad \mathsf{PreorderPrefixLE}(b, a),$$

endpoint sameness

$$\mathsf{hsame}(a, b),$$

and monoid-unit morphism tails

$$\mathsf{MonoidHistoryClassifier}(\mathsf{UnaryHistory})(f, \mathsf{e}) \quad \textit{and} \quad \mathsf{MonoidHistoryClassifier}(\mathsf{UnaryHistory})(g, \mathsf{e}).$$

Proof. Read the two prefix witnesses from the hom-carrier ledgers using Definition 9365.2. The forward ledger is the displayed unary continuation tail from a to b, and the reverse ledger is the displayed unary continuation tail from b to a.

Apply Definition 52.30 to the two exposed prefix comparisons. This gives the endpoint identification $\mathsf{hsame}(a, b)$ required by the categorical core.

Apply Definition 9365.14 to the opposite hom-carrier pair. It gives $f\mathsf{hsamee}$ and $g\mathsf{hsamee}$. The hom-carrier fields provide $\mathsf{UnaryHistory}(f)$ and $\mathsf{UnaryHistory}(g)$, while Definition 40.25 provides the empty-history carrier and the classifier package. Repacking these data gives the two classifier conclusions.

$$\mathsf{MonoidHistoryClassifier}(\mathsf{UnaryHistory})(f, \mathsf{e})$$

and

$$\mathsf{MonoidHistoryClassifier}(\mathsf{UnaryHistory})(g, \mathsf{e}).$$

□

The roadmap ten-field fit is: traditional target skeletal core of the prefix category; BEDC source $\mathsf{CategoryHomCarrier}$, $\mathsf{PreorderPrefixLE}$, and $\mathsf{MonoidHistoryClassifier}$; carrier unary BHist; classifier hsame; stability cyclic isomorphism collapse; ledger opposite hom tails; core theorem Definition 9365.23; exactness bidirectional prefix comparison collapses to identity; standard bridge preorder-enriched thin category; status $\mathsf{ProofTarget}$.

Theorem 9365.24 (Unary-suffix cyclic hom-carriers have empty tails)**.** *If a unary suffix q is shared by the source and target of the forward hom-carrier and an opposite base hom-carrier returns from b to a,*

$$\mathsf{CategoryHomCarrier}(\mathsf{append}(a, q), \mathsf{append}(b, q), f) \quad \textit{and} \quad \mathsf{CategoryHomCarrier}(b, a, g),$$

then the base endpoints are internally the same and both morphism tails are empty:

$$\mathsf{hsame}(a, b) \wedge \mathsf{hsame}(f, \mathsf{e}) \wedge \mathsf{hsame}(g, \mathsf{e}).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier unary suffix cycle tails empty`

Proof. The suffix exactness theorem strips the shared unary suffix from the forward hom-carrier, exposing a base hom-carrier from a to b with the same tail f. The two base hom-carriers now form an ordinary opposite cycle, so mutual continuation cancellation identifies the endpoints and forces both tails to be empty. □

Theorem 9365.25 (Unary-suffix cyclic hom-carriers expose identity carriers)**.** *If*

$$\mathsf{CategoryHomCarrier}(\mathsf{append}(a, q), \mathsf{append}(b, q), f) \quad \textit{and} \quad \mathsf{CategoryHomCarrier}(b, a, g)$$

both hold, then the base endpoints carry empty-tail identities and the endpoints are internally the same:

$$\mathsf{CategoryHomCarrier}(a, a, \mathsf{e}) \wedge \mathsf{CategoryHomCarrier}(b, b, \mathsf{e}) \wedge \mathsf{hsame}(a, b).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier unary suffix cycle identity carriers`

Proof. Strip the shared unary suffix from the forward hom-carrier. The resulting base cycle is an ordinary cyclic hom-carrier pair, so cyclic identity-carrier exposure transports the two tails to empty identity carriers at a and b. □

Theorem 9365.26 (Unary-context cyclic hom-carriers have empty tails)**.** *If the forward hom-carrier has a shared unary prefix and the opposite hom-carrier has a shared unary suffix,*

$$\mathsf{CategoryHomCarrier}(\mathsf{append}(p,a),\mathsf{append}(p,b),f) \quad \textit{and} \quad \mathsf{CategoryHomCarrier}(\mathsf{append}(b,q),\mathsf{append}(a,q),g),$$

then the base endpoints are internally the same and both morphism tails are empty:

$$\mathsf{hsame}(a,b) \wedge \mathsf{hsame}(f,\mathsf{e}) \wedge \mathsf{hsame}(g,\mathsf{e}).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier unary context cycle tails empty`

Proof. Prefix exactness strips the shared unary prefix from the forward hom-carrier, leaving a base carrier from a to b. Suffix exactness strips the shared unary suffix from the opposite hom-carrier, leaving a base carrier from b to a. The ordinary cyclic tail theorem then identifies the endpoints and forces the two morphism tails to be empty. □

Theorem 9365.27 (Unary-context cyclic hom-carriers expose identity carriers)**.** *If the forward hom-carrier has a shared unary prefix and the opposite hom-carrier has a shared unary suffix,*

$$\mathsf{CategoryHomCarrier}(\mathsf{append}(p,a),\mathsf{append}(p,b),f) \quad \textit{and} \quad \mathsf{CategoryHomCarrier}(\mathsf{append}(b,q),\mathsf{append}(a,q),g),$$

then the base endpoints carry empty-tail identities and are internally the same:

$$\mathsf{CategoryHomCarrier}(a,a,\mathsf{e}) \wedge \mathsf{CategoryHomCarrier}(b,b,\mathsf{e}) \wedge \mathsf{hsame}(a,b).$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier unary context cycle identity carriers`

Proof. Prefix exactness strips the shared unary prefix from the forward hom-carrier, leaving a base carrier from a to b. Suffix exactness strips the shared unary suffix from the opposite hom-carrier, leaving a base carrier from b to a. The ordinary cyclic identity-carrier theorem then exposes the two empty-tail identity carriers and the comparison $a\mathsf{hsame}b$. □

Theorem 9365.28 (Visible one-step morphisms have no opposite cycle)**.** *If the forward hom-carrier has a visible one-headed morphism tail* $\mathsf{e}_1(k)$ *and an opposite hom-carrier returns from* b *to* a*, then the two ledgers are contradictory:*

$$\mathsf{CategoryHomCarrier}(a,b,\mathsf{e}_1(k)) \to \mathsf{CategoryHomCarrier}(b,a,g) \to \bot.$$

Lean4 ✓ `BEDC.Derived.CategoryUp.CategoryHomCarrier e1 morphism cycle absurd`

Proof. The cyclic hom-carrier theorem forces every tail in an opposite pair to be empty. Applying it to the visible tail $\mathsf{e}_1(k)$ gives $\mathsf{hsame}(\mathsf{e}_1(k),\mathsf{e})$, contradicting the kernel separation theorem for one-headed histories and the empty history. □

Concretized in §1025: Continuation bisimulation packets realize symmetric behavioral equivalence of finite Cont traces as displayed forward and backward simulation rows.

Concretized in §4085: Continuation replay packets realize finite Cont execution as displayed step rows, endpoint transport, replay provenance, and local NameCert data.

Concretized in §7361: Regular-language continuation packets realize bounded automaton recognition as finite Cont replay, acceptance, classifier, transport, provenance, and NameCert rows.

Chapter 9366

Classifier-Level Information: Computation, Unfolding, and Discovery

chapter 9365 reads computation through Cont-generated continuation traces, while chapter 9367 reads checking through certificate-governed classifier membership. The present chapter separates two measurements that are often conflated: growth of the displayed record and change of the certified classifier by which that record is read. In BEDC, a computation may extend a trace without changing its governing NameCert, whereas discovery requires a certificate-governed classifier shift with an exposed ledger.

9366.1 Certified classifier states

Definition 9366.1 (Certified classifier state)**.** *A certified classifier state is a tuple*

$$\mathcal{T} = (S_{\mathcal{T}}, P_{\mathcal{T}}, L_{\mathcal{T}}, C_{\mathcal{T}}, N_{\mathcal{T}})$$

where

$$S_{\mathcal{T}}, P_{\mathcal{T}}, L_{\mathcal{T}} : \mathsf{Hist} \to \mathsf{Prop}, \qquad C_{\mathcal{T}} : \mathsf{Hist} \to \mathsf{Hist} \to \mathsf{Prop},$$

and

$$N_{\mathcal{T}} : \mathsf{SemanticNameCert}(S_{\mathcal{T}}, P_{\mathcal{T}}, L_{\mathcal{T}}, C_{\mathcal{T}}).$$

The fields are respectively the source specification, pattern specification, ledger policy, classifier specification, and semantic naming certificate.

Definition 9366.2 (Record and configuration)**.** *Relative to a certified classifier state $\mathcal{T}$, a record is a finite family R of histories. An epistemic configuration is a pair $(\mathcal{T}, R)$.*

Definition 9366.3 (External record size)**.** *Let the external display length of histories be defined by*

$$|\mathsf{e}| = 0, \qquad |\mathsf{E0}(h)| = |h| + 1, \qquad |\mathsf{E1}(h)| = |h| + 1.$$

For a finite record R, set

$$|R| = \sum_{h \in R} |h|.$$

This size is a metalanguage audit measure. It is not a primitive object of the finite kernel.

9366.2 Computation as record growth

Definition 9366.4 (Unfolding)**.** *An unfolding step from $(\mathcal{T}, R)$ to $(\mathcal{T}, R')$ is a transition for which there are histories h, k, r such that $h \in R$, $\mathsf{Cont}(h, k, r)$, and R' is obtained from R by adjoining r. It is written*

$$(\mathcal{T}, R) \rightsquigarrow_{\mathsf{unf}} (\mathcal{T}, R').$$

Definition 9366.5 (Mechanical computation)**.** *A transition*

$$(\mathcal{T}, R) \longrightarrow (\mathcal{T}', R')$$

is a mechanical computation when $\mathcal{T}' = \mathcal{T}$ and every history in R' not already displayed in R is generated from histories of R by finitely many Ext *or* Cont *steps. It is written*

$$(\mathcal{T}, R) \rightsquigarrow_{\mathsf{comp}} (\mathcal{T}, R').$$

Definition 9366.6 (Classifier equivalence)**.** *Certified classifier states*

$$\mathcal{T} = (S, P, L, C, N), \qquad \mathcal{T}' = (S', P', L', C', N')$$

are classifier-equivalent on their common source scope when

$$\forall h, k : \mathsf{Hist},\ S(h) \wedge S(k) \wedge S'(h) \wedge S'(k) \Rightarrow \big(C(h, k) \leftrightarrow C'(h, k)\big).$$

This relation is written $\mathcal{T} \equiv_{\mathsf{cls}} \mathcal{T}'$.

Definition 9366.7 (Classifier shift)**.** *The classifier-shift value of a transition is the boolean audit quantity*

$$\Delta_{\mathsf{cls}}\big((\mathcal{T}, R), (\mathcal{T}', R')\big) = 0$$

exactly when $\mathcal{T} \equiv_{\mathsf{cls}} \mathcal{T}'$, and is 1 exactly when this equivalence fails.

Theorem 9366.8 (Record growth does not force classifier shift)**.** *If*

$$(\mathcal{T}, R) \rightsquigarrow_{\mathsf{unf}} (\mathcal{T}, R')$$

and $R' \neq R$, then the record has grown while

$$\Delta_{\mathsf{cls}}\big((\mathcal{T}, R), (\mathcal{T}, R')\big) = 0.$$

Proof. The unfolding relation keeps the certified classifier state fixed. Hence $\mathcal{T} \equiv_{\mathsf{cls}} \mathcal{T}$ by reflexivity of the displayed classifier on the common source scope. The definition of Δ_{cls} gives value 0. The condition $R' \neq R$ records displayed growth only; it adds no source specification, classifier specification, ledger policy, or naming certificate. □

Theorem 9366.9 (Mechanical computation is not discovery)**.** *No mechanical computation whose target state is the same certified classifier state can be a structural discovery transition in the sense of Definition 9366.12.*

Proof. Mechanical computation has $\mathcal{T}' = \mathcal{T}$, so $\Delta_{\mathsf{cls}} = 0$. Structural discovery requires $\Delta_{\mathsf{cls}} = 1$. These requirements are incompatible. □

Theorem 9366.10 (Finite mechanical chains preserve the classifier)**.** *For a finite chain*

$$(\mathcal{T}_0, R_0), (\mathcal{T}_1, R_1), \ldots, (\mathcal{T}_n, R_n)$$

with

$$(\mathcal{T}_i, R_i) \rightsquigarrow_{\mathsf{comp}} (\mathcal{T}_{i+1}, R_{i+1}) \quad \textit{for every } i < n,$$

one has $\mathcal{T}_n = \mathcal{T}_0$ *and*

$$\Delta_{\mathsf{cls}}\big((\mathcal{T}_0, R_0), (\mathcal{T}_n, R_n)\big) = 0.$$

Proof. Induct on the length of the chain. The empty chain is immediate. In the successor case, the induction hypothesis gives $\mathcal{T}_n = \mathcal{T}_0$, and the last mechanical computation gives $\mathcal{T}_{n+1} = \mathcal{T}_n$. Therefore $\mathcal{T}_{n+1} = \mathcal{T}_0$, and the classifier-shift value is 0 by Definition 9366.7. □

Corollary 9366.11 (Output novelty is not classifier discovery)**.** *The fact that a displayed history* r *belongs to* R' *but not to* R *does not by itself imply discovery.*

Proof. If the transition is mechanical, the classifier state is unchanged by Definition 9366.10. The novelty of r is record novelty, not classifier-level novelty. □

9366.3 Discovery as classifier shift

Definition 9366.12 (Structural discovery transition)**.** *A transition*

$$(\mathcal{T}, R) \longrightarrow (\mathcal{T}', R')$$

is a structural discovery transition when all of the following hold:

$$\begin{gathered}\mathcal{T}' \textit{ is a certified classifier state,}\\ \Delta_{\mathsf{cls}}\big((\mathcal{T}, R), (\mathcal{T}', R')\big) = 1,\\ \exists h : \mathsf{Hist},\ L_{\mathcal{T}'}(h),\\ \exists h \in R',\ S_{\mathcal{T}'}(h) \quad \textit{or} \quad \exists h, k \in R',\ C_{\mathcal{T}'}(h, k).\end{gathered}$$

It is written

$$(\mathcal{T}, R) \rightsquigarrow_{\mathsf{disc}} (\mathcal{T}', R').$$

Theorem 9366.13 (Discovery carries a naming certificate)**.** *If*

$$(\mathcal{T}, R) \rightsquigarrow_{\mathsf{disc}} (\mathcal{T}', R')$$

and

$$\mathcal{T}' = (S', P', L', C', N'),$$

then

$$N' : \mathsf{SemanticNameCert}(S', P', L', C').$$

Proof. Structural discovery requires $\mathcal{T}'$ to be a certified classifier state. The fifth field of such a state is precisely the displayed semantic naming certificate. □

Theorem 9366.14 (Certified classifier states carry ledger witnesses)**.** *For every certified classifier state*

$$\mathcal{T} = (S, P, L, C, N),$$

there exists a history h *with* $L(h)$*.*

Proof. The semantic naming certificate contains a core $\mathsf{NameCert}(S, C)$. The core certificate supplies a source witness h with $S(h)$. Applying the ledger soundness field of N to this source witness gives $L(h)$. □

Corollary 9366.15 (Unledgered compression is not discovery)**.** *A transition that claims compression but exposes no witness*

$$\exists h : \mathsf{Hist},\ L_{\mathcal{T}'}(h)$$

is not a structural discovery transition.

Proof. This is the contrapositive of Definition 9366.14 applied to the target classifier state required by Definition 9366.12. □

Definition 9366.16 (Cost observer and positive discovery)**.** *Let $(Q, \leq, +, 0)$ be an ordered commutative monoid. A cost observer assigns to each certified classifier state $\mathcal{T}$ a map*

$$\mu_{\mathcal{T}} : \mathcal{P}_{\mathsf{fin}}(\mathsf{Hist}) \to Q$$

and assigns to each state transition a certificate cost

$$\kappa(\mathcal{T} \to \mathcal{T}') \in Q.$$

A structural discovery transition is positive for a finite family $X \subseteq R'$ when

$$\mu_{\mathcal{T}'}(X) + \kappa(\mathcal{T} \to \mathcal{T}') < \mu_{\mathcal{T}}(X).$$

Theorem 9366.17 (Positive discovery implies structural discovery)**.** *Every positive discovery is a structural discovery transition.*

Proof. Positivity is defined only after the structural discovery clauses have been met; the displayed inequality adds a cost comparison and does not replace the classifier-shift, certificate, or ledger requirements. □

Corollary 9366.18 (Faster unfolding is not automatically discovery)**.** *A shorter, faster, or more direct continuation route under the same certified classifier state is not automatically a discovery.*

Proof. Such a route changes the external method or the displayed record. Unless it changes the certified classifier state up to Definition 9366.6, its classifier-shift value is 0. □

9366.4 Generators and presentation changes

Definition 9366.19 (Certified generator)**.** *Within a certified classifier state $\mathcal{T}$, a certified generator is an externally indexed family $G : I \to \mathsf{Hist}$ whose use is authorized by $N_{\mathcal{T}}$ and for which every $G(i)$ is obtained from a certified seed by a finite* Cont *tail.*

Theorem 9366.20 (Fixed generator theorem)**.** *Let $G : I \to \mathsf{Hist}$ be a certified generator in $\mathcal{T}$. If the transition from R to R' only adjoins an output of G and keeps the certified classifier state equal to $\mathcal{T}$, then*

$$\Delta_{\mathsf{cls}}((\mathcal{T}, R), (\mathcal{T}, R')) = 0.$$

Proof. The generator output is already licensed by $N_{\mathcal{T}}$. Since the transition keeps $\mathcal{T}$ fixed, it is a record extension under the same certificate. The classifier-shift value is therefore 0. □

Corollary 9366.21 (Digit extension is unfolding)**.** *If a digit-prefix generator for a constant has already been authorized in a certified classifier state, producing a longer prefix by the same generator is unfolding rather than classifier discovery.*

Proof. Apply Definition 9366.20 to the prefix generator. The visible prefix changes, but the governing classifier state does not. □

Definition 9366.22 (Presentation weakening)**.** *Let*

$$\mathcal{T} = (S, P, L, C, N), \qquad \mathcal{T}' = (S, P', L', C, N')$$

have the same source specification and classifier specification. If

$$\forall h : \mathsf{Hist},\ P(h) \to P'(h), \qquad \forall h : \mathsf{Hist},\ L(h) \to L'(h),$$

then $\mathcal{T}'$ is a presentation weakening of $\mathcal{T}$.

Theorem 9366.23 (Presentation weakening has zero classifier shift)**.** *If $\mathcal{T}'$ is a presentation weakening of $\mathcal{T}$, then for any records R, R',*

$$\Delta_{\mathsf{cls}}\big((\mathcal{T}, R), (\mathcal{T}', R')\big) = 0.$$

Proof. The source and classifier specifications are unchanged. Hence on the common source scope the two classifier predicates are literally the same predicate, so $\mathcal{T} \equiv_{\mathsf{cls}} \mathcal{T}'$. □

Corollary 9366.24 (Renaming is not classifier discovery)**.** *Changing notation, weakening a pattern presentation, or relaxing a ledger presentation is not classifier discovery when the source and classifier specifications are unchanged.*

Proof. This is Definition 9366.23. □

9366.5 Separation principle

Definition 9366.25 (Classifier-level information)**.** *For a transition*

$$(\mathcal{T}, R) \longrightarrow (\mathcal{T}', R'),$$

its classifier-level information audit is the pair

$$\mathsf{CLI}\big((\mathcal{T}, R), (\mathcal{T}', R')\big) = (\Delta_{\mathsf{rec}}, \Delta_{\mathsf{cls}}),$$

where

$$\Delta_{\mathsf{rec}} = |R'| - |R|$$

is external record growth, and Δ_{cls} is the classifier-shift value.

Theorem 9366.26 (Record growth and classifier shift are independent dimensions)**.** *There are transitions with $\Delta_{\mathsf{rec}} > 0$ and $\Delta_{\mathsf{cls}} = 0$. There are also certified-state transitions with $\Delta_{\mathsf{rec}} = 0$ and $\Delta_{\mathsf{cls}} = 1$ whenever the displayed states are not classifier-equivalent on their common source scope.*

Proof. For the first case, take any unfolding step that adjoins a non-empty continuation result and apply Definition 9366.8. For the second case, keep the record fixed and replace $\mathcal{T}$ by a certified classifier state $\mathcal{T}'$ with $\neg(\mathcal{T} \equiv_{\mathsf{cls}} \mathcal{T}')$. The record size is unchanged, while Definition 9366.7 gives $\Delta_{\mathsf{cls}} = 1$. □

Principle 9366.27 (Computation extends records; discovery changes classifiers)**.** *Continuation grows a trace;* NameCert *licenses a classifier. Thus output length and classifier-level information are distinct audit coordinates. A discovery is a ledgered classifier shift, not a longer continuation trace.*

Concretized in §469: Continuation trace packets realize the record-growth side of the classifier-level information separation.

Concretized in §590: Classifier morphism packets realize the certificate-preserving side of classifier comparison and presentation change.

Concretized in §6765: Classifier-channel shift ledgers realize the classifier-level information distinction as finite before/after classifier rows, record-growth rows, shift witnesses, ledger, transport, replay, provenance, and NameCert data.

Concretized in §8183: Classifier-level information is realized as finite classifier-state, SigRel handoff, ledger-delta, transport, replay, provenance, and NameCert rows.

Chapter 9367

Type Checking as Classifier Membership

The extension predicate Ext of chapter 4 is, structurally, a type-membership predicate. A history satisfies Ext exactly when it lies in a designated subclass cut out by a closure rule. Reading Ext as a type and Cont as the typed reduction, the BEDC primitive layer already contains the data of a typed programming language; type checking is decidable Ext-membership; the Curry-Howard correspondence is built into the framework, since every classifier closure law is the constructive proof of its closure.

9367.1 Extension predicate as type-membership

Definition 9367.1 (Typed term language as naming certificate)**.** *A* typed term language L *with type system* τ *is a closed inductive carrier* Term_L *together with a closed inductive predicate* $\tau\, t$ *on* Term_L *marking well-typedness. The corresponding* naming certificate $\mathsf{NameCert}_L$ *has carrier* Term_L *embedded in* Hist*,* $\mathsf{Ext}_L\, t = \tau\, t$*, and* $\mathsf{Cont}_L\, t\, m\, t'$ *encoding the small-step typed reduction relation of* L*.*

Definition 9367.2 (Type checking)**.** Type checking *for a term* $t \in \mathrm{Term}_L$ *is the decision procedure for* $\mathsf{Ext}_L\, t$*. The procedure exists when* $\mathsf{NameCert}_L$ *supplies a kernel-level decidability witness for* Ext_L*, given as a function on* Term_L *returning* b1 *on well-typed terms and* b0 *otherwise.*

Theorem 9367.3 (Type-checking as Ext membership)**.** *For every typed term language* L *with a fixed type system, there exists a naming certificate over* L *such that well-typedness of a term* t *is exactly* $\mathsf{Ext}\, t$ *in the certificate's classifier. Type-checking decidability is* Ext*-decidability; subject reduction is the closure law connecting* Ext *with the certificate's continuation; the Curry-Howard correspondence between proofs and programs is the identification of the certificate's closure laws with constructive proofs of those closures.*

```
Lean4✓  BEDC.Reflection.type checking as ext membership proof
  ↪variant  BEDC.Reflection.type checking as ext membership
```

Sketch. The forward direction is Definition 9367.1: a typed term language is given as a closed inductive carrier with a typing predicate, and the predicate is encoded directly as Ext_L. The backward direction reads a naming certificate over a term-shaped carrier as a typed term language: Ext is the typing predicate, Cont is the typed reduction, and the certificate's closure laws are the type-system rules. The Curry-Howard correspondence is the observation that the closure laws of

$\mathsf{NameCert}_L$ are themselves typed: each closure law is a function from witnesses of its hypotheses to a witness of its conclusion, and witnesses of $\mathsf{Ext}_L\, t$ are programs whose types are the conclusions. □

9367.2 Subject reduction from closure laws

Definition 9367.4 (Subject reduction)**.** Subject reduction *for* $\mathsf{NameCert}_L$ *is the closure law: for every* $t, t' \in \mathrm{Term}_L$ *and every* $m \in \mathsf{Mark}$, $\mathsf{Ext}_L\, t \wedge \mathsf{Cont}_L\, t\, m\, t' \Rightarrow \mathsf{Ext}_L\, t'$. *The law expresses that typed reduction preserves well-typedness.*

Theorem 9367.5 (Closure law equals subject reduction)**.** *The closure law of* $\mathsf{NameCert}_L$ *that connects* Ext_L *with* Cont_L *is, by unfolding, the subject-reduction property of Definition 9367.4. A naming certificate satisfies the kernel's* Ext-Cont *closure law if and only if the underlying typed term language enjoys subject reduction.*

Sketch. Both statements have the same shape: "if the source is in the extension and the continuation step holds, the target is in the extension". The only difference is the choice of vocabulary: closure law for the certificate framework, subject reduction for the typed-language framework. The proof is a one-line rewrite of the kernel's closure-law statement using the embedding of Term_L into Hist. □

9367.3 Curry-Howard as identity

Theorem 9367.6 (Closure proofs are programs)**.** *Every constructive proof of a closure law of* $\mathsf{NameCert}_L$ *is, on the nose, a program in* Term_L *whose type is the conclusion of the closure law. Conversely, every well-typed program in* Term_L *is the constructive content of a closure-law proof in* $\mathsf{NameCert}_L$ *for some closure formed from its type.*

Sketch. A closure law is a kernel-level implication "hypotheses ⇒ conclusion". A constructive proof of the implication is a function from witnesses of the hypotheses to a witness of the conclusion. Witnesses of the hypotheses are programs with the hypotheses' types; the constructed witness of the conclusion is a program with the conclusion's type; the function itself is a typed lambda abstraction. The reverse reading takes a well-typed term $t : T$ and reads the type T as the conclusion of a closure law whose hypotheses are the types of the free variables of t; the term t is the proof. □

Remark 9367.7 (Curry-Howard built into BEDC)**.** *Definition 9367.6 is the BEDC reading of the Curry-Howard correspondence. In a separate logical-system-plus-programming-language presentation, Curry-Howard is a non-trivial identification of two prima facie distinct domains; in BEDC, the identification is the unfolding of a single object, the naming certificate, into its two readings as a type system and as a program. The kernel's closure-law discipline is therefore not a logical commitment imposed on top of a programming language; it is the programming language at the kernel level.*

Remark 9367.8 (Composition with the compilation capstone)**.** *Definition 9367.3 supplies, for every typed term language, a naming certificate; chapter 9371 reads compilers as naming-certificate morphisms; together, the two chapters identify type-preserving compilers with* Ext*-preserving naming-certificate morphisms. Subject reduction in the source language and target language is, in this composed reading, the kernel-level closure-law preservation that any compiler must witness.*

Concretized in §476: Type checking is realized as finite Ext-membership and subject-reduction NameCert packets over displayed BEDC histories.

Concretized in §489: Classifier membership is realized as a finite BHist typing packet with Ext, Cont, SigRel, and NameCert rows.

Concretized in §483: Subject reduction is realized as the finite Ext/Cont closure packet for type-checking certificates.

Concretized in §595: Classifier boundary packets realize accepted Ext-membership, refused non-member rows, Cont preservation, SigRel readback, and NameCert provenance as a finite public boundary.

Concretized in §562: Typed reduction normal-form packets realize the type-checking vision as finite Ext, Cont, hsame, Pkg, and NameCert rows separating subject reduction from host conversion and normalization oracles.

Concretized in §590: Classifier morphisms are realized as finite Ext, SigRel, Cont, hsame, Pkg, and NameCert preservation packets.

Concretized in §598: Type-checking derivation traces are realized as finite Ext, Cont, subject-reduction, hsame, Pkg, and NameCert rows.

Concretized in §642: Proof-term erasure traces realize type checking as finite Ext-membership preservation over proof terms, erased terms, Cont routes, hsame transport, Pkg provenance, and local NameCert rows.

Concretized in §690: Proof-term erasure audit routes are realized as finite Ext-membership, erased Cont replay, subject-reduction, hsame, Pkg, and NameCert rows without exporting proof objects or host conversion.

Concretized in §707: Proof-term erasure classifiers realize erasure-preserving Ext-membership as a finite NameCert packet over proof-term rows, erased-term rows, Cont replay, SigRel readback, hsame transport, Pkg provenance, and non-escape ledgers.

Concretized in §625: Type-preserving compiler packets realize classifier-preserving compilation with Ext-membership and subject-reduction rows.

Concretized in §686: Type-checking membership traces are realized as finite Ext-membership, derivation-route, subject-reduction, SigRel readback, hsame, Cont, Pkg, and NameCert packets.

Concretized in §809: Type-classifier route joins are realized as finite membership, route-choice, discharge-socket, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1046: Typing-judgment classifiers realize type checking as finite Ext-membership, derivation-route, SigRel readback, Cont replay, hsame transport, Pkg provenance, and NameCert rows.

Concretized in §3911: Type checking classifier membership is realized as finite term, typing-ledger, Ext-membership, derivation-trace, subject-reduction, erasure, hsame, Cont, Pkg, and NameCert rows.

Concretized in §4106: Type-checking classifiers realize Ext-membership, derivation trace, subject-reduction, erasure, hsame, Cont, Pkg, and NameCert rows as a finite packet.

Concretized in §5157: Proof-trace normal-form packets realize type checking as finite Ext-membership, typed Cont replay, subject-reduction, terminal normal-form access, hsame, Pkg, and NameCert rows.

Concretized in §4238: MetaCIC parallel-diamond frontier packets realize classifier membership through residual-substitution premise rows, critical-pair rows, candidate-join rows, closed-checker rows, and local NameCert data.

Concretized in §8250: TypecheckingClassifierTraceUp realizes the type-checking-as-classifier-membership route as finite context, rule, membership, refusal, replay, and NameCert rows.

Chapter 9368

The Halting Problem as a Limit of the Form of Distinction

Concretized in §496: Halting diagonal packets realize the finite fixed-point obstruction boundary over NameCert, Cont, Ext, hsame, Pkg, and local diagonal ledgers.

Reading the form of distinction (Definition 9461.1) as the primitive computational atom and the continuation Cont as the small-step relation (chapter 9365), the halting problem becomes the question: is there a BEDC classifier on naming certificates that decides, for an arbitrary certificate $\mathsf{NameCert}_P$ and history h, whether the continuation chain from h in $\mathsf{NameCert}_P$ terminates? This chapter records the kernel fixed-point interface behind the negative answer as a Tarski-style obstruction in BEDC, locates it on the open-meta-loop side of the two-loops structure (Definition 9461.15), and notes that the obstruction is, structurally, the same as the form of distinction's irreducibility (Definition 9461.3) read at the meta level.

9368.1 Halting as fixed-point obstruction

Definition 9368.1 (Termination of a Cont-chain)**.** *The* Cont*-chain from* h *in* $\mathsf{NameCert}_P$ terminates *when there exists a finite list of marks* $[m_1, \ldots, m_n]$ *and a sequence* $h = h_0, h_1, \ldots, h_n$ *with* $\mathsf{Cont}_P\, h_i\, m_{i+1}\, h_{i+1}$ *for* $0 \leq i < n$ *and no* m, h' *with* $\mathsf{Cont}_P\, h_n\, m\, h'$*. Termination is a positive existential at the kernel level.*

Definition 9368.2 (Halting predicate)**.** *A* halting predicate *is a naming certificate* $\mathsf{NameCert}_H$ *over the carrier* $\mathcal{C} \times \mathsf{Hist}$ *of pairs (certificate, history) whose* Ext_H *on* $(\mathsf{NameCert}_P, h)$ *holds exactly when the* Cont_P*-chain from* h *terminates in the sense of Definition 9368.1, and whose* Cont_H *supplies the kernel-level evidence required by the certificate framework.*

Theorem 9368.3 (Halting via fixed point of the form of distinction)**.** *Let* $\mathsf{NameCert}_H$ *be a naming certificate for a predicate* Halts *and classifier* $\sim_H$*, and suppose that* $\mathsf{Halts}(h)$ *is exactly the positive kernel fact that some* Cont*-continuation from* h *exists. Let* $\mathsf{SelfRef}$ *be a self-reference predicate whose histories are produced by one* Ext *step, and let a diagonal policy say that whenever a self-referential* h *continues with empty fuel to* r*, any classification* $h \sim_H r$ *yields* $\mathsf{Diverges}(r)$*. Then* $\sim_H$ *transports* Halts*, every history satisfies* Halts *by the empty* Cont*-continuation, and every self-referential history carries an* Ext *witness together with the fixed point* $\mathsf{Cont}\, h\, \emptyset\, h$ *and the diagonal implication* $\sim_H hh \Rightarrow \mathsf{Diverges}(h)$*. This is the kernel form of the halting obstruction: the contradiction is not a separate primitive but appears only when a classifier is also required to close that diagonal divergence claim.*

Lean4✓ BEDC.Reflection.halting as form of distinction fixed point proof
↪ *variant BEDC.Reflection.halting as form of distinction fixed point*

Sketch. The certificate field `carrier_respects_equiv` gives transport of Halts along $\sim_H$. The empty continuation law gives $\mathsf{Cont}\, h\, \emptyset\, h$ for every h, hence $\mathsf{Halts}(h)$ under the stated equivalence. If h is self-referential, the self-reference hypothesis supplies an Ext predecessor and mark for h; using the empty continuation as the fixed point gives the witness $r = h$. The diagonal implication is then exactly the supplied policy applied to this empty-fuel continuation. □

9368.2 Halting as open-meta-loop closure

Theorem 9368.4 (Halting decidability is open-meta-loop closure)**.** *Accepting a halting predicate as in Definition 9368.2 closes the open meta loop of chapter 9461 at the certificate stratum: it supplies a* $\mathsf{NameCert}$*-level decision for a predicate over the carrier of all naming certificates, which is precisely the stratum the meta loop refuses to settle.*

Sketch. A halting predicate is, by Definition 9368.2, a $\mathsf{NameCert}$-level decision procedure indexed by the certificate-of-certificates carrier $\mathcal{C}$. By the unification theorem of Definition 9458.6, supplying a $\mathsf{NameCert}$-level decision indexed by $\mathcal{C}$ closes the open meta loop. The diagonal interface of Definition 9368.3 is the kernel-level witness showing where such a closure must also account for self-reference. □

9368.3 Connection to the form of distinction

Theorem 9368.5 (Halting irreducibility is form-of-distinction irreducibility at the meta level)**.** *The fixed-point interface for the halting predicate (Definition 9368.3) is the meta-level reading of the irreducibility of the form of distinction (Definition 9461.3): both expose a primitive distinction that a classifier must already respect. The form of distinction is the irreducible primitive at the constructor stratum (telling* $\mathsf{b0}$ *and* $\mathsf{b1}$ *apart); halting is the corresponding pressure point at the certificate stratum (telling terminating from non-terminating* Cont*-chains apart).*

Sketch. Definition 9461.3 shows that any classifier $\sim$ on a carrier G presupposes the form of distinction in its very statement. Read G as $\mathcal{C}$ and $\sim$ as the would-be halting classifier: deciding whether $(\mathsf{NameCert}_P, h) \sim (\mathsf{NameCert}_Q, k)$ in the sense of having the same termination status is an instance of the form of distinction at the certificate stratum. The halting interface is therefore the form-of-distinction irreducibility specialised to $G = \mathcal{C}$ and $\sim\, =$ halting equivalence; the diagonal fixed point is the explicit witness that this instance does not collapse to a simpler kernel primitive. □

Remark 9368.6 (Two-loops architecture)**.** *Definition 9368.3 and Definition 9461.3 sit on the two opposite faces of Definition 9461.15: the form of distinction must close at the bottom for the kernel to start (closed ground loop), and the same closure exposes the self-reference burden carried by halting decidability at the top (open meta loop). The two-loops structure is, read through this chapter, the discipline that the closure paid at the bottom is not silently transferred to the top.*

Theorem 9368.7 (Halting predicate exists iff the meta loop closes at the certificate stratum)**.** *Let*

$$\mathsf{Halts}(\mathsf{NameCert}_P, h)$$

denote the predicate that the Cont_P*-chain from* h *terminates in the sense of Definition 9368.1. The following are equivalent:*

1. *there exists a halting predicate* $\mathsf{NameCert}_H$ *in the sense of Definition 9368.2;*
2. *there exists a* $\mathsf{NameCert}$*-level decision procedure indexed by the certificate-of-certificates carrier* $\mathcal{C}$*, with carrier* $\mathcal{C} \times \mathsf{Hist}$*, whose extension predicate decides* $\mathsf{Halts}(\mathsf{NameCert}_P, h)$ *for every pair* $(\mathsf{NameCert}_P, h)$*.*

In this situation the open meta loop is closed at the certificate stratum precisely by that deciding certificate.

Proof. Assume (1). By Definition 9368.2, the certificate $\mathsf{NameCert}_H$ is already a naming certificate over $\mathcal{C} \times \mathsf{Hist}$ whose extension predicate on $(\mathsf{NameCert}_P, h)$ holds exactly when the Cont_P-chain from h terminates. Its continuation field is the kernel-level evidence required by the certificate framework. Therefore $\mathsf{NameCert}_H$ is exactly a $\mathsf{NameCert}$-level decision procedure of the form stated in (2). By Definition 9368.4, this deciding certificate is exactly what closes the open meta loop at the certificate stratum for the halting predicate.

Assume (2). Let $\mathsf{NameCert}_D$ be the stated $\mathsf{NameCert}$-level decision procedure. By hypothesis, $\mathsf{NameCert}_D$ lives over the carrier $\mathcal{C} \times \mathsf{Hist}$, its extension predicate on $(\mathsf{NameCert}_P, h)$ holds exactly when the Cont_P-chain from h terminates, and its continuation field supplies the certificate-level evidence attached to that decision. But these are precisely the clauses of Definition 9368.2. Therefore $\mathsf{NameCert}_D$ is a halting predicate; rename it $\mathsf{NameCert}_H$.

Thus (1) and (2) are equivalent, and the final sentence follows from Definition 9368.4 applied to that same deciding certificate. □

Concretized in §490: Halting obstruction is realized as a finite NameCert packet over certificates, histories, finite Cont traces, self-reference rows, diagonal obstruction ledgers, hsame transport, Pkg, and local NameCert provenance.

Concretized in §491: Halting distinction packets realize the fixed-point obstruction as a finite NameCert carrier over certificate-history pairs.

Concretized in §495: The halting fixed-point obstruction is realized as a finite NameCert packet over BHist, Cont, classifier transport, diagonal rows, and non-decision ledgers.

Concretized in §492: Halting distinction traces realize the certificate-level fixed-point obstruction as finite Cont, Ext, Pkg, and NameCert rows.

Concretized in §985: Halting finite boundaries realize finite Cont-trace evidence and diagonal refusal as a NameCert packet without deciding divergence.

Concretized in §978: Halting trace classifiers realize positive finite Cont-trace evidence and diagonal refusal as a finite NameCert packet without deciding divergence outside the displayed trace.

Concretized in §1197: Termination refusal boundaries realize the halting distinction as finite trace rows plus refusal-to-decide rows without deciding divergence.

Concretized in §597: Continuation termination packets realize halting-as-distinction-limit as finite Cont traces with terminal-read and classifier non-escape boundaries.

Chapter 9369

Channel Termination and the Halting Boundary

This vision chapter records the boundary exposed by the active channel compiler: the Zeckendorf-safe channel solves the local problem of where a finite event ends, but it does not solve the global problem of whether an arbitrary certificate computation halts. The two uses of "termination" therefore live at different strata. Channel termination belongs to the compiled display layer of chapter 9208 and chapter 9209; halting belongs to the certificate stratum of chapter 9368.

9369.1 Local channel termination

Definition 9369.1 (Source event and channel event)**.** *Let* $\Sigma = \{0, 1\}$*. A* source event *is any finite word* $w \in \Sigma^*$*. The source layer therefore admits* 11*,* 011*, and* 0011 *as ordinary raw events. The active channel layer uses the Zeckendorf-safe body encoding*

$$\zeta(\epsilon) = \epsilon, \qquad \zeta(0w) = 0\zeta(w), \qquad \zeta(1w) = 10\zeta(w),$$

and the channel event associated to w *is*

$$\mathsf{Ev}(w) = \zeta(w)\,11.$$

The final displayed 11 *is a channel-level terminator, not a source-level substring judgment.*

Definition 9369.2 (Legal channel event and legal channel stream)**.** *The legal single-event language is*

$$\mathsf{LegalEvent} := (0 \mid 10)^*\,11,$$

and the legal channel-stream language is

$$\mathsf{LegalZStream} := ((0 \mid 10)^*\,11)^*.$$

A legal stream is thus a finite concatenation of self-delimiting channel events.

Theorem 9369.3 (Channel bodies contain no terminator pattern)**.** *For every source event* $w \in \Sigma^*$*, the body* $\zeta(w)$ *contains no adjacent substring* 11*.*

Proof. By construction, $\zeta(w)$ is a finite concatenation of fragments from $\{0, 10\}$. Neither fragment contains 11. The only possible fragment junctions are 0|0, 0|10, 10|0, and 10|10, producing the local strings 00, 010, 100, and 1010. None contains adjacent 11. Hence no adjacent 11 occurs inside the encoded body. □

Corollary 9369.4 (The first 11 is the event terminator)**.** *For every source event w, the first adjacent occurrence of* 11 *in* $\mathsf{Ev}(w) = \zeta(w)11$ *is the appended channel terminator.*

Proof. The body contains no adjacent 11 by Definition 9369.3. The appended suffix is 11. Therefore the first adjacent 11 seen by a left-to-right decoder is precisely the terminator. □

Theorem 9369.5 (The source event 11 is encodable)**.** *The raw source event* 11 *is not forbidden. Its channel encoding is*

$$\mathsf{Ev}(11) = 101011.$$

The last two glyphs are the channel terminator; the two source glyphs $1, 1$ *are represented by the body* $10\,10$*.*

Proof. The body rule sends each source glyph 1 to the channel fragment 10. Thus

$$\zeta(11) = 10\,10 = 1010.$$

Appending the event terminator gives

$$\mathsf{Ev}(11) = \zeta(11)11 = 101011.$$

A decoder reads 10 as the first source 1, reads the next 10 as the second source 1, and stops only at the final 11. □

Corollary 9369.6 (Layer separation for the glyph pair 11)**.** *The displayed pair* 11 *has two distinct readings:*

$$\textit{source-level } 11 = \textit{two raw source glyphs}, \qquad \textit{channel-level } 11 = \textit{event terminator}.$$

The readings are selected by layer and must not be silently interchanged.

Proof. Definition 9369.5 shows that source-level 11 is preserved as body 1010 followed by the terminator. By Definition 9369.4, any channel-level first occurrence of adjacent 11 in a generated event is the boundary marker. Hence the same displayed glyph pair cannot be assigned both readings in the same judgment. □

9369.2 Bare bitstreams and self-delimitation

Definition 9369.7 (Bare bitstream encoding)**.** *A bare bitstream encoding writes each source event w as the same word w and writes an event flow $(w_0, \ldots, w_{n-1})$ as the concatenation $w_0 \cdots w_{n-1}$, without an event terminator, length table, schema, manifest, host parser, or prefix discipline.*

Theorem 9369.8 (Bare bitstream encoding is not self-delimiting)**.** *Bare bitstream encoding cannot recover event boundaries from the resulting glyph string alone.*

Proof. The displayed glyph string 011 admits several source-flow readings:

$$(011), \qquad (0, 11), \qquad (0, 1, 1).$$

All produce the same bare concatenation. Without extra boundary data, there is no intrinsic rule selecting one decomposition. Thus the bare bitstream carries content glyphs but not self-delimiting event boundaries. □

Theorem 9369.9 (Zeckendorf-safe channel termination)**.** *Every legal channel event has a streaming-decoded endpoint: scanning left-to-right, the first adjacent* 11 *ends the current event, and the body before it decodes uniquely to a source event.*

Proof. A legal event has the form $(0 \mid 10)^*11$. Each body fragment is read locally: 0 emits source 0, and 10 emits source 1. By Definition 9369.3, the body contains no adjacent 11. Hence the first adjacent 11 cannot be body data and must be the terminator. The decoder therefore stops after a finite scan and recovers the unique source event encoded by the body. □

Corollary 9369.10 (Constraint-minimal reading)**.** *Under the constraints of a binary alphabet, no third glyph, no external length table, no schema or manifest, streaming decoding, and reserved terminator* 11*, the rule*

$$0 \mapsto 0, \qquad 1 \mapsto 10, \qquad \mathrm{End} = 11$$

provides the minimal active BEDC channel discipline: it internalizes finite event boundaries without adding an additional kernel mark.

Proof. The body fragment for source 0 is already the one-glyph fragment 0. The source glyph 1 cannot be represented by 1, because a following 1 would collide with the terminator 11; it cannot be represented by 11, because 11 is reserved as End. The shortest remaining safe fragment is 10. The fragment set $\{0, 10\}$ is exactly the body language used in Definition 9369.9, so the resulting discipline is streaming, binary, and self-delimiting. This is a structural minimality claim under the displayed constraints, not a Shannon- or Huffman-optimality claim for an arbitrary probability distribution. □

9369.3 Channel grammar and finite window geometry

Definition 9369.11 (Three readings of the no-adjacent grammar)**.** *The no-adjacent-*11 *grammar has three distinct BEDC readings:*

$$\textit{channel reading: } \mathsf{LegalEvent} = (0 \mid 10)^*11,$$
$$\textit{finite-window reading: } X_m = \{w \in \{0,1\}^m : w \textit{ has no adjacent } 11\},$$
$$\textit{spectral reading: } |X_m| = F_{m+2} \textit{ with growth scale } \varphi.$$

The first is a compiler-channel discipline, the second is a finite address-geometry discipline, and the third is the growth invariant of the same finite-type grammar.

Principle 9369.12 (Ground channel is a streaming use of the golden-mean grammar)**.** *The Zeckendorf-safe compiler does not identify channel streams with Window-six geometry. It uses the same local forbidden pattern for a different task. In the compiler, bodies lie in*

$$(0 \mid 10)^*$$

and the first adjacent 11 *is reserved as boundary. In the Axis-Zeckendorf window geometry of Definition 9347.1, the same forbidden pattern defines the admissible finite windows X_m and the inverse-limit address carrier $X_\infty^{\mathbb{Z}}$. In Definition 9347.15, the transition kernel records the associated golden-mean shift.*

Thus the shared object is the local grammar, not a collapse of compiler channels, finite windows, and source-level Zeckendorf normal forms into one type.

Theorem 9369.13 (Channel bijection is not source-level Zeckendorf rewriting)**.** *The GroundCompiler channel bijection*

$$\mathsf{EventFlow} \cong \mathsf{LegalZStream}$$

is a self-delimiting display theorem for event flows. It is not a source-level Zeckendorf carry or normal-form theorem.

Proof. By Definition 9222.4, the legal channel stream language is

$$\mathsf{LegalZStream} = ((0 \mid 10)^*11)^*,$$

and Compile and Decode are inverse maps. By Definition 9222.7, source events and channel streams are strictly separated: channel-level 11 is a terminator, source-level 11 may be raw data, and source-level normalization acts only after decoding. Therefore the channel bijection licenses lossless event flow display, not a direct string rewrite by a Zeckendorf carry classifier. □

Principle 9369.14 (Boundary recovery pattern)**.** *The compiler channel realizes the pattern*

local forbidden body pattern → detectable boundary → streaming decoder → round-trip certificate.

Window six realizes the related finite-geometry pattern

local forbidden window pattern → finite admissible carrier → inverse-limit extension boundary.

The analogy is structural. It does not turn legal-stream membership into a theorem, a proof, a recognized NameCert, an accepted object flow, or a source-level Zeckendorf normal form.

9369.4 The halting boundary

Definition 9369.15 (Local event termination versus certificate halting)**.** Local event termination *asks where the current compiled channel event ends. It is answered by the first channel-level terminator* 11.

Certificate halting *asks whether, for an arbitrary naming certificate* $\mathsf{NameCert}_P$ *and history* h*, the* Cont_P*-chain from* h *terminates in the sense of Definition 9368.1.*

Theorem 9369.16 (Channel termination does not decide halting)**.** *The Zeckendorf-safe channel gives a decision procedure for local event boundaries in* LegalZStream*, but it does not provide a BEDC internal total classifier deciding certificate-level halting for all pairs* $(\mathsf{NameCert}_P, h)$*.*

Proof. The local channel claim follows from Definition 9369.9: a legal event is a finite word in $(0 \mid 10)^*11$, and its first 11 is a boundary. The question is syntactic and channel-local.

A halting classifier would instead live over the carrier $\mathcal{C} \times \mathsf{Hist}$ of certificates and histories and would decide, for each pair $(\mathsf{NameCert}_P, h)$, whether the Cont_P-chain terminates. By Definition 9368.7, such a predicate is exactly a certificate-level decision procedure at the certificate stratum, and by Definition 9368.4 that assumption closes the open meta loop. The diagonal obstruction of Definition 9368.3 is not affected by knowing where a finite channel event ends. Therefore channel termination and global halting live at different strata. □

Corollary 9369.17 (Stop codon versus meta-stop)**.** *The channel-level terminator* 11 *is a local stop marker for event parsing. The halting problem is the refusal of a global meta-stop: no internal total classifier may close the certificate stratum by deciding termination of every possible* Cont*-chain.*

Proof. The first sentence is exactly Definition 9369.4. The second follows from Definition 9369.16: a local parser boundary does not supply the certificate-of-certificates classifier whose existence is equivalent to meta-loop closure. □

Remark 9369.18 (Compressed reading)**.** *The compressed reading is therefore:* 11 *is the channel layer's stop codon; the halting theorem is the certificate layer's refusal of a universal meta-stop. The first is engineered by excluding* 11 *from encoded bodies. The second is blocked by the diagonal fixed-point obstruction that appears when the open meta loop is treated as closed.*

Concretized in §3996: The local channel boundary is realized as a finite NameCert packet separating event termination from certificate-level halting.

Concretized in §1197: Termination refusal boundaries realize the local-channel-termination versus global-halting boundary as finite refusal, visibility, and NameCert rows.

Concretized in §5967: The local channel terminator/global halting boundary is realized as finite budget-certificate NameCert data.

Concretized in §6725: Halting refusal ledgers realize the local channel terminator/global halting boundary as finite fuel, trace, timeout-refusal, and global-refusal NameCert rows.

Concretized in §985: Halting finite-boundary packets realize the channel-termination vision as finite trace evidence plus diagonal refusal, terminal trace, inscription, transport, replay, provenance, and NameCert rows.

Concretized in §7098: Certified event flows realize source/channel endpoint separation as finite NameCert data.

Concretized in §7790: Channel termination boundary packets realize the first-11 local delimiter as finite NameCert data separated from global halting claims.

Chapter 9370

Strong Normalisation versus Turing Completeness: The Total-Language Position of BEDC

The cellular reading of chapter 9390 identifies Rule 110 as a minimal universal cellular substrate, and locates the project's `rule110/` sub-system as the smallest substrate-side instantiation of the closed-observational framework. A complementary axis is the relationship between the *host system* (BEDC, sitting inside CIC) and Turing completeness in the sense relevant to the substrate. The host system is not Turing complete in the same sense; it is a total functional language. This chapter makes the precise statement of that fact, locates BEDC against other total functional languages (Coq, Agda, Lean, Idris 2 with quantitative type theory), and shows how the closed-observational framework forces the total-language position rather than treats it as an incidental design choice.

9370.1 Setup: total functional language as discipline

Definition 9370.1 (Total functional language)**.** *A* total functional language *is a programming or type-theoretic system in which every well-typed term reduces to a normal form in finitely many reduction steps under the system's reduction relation. Equivalently, no well-typed term computes forever; partial functions cannot be defined as functions; general recursion is admitted only when accompanied by a well-founded measure that the type checker can verify. The Calculus of Inductive Constructions in its Lean 4 implementation is a total functional language under this definition.*

Definition 9370.2 (Turing-complete computational model)**.** *A* Turing-complete *computational model is a specification of a class of computational processes such that every partial recursive function on natural numbers is realised as some process in the class. Equivalent formulations include the lambda calculus, the unrestricted register machine, the cyclic tag system, and any system Cook 2004 reduces to as a universality witness, in particular the orbit of Rule 110 on a suitable initial configuration.*

Principle 9370.3 (BEDC is total; substrate is universal)**.** *BEDC, as a Lean 4 development under CIC, is a total functional language in the sense of Definition 9370.1. The cellular substrate* `rule110/` *is a Turing-complete computational model in the sense of Definition 9370.2. These two facts coexist without contradiction precisely because they describe two structurally different layers: the host (BEDC) reasons* about *computations, while the substrate* performs *them. The host's totality is not a weakening of the substrate's universality; it is a separate axis of discipline.*

9370.2 The expressive gap, made precise

Remark 9370.4 (What a total host cannot directly express)**.** *A total functional language cannot define, as a function of type $A \to B$, an algorithm whose termination is not internally provable. There exist Turing-computable functions whose totality is provable in a stronger meta-theory but not in CIC itself; these functions, while Turing-realisable, are not directly definable as BEDC functions. The set of BEDC-definable functions is therefore a strict subset of the set of Turing-realisable partial functions on natural numbers; the difference is the set of functions whose totality is unprovable within CIC.*

Definition 9370.5 (Step-indexed encoding of partial computation)**.** *A* step-indexed encoding *of a partial recursive function ϕ inside a total language is a function $\widehat{\phi}\colon \mathbb{N} \times \mathrm{Input} \to \mathrm{Output} + \{\bot\}$ such that $\widehat{\phi}(n, x) = \phi(x)$ whenever $\phi(x)$ converges in fewer than n reduction steps and $\widehat{\phi}(n, x) = \bot$ otherwise. The step parameter n is the* fuel*. Step-indexed encoding allows a total host to talk about every Turing-realisable partial function, at the cost that totality of $\widehat{\phi}$ is decoupled from convergence of ϕ.*

Example 9370.6 (Rule 110 evaluator in BEDC)**.** *The Lean 4 development `lean4/BEDC/FKernel/` provides `r110_run_n_steps`, a function that takes a fuel parameter and a starting cell row and returns the row after the specified number of Rule 110 update steps. This is a step-indexed encoding of the Rule 110 orbit, written as a total BEDC function. The cellular substrate's potentially-infinite computation is decomposed into a family of finite computations, one per fuel value. The substrate retains its universality; the encoding retains its totality.*

Principle 9370.7 (Step indexing as the bridge)**.** *Step indexing is the structural bridge between a total host and a universal substrate. The host can describe every state the substrate could reach at every finite step, and can prove any decidable assertion about those states; the host cannot, in general, assert that the substrate halts on a given input, because halting is undecidable. The bridge therefore preserves the substrate's universality on the substrate side and the host's totality on the host side; it does not transfer either property across the boundary.*

9370.3 Position among total functional languages

Remark 9370.8 (Coq, Agda, Lean, Idris 2: same axis, different commitments)**.** *Coq, Agda, Lean 4, and Idris 2's quantitative type theory mode all qualify as total functional languages in the sense of Definition 9370.1. They differ in: which inductive types are admitted, which co-inductive structures are admitted, which universe hierarchies are available, and which standard-library axioms are imported by default. BEDC, as a Lean 4 development with `axiom-purity -strict`, is the variant in this family that minimises imported commitments: no `Classical.choice`, no `Quot.sound`, no `propext`. Among total functional languages in active use, this is the smallest residual axiomatic footprint currently audited mechanically.*

Remark 9370.9 (Idris partial functions and the closure cost)**.** *Some total languages, notably Idris, admit a `partial` annotation that allows the language to host non-total functions when explicitly marked. The annotation effectively partitions the language: total subset versus partial subset. BEDC does not admit this partition; every BEDC function is total, with no partial escape hatch. The closure cost of admitting a partial annotation is the loss of the property that "every typed term has a normal form"; once partial functions exist, the meta-theory must be split into two grades.*

Principle 9370.10 (BEDC's total-only discipline is structural)**.** *The choice to admit no partial function annotation is not an aesthetic preference; it is what allows the closed-observational reading of the BEDC kernel to apply uniformly. A partial subset would correspond to a region of the host where computations can in principle not halt, which would break the structural premise that BEDC observations are finite bit strings at finite reduction depth. Total-only discipline is a precondition for the closure theorems of chapter 9393 to transfer cleanly to the BEDC kernel.*

9370.4 The forced choice, read structurally

Theorem 9370.11 (Closed observation forces totality at the host)**.** *Let H be a host system that claims to describe a closed observational system S (Definition 9393.1) by recording finite observations of S as terms of H. Then H must itself be total in the sense of Definition 9370.1, on pain of contradicting the closure premise.*

Sketch. Suppose for contradiction H is non-total. Then H admits a term t whose reduction does not terminate. The semantic content of t is not a finite observation; it is a divergent process. If t is offered as a record *of* an observation of S, then either (i) the observation is itself divergent, contradicting the closure premise that observations of S are finite, or (ii) the observation is finite but the record is not, contradicting the structural correspondence between observations and records. Either way the closure premise fails. Hence H is total. □

Remark 9370.12 (Why this matters for the project framing)**.** *The result of Definition 9370.11 is a forced-choice argument: once the host is committed to recording a closed observational system, totality is not optional. It also clarifies why total functional languages are the correct host class for projects of the BEDC kind: Coq, Agda, Lean 4, Idris 2 in total mode are all instances of host systems whose semantic discipline matches the substrate's closure discipline. A host system based on a non-total language (Standard ML, OCaml, Haskell, Python) would silently violate the structural correspondence and would have to mark every observation record by an explicit termination certificate, which is precisely what total languages enforce statically.*

9370.5 Curry-Howard, and what it means here

Principle 9370.13 (Curry-Howard reading of totality)**.** *Under the Curry-Howard correspondence, a total functional language is one in which every well-typed term is a proof. Allowing non-termination would correspond to allowing proofs that "go on forever", which logically is the same as allowing arbitrary statements to be "derived" by an infinite loop. A non-total language is therefore inconsistent as a proof system. BEDC's totality is the proof-side reading of the closure premise: every typed term is a finite, terminating proof; every proof is a finite observation record; the structural correspondence between observation and proof is unbroken.*

Remark 9370.14 (Universal computation does not require universal proof)**.** *The cellular substrate's Turing universality means it can host any computation. The host's totality means every host proof is finite. These two are compatible because computation and proof are not the same relation. The substrate's computation is something the host* describes *as a step-indexed family; the host's proof is something the host* performs *on its own typed terms. The substrate's universality does not back-propagate to require the host to be universal. The closed-observational reading of BEDC depends on this clean separation; an attempt to unify the two would either weaken the host into a non-total language or weaken the substrate into a sub-universal model.*

9370.6 Mapping to BEDC engineering

Strong-normalisation reading	**BEDC engineering realisation**
Host as total functional language	`lean4/` build is `lake build` exit 0; every theorem terminates by the Lean 4 kernel's termination checker.
Step-indexed substrate computation	`r110_run_n_steps` in `lean4/BEDC/FKernel/` takes a fuel parameter and returns a finite orbit segment.
Substrate universality, host-internal	`rule110/encoder/tm_to_tag.c` and `rule110/encoder/tag_to_cyclic.c` compile a TM to a cyclic tag system; the cyclic tag is then evaluated by the host as a step-indexed computation.
Axiom-pure totality audit	`axiom-purity -strict` traces every theorem's `#print axioms` and rejects any Lean stdlib axiom.
No partial-function escape hatch	`tools/check-axioms.py` rejects `axiom` keyword in `lean4/BEDC/` anywhere; structural enforcement is mechanical.
Closure-discipline transfer to substrate	Definition 9390.10 carries the closure premise into the cellular substrate at the same totality discipline.

9370.7 Closure remarks

This chapter has located BEDC's total-functional-language position as the host-side correlate of the closed-observational framework of chapter 9393. The total-language discipline is not a design preference; it is structurally required if the host is to record finite observations of a closed substrate without violating the closure premise.

The Turing universality of the cellular substrate and the totality of the BEDC host are therefore independent axes that meet without interfering. The host describes the substrate via step-indexed encodings; the substrate's universality is preserved inside the encoding; the host's totality is preserved outside it. Curry-Howard gives the proof-side reading of the same discipline: every typed term is a finite proof, just as every observation record is a finite bit string.

The boundary of this chapter is precisely: BEDC is total in the sense of Definition 9370.1; the cellular substrate is Turing complete in the sense of Definition 9370.2; the two facts coexist without contradiction. This chapter does not enlarge BEDC's expressive power, does not weaken the substrate's universality claim, and does not propose to merge the two axes. It identifies the axes as separate and explains why their separation is structurally required by the closure premise.

Concretized in §936: Finite normal-form packets realize the total-host boundary of strong normalization.

Concretized in §944: Bounded finite trace packets realize the total-host side of the strong-normalization boundary.

Concretized in §963: Fuel-bounded partial traces realize the total-host side of substrate universality as finite NameCert packets.

Concretized in §960: FuelIndexedSubstrateBridge realizes the total-host and universal-substrate separation as a finite fuel-indexed NameCert packet.

Concretized in §964: StepIndexedTotalHost realizes the total-host and universal-substrate boundary as finite fuel-indexed trace, normal-form, refusal, hsame, Cont, Pkg, and NameCert rows.

Concretized in §962: Total-host fuel handoffs realize the strong-normalization bridge as finite fuel, substrate-trace, terminal-readback, hsame, Cont, Pkg, and NameCert rows.

Concretized in §970: Reduction fuel boundaries realize the total-host side of bounded substrate computation as finite fuel, trace, endpoint, timeout-refusal, audit, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1050: Host total traces realize finite fuel, normal-form readback, substrate endpoint, timeout refusal, hsame, Cont, Pkg, and NameCert rows.

Concretized in §3706: Closed-observation total-host discipline is realized as finite observation, termination, substrate-step, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §3954: The total-host and universal-substrate separation is realized as finite MetaCIC fuel, normal-form, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §5925: Candidate-mediated strong-normalization boundaries are realized as finite MetaCIC candidate, fuel, normal-form endpoint, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §7962: Residual fuel-rank packets realize the MetaCIC total-host boundary as finite residual, fuel, rank, candidate, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §6838: PartialityBoundaryUp realizes the total-host versus partial-escape boundary as finite NameCert data.

Concretized in §8123: Step-indexed trace packets realize the total-host/substrate bridge as finite fuel, prefix, endpoint, refusal, replay, provenance, and NameCert rows.

Concretized in §8434: Normalization budget traces realize the total-host/substrate boundary as finite fuel, prefix, endpoint, refusal, replay, provenance, and NameCert rows.

Chapter 9371

Compilation as Naming-Certificate Morphism

A compiler from source language S to target language T is a structure-preserving translation that respects the semantics of both. In BEDC terms, S and T each carry a naming certificate (chapter 9367, chapter 9365); a compiler is a morphism between the two certificates that preserves the classifier; compiler correctness is the assertion that the morphism preserves hsame. The chapter records this identification and locates compositional compilation, optimisation correctness, and decompilation in the same framework.

9371.1 Compiler as classifier-preserving morphism

Definition 9371.1 (Naming-certificate morphism)**.** *A* morphism *from* $\mathsf{NameCert}_S$ *to* $\mathsf{NameCert}_T$ *is a kernel-level function* Φ *on the carriers of* S *and* T *together with two preservation witnesses:* Φ *sends every* Ext_S*-marked source history to an* Ext_T*-marked target history, and* Φ *commutes with the continuation chains,* $\Phi(\mathsf{Cont}_S\, h\, m\, h') = \mathsf{Cont}_T\, (\Phi h)\, m'\, (\Phi h')$ *for an explicit mark translation* $m \mapsto m'$*. The morphism preserves* classifier membership *because every classifier-decided fact about* h *becomes a classifier-decided fact about* Φh *via the preservation witnesses.*

In the Lean kernel this is expressed relationally by a compiler graph $G(h, k)$*. The graph is a certificate morphism when every graph edge starts in the source carrier and lands in the target carrier, every source-classified input has a lifted graph edge, and paired graph edges transport source classifier membership to target classifier membership.*

Definition 9371.2 (Compiler)**.** *A* compiler *from* S *to* T *is a naming-certificate morphism* $\Phi\colon \mathsf{NameCert}_S \to \mathsf{NameCert}_T$ *together with the additional witness that* Φ *preserves* hsame*: if two source histories are* hsame*-equivalent, their images are* hsame*-equivalent in the target.*

Theorem 9371.3 (Compilation as naming-certificate morphism)**.** *For every pair of naming certificates* $(\mathsf{NameCert}_S, \mathsf{NameCert}_T)$*, every compiler graph from* S *to* T *whose edges land in the certified carriers, lift along source classifier membership, and preserve classifier membership across paired edges is a naming-certificate morphism* $\mathsf{NameCert}_S \to \mathsf{NameCert}_T$*. Compiler correctness is the assertion that this morphism is a* hsame*-preserving classifier morphism. Sequential composition of correct compilers is composition of morphisms in this category; an optimisation is an endomorphism whose source and target certificates coincide.*

Lean4✓ `BEDC.Reflection.compilation as namecert morphism proof`

↪ variant `BEDC.Reflection.compilation as namecert morphism`

Sketch. The forward direction is the unfolding of Definition 9371.2: a compiler is, by definition, the data of a naming-certificate morphism plus the hsame-preservation witness. In the graph presentation, source classifier membership supplies a lifted output edge, and the morphism witness turns the paired source edges into a target classifier edge. Target carrier preservation then follows from the target naming certificate's carrier transport field. Sequential composition of compilers $\Phi_2 \circ \Phi_1$ inherits the preservation witnesses by composing them, and the resulting hsame-preservation is a kernel-level conjunction of the two component witnesses. □

9371.2 Compositional compilation

Theorem 9371.4 (Composition of correct compilers is correct)**.** *Given correct compilers* $\Phi_1 \colon \mathsf{NameCert}_S \to \mathsf{NameCert}_M$ *and* $\Phi_2 \colon \mathsf{NameCert}_M \to \mathsf{NameCert}_T$*, the composition* $\Phi_2 \circ \Phi_1 \colon \mathsf{NameCert}_S \to \mathsf{NameCert}_T$ *is a correct compiler from* S *to* T*.*

Sketch. Both Ext-preservation and Cont-commutation are closed under function composition: applying Φ_2 to the output of Φ_1 produces a target-marked, target-continuing image of every source-marked, source-continuing input. hsame-preservation composes by transitivity of hsame. □

9371.3 Optimisation and decompilation

Definition 9371.5 (Optimisation)**.** *An* optimisation *on* $\mathsf{NameCert}_S$ *is an endomorphism* $\Phi \colon \mathsf{NameCert}_S \to \mathsf{NameCert}_S$ *in the sense of Definition 9371.1 that preserves* hsame*.*

Theorem 9371.6 (Optimisation correctness as endomorphism preservation)**.** *An optimisation* Φ *on* $\mathsf{NameCert}_S$ *is correct exactly when, for every source history* h*,* $\mathsf{hsame}(h, \Phi h)$ *holds. Equivalently,* Φ *acts as the identity in the category of naming certificates modulo* hsame*.*

Sketch. The endomorphism condition $\mathsf{hsame}(h, \Phi h)$ is the assertion that the optimisation's output is observationally identical to the input under the certificate's classifier. By Definition 9371.1, this preserves Ext and Cont, so the kernel-level behaviour is unchanged. □

Definition 9371.7 (Decompilation)**.** *A* decompilation *from* $\mathsf{NameCert}_T$ *to* $\mathsf{NameCert}_S$ *is a naming-certificate morphism* $\Psi \colon \mathsf{NameCert}_T \to \mathsf{NameCert}_S$ *such that* $\Phi \circ \Psi$ *is an optimisation on* $\mathsf{NameCert}_T$ *in the sense of Definition 9371.5, where* Φ *is the compiler from* S *to* T*. Decompilation is therefore not always available; when* Φ *has no morphism right-inverse modulo* hsame*, decompilation does not exist.*

Remark 9371.8 (Compiler category)**.** *The naming certificates over a fixed mark alphabet, together with the morphisms of Definition 9371.1, form a category by chapter 9363: identities are kernel identity functions, composition is function composition, and the laws follow from* Cont *associativity and unit. Compilers are the* hsame*-preserving morphisms, optimisations are the endomorphisms, and decompilations are the partial right-inverses. The framework subsumes intermediate-representation pipelines (chains* $\Phi_n \circ \cdots \circ \Phi_1$*) and source-to-source transformations (loops in the morphism graph).*

Concretized in §481: Compiler correctness is realized as a classifier-preserving morphism between source and target naming certificates.

Concretized in §473: Compiler graphs are realized as finite NameCert morphism packets preserving carrier, continuation, and classifier rows.

Concretized in §574: Certificate pipeline stage boundaries are realized as finite NameCert packets for adjacent compiler graphs, middle-stage compatibility, classifier transport, continuation composition, and non-escape ledgers.

Concretized in §614: Decompiler right-inverse packets realize decompilation as a finite compiler-graph, optimization, hsame-transport, Cont-route, Pkg, and NameCert boundary.

Concretized in §620: Kernel morphism packets realize classifier-preserving NameCert graph morphisms as finite BHist, hsame, Cont, Pkg, and NameCert rows.

Concretized in §639: Compiler optimisations are realized as finite NameCert endomorphism packets over displayed compiler graph, classifier, hsame, Cont, Pkg, and local naming rows.

Concretized in §679: Compiler composition traces are realized as finite BHist packets for adjacent compiler graphs, middle-certificate compatibility, classifier transport, continuation composition, and associativity non-escape.

Concretized in §1055: Compiler trace faithfulness realizes compiler correctness as finite graph replay, classifier preservation, hsame transport, provenance, and NameCert rows.

Concretized in §1097: Compiler-classifier routes realize compiler correctness as one finite route tying classifier membership, classifier morphism, NameCert morphism, certificate compiler graph replay, and trace faithfulness rows.

Chapter 9372

Closed-term substitution as the self-compilation step

9372.1 The setup

BEDC.MetaCIC represents a small CIC-like term language by the closed generator `Term`.

The generator has exactly five surface forms: `var`, `app`, `lam`, `pi`, and `sort`.

The closedness classifier for this generator is `ClosedAt`.

For a depth d and a term t, `ClosedAt` d t says that every free de Bruijn index visible in t lies below the boundary d.

The boundary is not cosmetic.

It is the local budget by which the term may use names already present in the ambient binder context.

At depth 0 the classifier marks genuinely closed terms.

At larger depth it marks terms closed relative to the registered variables below that depth.

Thus `ClosedAt` is not merely a syntactic predicate.

It is the classifier that tells the MetaCIC layer which terms remain inside the registered binder ledger.

The two operations at issue are `shift` and `substitute`.

`shift` raises free indices at or above a cutoff.

`substitute` replaces the variable at a specified depth and adjusts indices around the removed binder.

Both operations are ordinary generators over `Term`: they traverse the closed constructor list and produce another `Term`.

But only some generator actions preserve a given classifier.

The self-compilation reading depends exactly on that distinction.

A compiler that compiles itself must feed compiler-shaped source terms through the evaluator it implements.

Inside that evaluator, substitution is not optional bookkeeping.

It is the step that pushes an actual argument into a binder body.

If this step could cross the closedness boundary, the self-compilation chain would silently acquire an unregistered free variable.

The chain would then cease to be a chain of BEDC-certified records.

It would be a chain whose later stage contains a name that no prior certificate licensed.

BEDC therefore reads closed-term substitution as a certificate closure condition.

The relevant claim is not that every substitution preserves every semantic property.

The relevant claim is narrower and sharper: when a term is already closed at the substitution depth, the attempted substitution at that boundary is syntactically inert.

No hidden variable is consumed.

No variable is smuggled through the boundary.

No future binder budget is borrowed to make the operation typecheck.

In formula form, the MetaCIC witness says:

$$\mathsf{ClosedAt}(d, t) \Rightarrow \mathsf{substitute}(d, v, t) = t.$$

This is the form of closure that self-compilation needs at the substitution site.

The evaluator may attempt the syntactic operation, but the registered closedness certificate proves that the operation cannot alter a term whose free variables all sit below the boundary.

The source term remains inside the classifier.

The self-application step remains inside the same record discipline.

The compiler does not borrow an unrecorded name from the future of its own compilation chain.

9372.2 The Lean witness

Two theorems from `lean4/BEDC/MetaCIC/ClosedTerm.lean` carry the technical content:

- `shift_closed` –

  ↪variant `BEDC.MetaCIC.shift closed`

- `substitute_closed` –

  ↪variant `BEDC.MetaCIC.substitute closed`

- `closed_under_substitute_classifier` –

  ↪variant `BEDC.MetaCIC.closed under substitute classifier`

  (instance of

  ↪variant `BEDC.MetaCIC.GeneratorClosureClassifier`

)

`shift_closed` states that shifting a term at its closedness boundary by one position leaves the term unchanged.

Its statement is:

$$\mathsf{ClosedAt}(n, t) \Rightarrow \mathsf{shift}(n, 1, t) = t.$$

The proof is structural over the `ClosedAt` witness.

In the variable case, the inequality $i < n$ forces the cutoff test $n \leq i$ to be false.

In the compound cases, the induction hypotheses pass through `app`, `lam`, and `pi`.

The binder cases raise the boundary on the body or codomain, matching the definition of `ClosedAt`.

The universe case is immediate.

The theorem says that a closed term already pays its depth bill.

Raising the external context boundary does not require rewriting the term, because no free index reaches the cutoff.

This is the boundary budget law for self-compilation.

When a closed source fragment is moved into a deeper binder context, the chain does not reach into a later context to justify the move.

The proof spends only the already recorded inequality inside `ClosedAt`.

`substitute_closed` states that substituting at the boundary of a closed term leaves the term unchanged:

$$\mathsf{ClosedAt}(d, t) \Rightarrow \mathsf{substitute}(d, v, t) = t.$$

The value v is arbitrary.

That arbitrariness matters.

The theorem does not inspect v because the substitution site is absent.

For a variable index i in a term closed at d, the witness gives $i < d$.

Consequently $i = d$ is false, and $d < i$ is false.

The substitution branch cannot fire, and the decrement branch cannot fire.

The variable is returned as itself.

The compound cases again follow the `ClosedAt` constructor tree.

Under binders, the implementation shifts the substitution value while increasing the depth, but the theorem proves that this shifted value is never observed in a closed-at-boundary body.

That is the self-compilation content.

The evaluator may carry a substitution payload through the recursive traversal, yet the classifier prevents the payload from becoming a hidden source of free variables.

The accepted record is the equality of the syntactic output with the input term.

The certificate is the `ClosedAt` derivation.

The generator is `substitute`.

The closure law is that the generator action is inert on the classified slice.

9372.3 Why this is the self-compilation step

Self-compilation is not a single mystical event.

In BEDC it is a chain of ordinary certified steps.

Each step takes a record already admitted by a classifier, applies an authorized generator, and checks that the resulting record remains inside the promised scope.

For MetaCIC, evaluation under binders inevitably uses substitution.

A compiler source term contains binder bodies.

The evaluator implemented by the compiler opens those binders when it applies functions.

The self-compilation chain therefore cannot avoid the following local question: when the compiler's own evaluator substitutes during evaluation, does the operation preserve the closedness ledger of the source term?

`substitute_closed` answers the question at the exact boundary where the risk appears.

If the source fragment is closed relative to depth d, then a substitution at d has no target inside the fragment.

The operation returns the same term.

Hence the self-compilation chain does not create an unregistered free variable at that step.

The compiler may feed its own term representation to its own evaluator without turning closed source into boundary-leaking source at this operation.

The theorem is therefore a local non-escape certificate.

Concretized in §531: Closed substitution is realized as a finite seal whose inert boundary is certified by the MetaCIC closedness classifier.

It is local because it speaks only about the `substitute` operation at a single depth.

It is a certificate because it is a checked Lean theorem whose proof follows only the closed constructor tree and elementary Nat tests.

It is a non-escape claim because every possible route for the substitution payload to enter the term is blocked by the inequalities in the `ClosedAt` witness.

The same reading applies to `shift_closed`.

Self-compilation moves term fragments through binder contexts.

Moving through a binder context normally requires shifting free variables.

But a term closed below the relevant cutoff contains no free variable at that cutoff.

Shifting it at the boundary is therefore inert.

The chain can deepen the surrounding context without borrowing a depth that has not yet been registered.

This is why `shift_closed` is the boundary budget law.

Depth behaves monotonically with respect to the certificate already held by the term.

The term does not need a later binder to justify its present closedness.

The pair of theorems gives the self-compilation step its exact BEDC shape:

$$\text{registered closed source} \xrightarrow{\text{shift}} \text{same registered source},$$

$$\text{registered closed source} \xrightarrow{\text{substitute}} \text{same registered source}.$$

The equalities are stronger than mere preservation of a predicate.

They state that, at the closed boundary, the operational generator cannot alter the term at all.

The self-compilation chain is therefore protected at the exact place where capture, escape, or name leakage would otherwise enter.

9372.4 Generator-closure classifier reading

The same facts can be read in the certificate-closure vocabulary.

`ClosedAt` is the classifier.

`Term` is the authorized generator carrier.

`shift` and `substitute` are authorized generator operations over that carrier.

`shift_closed` and `substitute_closed` are generator-closure laws for the classified slice.

This is not an analogy.

It is the literal BEDC structure.

A generator-closure classifier states which records remain inside the licensed generator scope after an authorized operation is applied.

Here the records are MetaCIC terms.

The classifier is `ClosedAt`.

The authorized operations are the syntactic traversals in `Syntax.lean`.

The closure law says that the operation cannot escape the classifier's boundary.

For `substitute`, the theorem is especially sharp.

The classifier does not merely say that the output is again closed.

It says the output is the input.

Thus every classified term is a fixed point of substitution at its boundary.

The name certificate reading is then immediate.

A naming certificate promotes a stable generated behaviour to a derived interface.

The stable behaviour here is:

$$t \in \mathsf{ClosedAt}(d) \Rightarrow \mathsf{substitute}(d, v, t) = t.$$

The certificate does not license arbitrary semantic substitution.

It licenses a boundary fact about closed terms.

It records that the generator action cannot access a variable whose existence the classifier has ruled out.

The NameCert surface therefore reads the theorem as a closure classifier over the `Term` generator.

The theorem belongs to the records side of BEDC because its proof is mechanical structural recursion over a closed inductive witness.

It does not ask for a free-floating universal principle over all possible syntax.

It ranges over the closure of the declared `Term` and `ClosedAt` generators.

Within that closure, it is fully internal.

Beyond that closure, BEDC does not pretend that the theorem has authority.

The NameCert classifier says "this generator, this boundary, this closure law".

It does not say "all imaginable binders in all possible metatheories".

That distinction is the exact difference between BEDC's generator-internal induction and the forward-binding belief whose far end is the T-socket.

9372.5 Audit gate as the executable form of the classifier

The audit gate is the executable form of this classifier discipline.

The paper marker `BEDC.MetaCIC.substitute_closed` points at a concrete Lean theorem.

The project audit verifies that the target exists.

The Lean build verifies that the proof elaborates.

The strict axiom-purity audit inspects the transitive dependency closure of the accepted theorem.

If the proof of `substitute_closed` depended on a hidden substrate commitment such as `Classical.choice`, `Quot.sound`, or `propext`, the audit would reject it.

This is not a separate quality check layered on top of the mathematics.

It is the operational classifier.

The classifier says that the generator action remains inside the authorized closure.

The audit checks that the Lean witness to that statement is itself generated inside the authorized proof discipline.

A proof that smuggled in a forbidden host axiom would be a generator escape at the proof layer, even if its statement had the right shape.

The strict audit therefore enforces the same closure law one stratum higher.

The syntactic generator `substitute` must not create a free variable in a closed term.

The proof generator used by Lean must not create a hidden axiom dependency in a closed BEDC theorem.

The two checks are not merely parallel.

They are the same generator-closure classifier pattern applied at two strata.

At the term stratum, `ClosedAt` classifies admissible MetaCIC terms.

At the proof-record stratum, the axiom-purity audit classifies admissible Lean proof dependencies.

The theorem is accepted only when both strata close.

Thus the audit gate is the executable manifestation of certificate closure.

It turns the prose promise "substitution does not leak names" into a checkable record whose proof also does not leak forbidden host commitments.

9372.6 Boundary: what this lemma does not claim

`substitute_closed` does not claim that substitution is semantically correct for arbitrary open terms.

It does not claim subject reduction for the whole evaluator.

It does not claim that every compiler pass preserves every classifier.

It does not claim that BEDC internalises the host CIC's truth predicate.

It does not claim that self-compilation is completed by a single syntactic lemma.

Its claim is exact:

$$\mathsf{ClosedAt}(d, t) \Rightarrow \mathsf{substitute}(d, v, t) = t.$$

The exactness is the point.

Concretized in §538: Closed substitution is represented by a finite boundary packet whose substitute route is inert on the `ClosedAt` slice.

At the boundary where a substitution payload could otherwise enter, the closedness classifier proves that there is no target for it.

The operation returns the original term.

The generator remains inside the classifier.

The proof remains inside the axiom-pure audit gate.

The self-compilation chain receives one local certificate that no unregistered free variable enters through this operation.

`shift_closed` has the matching boundary:

$$\mathsf{ClosedAt}(n, t) \Rightarrow \mathsf{shift}(n, 1, t) = t.$$

This law does not say that every shift is harmless.

It says that the shift at the closed boundary spends no future depth budget.

Together the two theorems give the self-compilation story a precise local socket:

the compiler may pass closed source through binder movement and boundary substitution without converting closure into name leakage.

Where the story asks for more than this, it must cite further certificates.

Where it asks for a universal claim beyond any authorized generator, BEDC marks the position as a T-socket rather than internalising it.

That is why the theorem is small but load-bearing.

It is the records-side generator-closure classifier instance at the substitution step of self-compilation.

It does not complete the entire compiler story.

It closes this boundary, with this classifier, for this authorized generator, under the executable audit gate.

Concretized in §537: Closed-term substitution is realized as a finite NameCert packet for boundary-inert substitution over MetaCIC closed terms.

Concretized in §531: Closed substitution seals realize the MetaCIC closedness boundary as a finite NameCert packet over Term, ClosedAt, substitution, shift, audit, and self-compilation rows.

Concretized in §527: Closed-term substitution boundary is realized as a finite NameCert packet over Term, ClosedAt, shift, substitute, closedness ledgers, and audit-visible non-escape rows.

Concretized in §532: Binder-budget seals realize the ClosedAt boundary as a finite NameCert packet for shift and substitution non-escape.

Concretized in §540: Closed-term substitution is realized as a finite compiler-boundary NameCert over ClosedAt, substitute, shift, BHist, Cont, Pkg, and NameCert.

Concretized in §621: Closed-term substitution is realized as a finite binder-boundary substitution seal packet over Term, ClosedAt, substitute, hsame, Cont, Pkg, and NameCert.

Concretized in §8006: Closed substitution self-compile packets realize closed-term, substitution, binder-seal, replay, refusal, transport, provenance, and local NameCert rows.

Chapter 9373

The recursor as an authorized generator

This chapter identifies the host CIC recursor, the eliminator generated for each accepted `inductive` declaration, as the canonical authorized generator behind BEDC's structural proof practice. The point is not that BEDC adds a new principle to CIC. The point is that BEDC reads the kernel's existing acceptance of `I.rec` as an authorization event: once the constructor signature is accepted, every legal use of the recursor is a generator action whose output carries a named certificate of membership in the associated closure.

9373.1 The setup

In Lean 4, an `inductive` declaration presents a closed constructor signature. The declaration of `Nat` gives zero and successor; the BEDC declaration of `BMark` gives `b0` and `b1`; the BEDC declaration of `BHist` gives `Empty`, `e0`, and `e1`; the BEDC.MetaCIC declaration of `Term` gives `var`, `app`, `lam`, `pi`, and `sort`. The corresponding eliminators `Nat.rec`, `BMark.rec`, `BHist.rec`, and `Term.rec` are not later postulates. They are emitted by the kernel from the accepted constructor signatures.

The associated reading is:

$$\begin{aligned} \text{constructor signature accepted} &\Longrightarrow \text{closed generated carrier}, \\ \text{closed generated carrier} &\Longrightarrow \text{kernel eliminator } I.\text{rec}, \\ I.\text{rec} &\Longrightarrow \text{structural computation over exactly that carrier.} \end{aligned}$$

This is the pure paradigm of a closed generator. The carrier has no hidden constructor outside the signature, and the eliminator has no hidden branch outside the constructor cases. For `Term`, for example, every structurally recursive definition must pay for the five visible cases. For `BHist`, every proof by cases or induction must pay for the empty case and the two extension cases. BEDC treats this exact finite payment as the operational content of authorization.

9373.2 The kernel principle

For each `inductive` declaration I, the Lean kernel emits an elimination principle I.rec. The acceptance criteria are the ordinary kernel criteria for inductive families: the constructor signature

must be strictly positive, and recursive uses exposed through definitions and proofs must be structurally decreasing or otherwise accepted by the kernel's termination checker. These criteria are not optional annotations. They are the gate through which the signature becomes a generator.

BEDC reads the gate as follows. Strict positivity prevents a constructor from smuggling a negative self-use that would turn the carrier into an uncontrolled truth device. Structural decrease prevents recursive computation from escaping the constructor spine it claims to consume. Kernel acceptance is therefore the generator's authorization stamp, and rejection is the absence of authorization. No further axiom is injected at the paper layer.

Principle 9373.1 (Recursor authorization)**.** *Let I be a Lean* `inductive` *declaration accepted by the kernel. The emitted eliminator I.rec is an authorized BEDC generator exactly over the closed carrier generated by I's accepted constructors. A use of I.rec is authorized only when its motive and branch data are accepted by the kernel and its recursive calls remain inside the structural closure of I.*

The host kernel is thus not merely checking a proof after the fact. It is sealing the generator at signature time and checking each generator call at use time. BEDC names this combination generator authorization.

9373.3 Generator role

The operational role of `I.rec` is to consume a generated I-object and produce an output by one branch per constructor. In non-dependent form the output type is fixed. In dependent form the motive may vary over the consumed object. Either way, the generator's closure is the same: every branch is tied to a constructor, and recursive hypotheses are available only for structurally smaller constructor arguments.

For a classifier C over the carrier I, the recursor gives the canonical closure pattern:

$$\frac{\begin{array}{r}\text{base branches certify } C \text{ on primitive constructors,}\\ \text{step branches transport } C \text{ across constructor extension,}\end{array}}{\text{the recursor certifies } C(x) \text{ for every } x : I.}$$

The phrase "for every $x : I$" is not a free-floating universal over an ambient totality. It is the generator-internal universal over the closure of the accepted constructor signature. This is the same boundary as Definition 9389.10: structural induction is internal to an authorized generator; the move to an unscoped "all" is external.

9373.4 NameCert structure

A legal `I.rec` call produces more than an isolated well-typed term. It produces a term whose well-typedness is backed by the closure of the generator that produced it. In BEDC vocabulary, that output is a $\mathsf{NameCert}$ at the relevant name:

$$\begin{aligned}\mathsf{NameCert}_{I.\mathrm{rec}(M,\beta,x)} = {} & \text{the named certificate that the recursor output is generated}\\ & \text{from the accepted } I \text{ signature, motive } M, \text{ and branch package } \beta.\end{aligned}$$

The certificate is named because the output can be referenced later as a stable proof object or definition. It is a certificate because its well-typedness is not supplied by an external assertion. It

is supplied by the recursor's sealed closure: the motive is checked, each branch is checked against its constructor boundary, and the recursive occurrences are accepted only where the kernel can see structural descent.

This is why a `cases` or `induction` proof in Lean is not an ad hoc proof script in BEDC's reading. The tactic elaborates to eliminator use. The resulting term is certified because the eliminator is certified. Every such proof object is therefore a named generator output, unless it imports a forbidden external principle through its transitive dependency chain.

9373.5 Generator-closure classifier view

Given an accepted inductive I, the natural classifier is:

$$I.\mathsf{WellFormed}(x) := x \text{ is generated by the accepted constructor signature of } I.$$

Inside Lean this classifier is not usually exposed as a separate predicate for plain inductive objects, because the judgment $x : I$ already carries it. BEDC makes the classifier explicit. The generator is the family of all legal calls to I.rec. The generator-closure statement is:

$$x : I \ \wedge \ \texttt{I.rec} \text{ is called with kernel-accepted motive and branches} \quad \Longrightarrow \quad I.\mathsf{WellFormed}(\texttt{I.rec}\ x).$$

When the recursor output does not itself have type I, the classifier is read at the output type: the output is well formed at its target type because the computation was generated through an authorized eliminator and accepted branch package. Thus the classifier-closure statement is not restricted to endomaps on I. It says that recursor-generated outputs remain inside the well-formed fragment of the target judgment selected by the motive.

No axiom appears in this classifier. The closure is the kernel's internal induction over the constructor signature. The audit-relevant object is the generated proof term itself, not an external statement that the proof term should be trusted.

9373.6 Comparison with classical "by definition" reading

Classical foundational prose often treats eliminators as available "by definition": once the inductive type is declared, induction and recursion are simply part of what the declaration means. That reading is extensionally correct but hides the authorization event. BEDC keeps the event visible.

In BEDC terms, "by definition" means:

$$\text{authorized at signature time} \quad + \quad \text{sealed at kernel-acceptance time} \quad + \quad \text{checked at each eliminator call.}$$

The difference is not a stronger logical assumption. BEDC does not place a deeper metaphysical principle underneath Lean's recursor. It records the operational structure already present in the kernel: strict positivity, constructor closure, structural descent, branch completeness, and type checking of the produced term. Classical prose compresses these into definitional availability. BEDC expands the compression into generator authorization and NameCert output, with the GAP ledger marking any remaining handoff to the host kernel as a T-socket in the sense of Definition 9389.15.

9373.7 Connection to closed-term substitution

The closed-term substitution lemma in BEDC.MetaCIC gives a direct analogue. The theorem `substitute_closed` says that substituting at a closed boundary does not change a closed term:

↪ variant BEDC.MetaCIC.substitute closed

The companion `shift_closed` theorem has the same closure shape for shifting:

↪ variant BEDC.MetaCIC.shift closed

Both are packaged as concrete instances of the generator-closure classifier structure:

↪ variant BEDC.MetaCIC.GeneratorClosureClassifier

↪ variant BEDC.MetaCIC.closed under shift classifier

↪ variant BEDC.MetaCIC.closed under substitute classifier

.

The structure is:

$$\begin{aligned} \text{classifier} &:= \texttt{ClosedAt}\ d\ t, \\ \text{generator} &:= \texttt{substitute}\ d\ v, \\ \text{closure} &:= \texttt{substitute}\ d\ v\ t = t \text{ whenever } \texttt{ClosedAt}\ d\ t. \end{aligned}$$

The proof proceeds by structural induction over the `ClosedAt` certificate. Each branch corresponds to one visible constructor of the classifier: variable, application, lambda, Pi, or sort. The proof is therefore a recursor-generated NameCert for the claim that the substitution generator cannot escape the closed-term classifier.

The `I.rec` case is the same pattern at the host-CIC level:

$$\begin{aligned} \text{closed-term substitution:} &\quad \texttt{ClosedAt} \text{ classifier closed under } \texttt{substitute}, \\ \text{inductive recursor:} &\quad \texttt{WellTyped} \text{ classifier closed under legal } I.\texttt{rec} \text{ calls.} \end{aligned}$$

The two claims are structurally isomorphic. In both cases, a classifier is preserved because the generator is constrained by the same constructor closure that produced the classifier. In both cases, no axiom is appended from outside the proof term.

9373.8 Audit gate as the executable form of the classifier

The executable form of the generator-closure classifier is the audit gate. Running `lake build` asks the Lean kernel to re-check every generated proof term: every `inductive` signature, every emitted or consumed recursor, every branch package, every definitional computation, and every theorem body. If a term depends on an unauthorized generator or fails its classifier, the kernel does not elaborate it.

BEDC adds two visible constraints on top of ordinary build success. The source audit rejects project-level `axiom` declarations, and the purity audit rejects forbidden transitive dependencies such as `Classical.choice`, `Quot.sound`, and `propext`. These gates make the classifier objective: the paper does not merely claim that recursor outputs stay inside their closure; the build graph and dependency audit decide whether the claim survives execution.

Thus the BEDC pipeline implements:

$$\begin{aligned} \texttt{lake build} &= \text{kernel execution of generator-closure checking}, \\ \texttt{check-axioms.py} &= \text{source-level rejection of axiom backdoors}, \\ \texttt{axiom-purity} &= \text{transitive rejection of forbidden host principles.} \end{aligned}$$

Together these gates state that the closure does not leak. A recursor-induced NameCert is accepted only if the kernel can replay the construction and the audit can find no axiom channel behind it.

9373.9 Boundary: what is not a recursor-induced NameCert

Not every well-typed Lean term is a recursor-induced NameCert in the strict BEDC sense. A proof whose transitive dependencies include `Classical.choice` imports a choice witness not generated by the relevant inductive closure. A proof depending on `Quot.sound` imports quotient equality as a host axiom. A proof depending on `propext` imports propositional extensionality. Such terms may be accepted by a broader Lean environment, but they are not BEDC-authorized generator outputs.

BEDC's project discipline forbids this family. The mathlib-free Lean tree, the no-`axiom` source gate, and the strict purity audit keep BEDC lemmas inside the recursor-and-constructor fragment. Within that fragment, a public lemma is generated either directly by constructors, by definitions unfolded over constructors, or by recursor use accepted by the kernel. Its certificate is therefore recursor-induced or constructor-induced, and its name is a NameCert rather than an imported classical closure.

This boundary is the practical content of the chapter. The CIC recursor is not an unexamined magic rule inside BEDC. It is the primary authorized generator: accepted by strict positivity, sealed by kernel checking, executed by structural recursion, named by its generated proof term, and audited so that no axiom backdoor can masquerade as closure.

Concretized in §522: The recursor-as-generator vision is realized as a finite NameCert packet for recursor-induced proof and definition outputs.

Concretized in §525: Authorized generator recursors are realized as finite NameCert packets over accepted constructor signatures, branch coverage, structural descent, and audit provenance.

Concretized in §534: Concrete recursor-generator packet for accepted inductive signatures, legal eliminator calls, audit non-escape, and closed-term handoff.

Concretized in §529: Recursor authorization is realized as a finite NameCert packet for constructor signatures, emitted eliminators, branch packages, and generator non-escape.

Concretized in §541: Authorized recursor packets realize legal eliminator calls as finite NameCert carriers over constructor signatures, motives, branches, output rows, and audit non-escape ledgers.

Concretized in §710: Recursion authorization ledgers realize accepted recursor calls as finite BHist packets over signature, motive, branch, descent, output, audit, and non-escape rows.

Concretized in §857: Bounded recursor replay is realized as finite BHist packets for signature, motive, branch, descent-budget, output, audit, route, provenance, and NameCert rows.

Concretized in §974: Recursor branch audits realize motive checking, constructor-indexed branch coverage, structural descent, and generator non-escape as a finite NameCert packet.

Concretized in §1187: Recursor closure classifier audits are realized as finite recursor, branch, classifier, audit-replay, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1345: Recursor branch-completeness packets realize authorized generator use as finite BHist, branch ledger, transport, replay, provenance, and NameCert data.

Concretized in §8079: Finite candidate-diamond packets realize authorized recursor generation as local MetaCIC join-audit ledgers over critical-path, parallel-frontier, and candidate-boundary rows.

Chapter 9374

Subject reduction discharge routes: explicit bundle

9374.1 The setup

BEDC.MetaCIC subject reduction for the closed CIC substrate is not an unparameterised theorem of the substrate itself. As recorded in chapter 9377, the checked theorem is parameterised by four named discharge hypotheses. A downstream carrier may supply those hypotheses explicitly, but the present raw relation does not supply a global discharge packet.

The public route is the explicit bundle route. It packages the four hypotheses as finite evidence and passes that packet to the subject-reduction theorem. The current substrate also exports checked obstruction facts showing that the application-argument, lambda-domain, and Pi-domain fields cannot be filled for the raw relation, and therefore the full bundle is not inhabited at this boundary.

9374.2 Bundle route

9374.2.1 Definition

The bundle route is centred on

↪ variant `BEDC.MetaCIC.SubjectReductionDischargeBundle`

. This Lean object is a structure of four propositions. Its fields are the beta-substitution preservation obligation, the application-argument stability obligation, the lambda-domain subject-reduction obligation, and the Pi-domain subject-reduction obligation.

The structure is carrier-agnostic: it does not say where the four propositions come from, which substrate implements them, or how an implementation proves them. Any caller that can provide the four fields can build the packet. No ambient instance route is part of the public MetaCIC audit surface.

9374.2.2 Subject reduction from bundle

The theorem

↪ variant `BEDC.MetaCIC.subject reduction from bundle`

consumes a

↪ variant `BEDC.MetaCIC.SubjectReductionDischargeBundle`

and yields the subject-reduction conclusion for the represented reduction step. The theorem does not prove the four hypotheses. It records that once those four hypotheses are explicitly supplied, the parameterised subject-reduction theorem has no remaining open argument.

This route is direct at a call site. Code constructs a bundle, passes it to the theorem, and receives the subject-reduction result. The discharge evidence is visible in the term that invokes the theorem.

9374.3 Checked obstruction ledger

The raw relation supplies checked negative facts for three fields:

↪variant `BEDC.MetaCIC.not appArgTypeStable`

,

↪variant `BEDC.MetaCIC.not lamDomainSubjectReduction`

, and

↪variant `BEDC.MetaCIC.not piDomainSubjectReduction`

. These facts are kernel-checked consequences of the closed counterexamples in the MetaCIC subject-reduction audit.

The bundle obstruction

↪variant `BEDC.MetaCIC.not subjectReductionDischargeBundle`

then follows by projecting the application-argument field from any purported bundle. Thus the current raw relation has a checked no-bundle ledger. This is a negative theorem about the present substrate, not a replacement for the beta-substitution obligation in future carriers.

9374.4 Boundary

This chapter does not solve beta-substitution preservation and does not construct a

↪variant `BEDC.MetaCIC.SubjectReductionDischargeBundle`

for the present substrate. It records one public discharge route and the checked obstruction ledger explaining why that route is not inhabited by the raw relation.

Future downstream carriers can still consume

↪variant `BEDC.MetaCIC.subject reduction from bundle`

by providing an explicit

↪variant `BEDC.MetaCIC.SubjectReductionDischargeBundle`

. At this boundary, however, the canonical published surface is explicit: bundle consumption plus checked no-bundle obstruction.

Concretized in §783: The explicit bundle discharge route is represented as a finite BEDC trace packet.

Concretized in §785: The explicit bundle discharge route is realized as a finite NameCert classifier over the shared subject-reduction discharge rows.

Concretized in §789: The explicit subject-reduction discharge route is realized as a finite NameCert route-audit packet with four-row payload and obstruction non-escape.

Concretized in §787: The explicit bundle subject-reduction discharge route is realized as one finite BEDC route packet.

Concretized in §784: Subject-reduction route equivalence is realized as finite bundle, socket, hsame, Cont, Pkg, and NameCert rows.

Concretized in §790: The explicit bundle discharge route is realized as a finite NameCert route certificate.

Concretized in §793: The explicit discharge-route comparison is represented as a finite route-audit NameCert packet.

Concretized in §796: The bundle/obstruction triangle is represented as a finite route-triangle NameCert packet.

Concretized in §798: The explicit bundle subject-reduction discharge route is realized as a finite route-choice NameCert packet with the obstruction boundary still explicit.

Concretized in §4200: The explicit bundle discharge route is realized as a finite dependency-audit packet over route, audit, triangle, and open-frontier rows.

Concretized in §5561: The subject-reduction discharge route is realized as a finite subject-reduction kernel packet.

Chapter 9375

Closed-MetaCIC consistency assembly: a partial closure map

9375.1 The setup

BEDC.MetaCIC aims at unconditional closed-term consistency of the substrate's internal CIC fragment. The canonical path is the standard one: subject reduction, strong normalisation on closed terms, and no closed normal proof of False. This chapter records which pieces of the path are already discharged and which constitute the open frontier.

The relevant distinction is between closed-normal consistency and full closed consistency. Closed-normal consistency speaks only about closed proof terms that are already beta-strong. Full closed consistency would also need to transport an arbitrary closed proof term along reduction until the normal-form theorem can be applied. That transport is exactly the subject-reduction boundary.

9375.2 The assembled positive content

9375.2.1 Closed-term strong normalisation

The strong-normalisation content is available through the candidate-mediated closed-term interface. The substrate verifies that an empty-context typed closed term is strongly normalising when the appropriate candidate evidence is supplied:

```
↪ variant  BEDC.MetaCIC.closed typed term sn from candidate
↪ variant  BEDC.MetaCIC.closed typed term sn from closedCandidate
↪ variant  BEDC.MetaCIC.closed typed term sn from candidateSet
```

.

These theorems are not themselves a closed subject-reduction theorem. They are the normalisation side of the assembly path. They say that the candidate interface can deliver termination of closed typed terms once the term has been placed inside the relevant reducibility certificate.

9375.2.2 No closed-normal proof of False

The contradiction-side theorem is also available:

```
↪ variant  BEDC.MetaCIC.no closed normal proof of false
```

. The substrate verifies that any closed proof term whose beta reduction is already strong cannot inhabit the internal false encoding.

In formula form, the checked content has the shape:

$$\mathsf{Closed}(t) \wedge \mathsf{BetaStrong}(t) \wedge \mathsf{HasType}([], t, \mathsf{False}) \Rightarrow \bot.$$

The theorem is closed over normal-form inhabitants of False. It does not need to assert that every closed proof term can be reduced while preserving its displayed type; that assertion belongs to the subject-reduction frontier.

9375.2.3 Closed-normal consistency assembly

The substrate also has the direct assembly statement:

```
↪variant BEDC.MetaCIC.closed normal consistency assembly
```

. It composes empty-context typing, closedness, and beta-strong normality into a single audit-checkable statement.

The theorem is the positive closed-normal node of the path:

$$\mathsf{HasType}([], t, \mathsf{False}) \wedge \mathsf{Closed}(t) \wedge \mathsf{BetaStrong}(t) \Rightarrow \bot.$$

Thus BEDC.MetaCIC already establishes the consistency statement for the normal-form fragment. The remaining question is whether every closed proof of False can be connected to that fragment without losing the typing certificate.

9375.3 The unassembled frontier

9375.3.1 Conditional subject reduction

Subject reduction is available as a parameterised theorem in BEDC.MetaCIC, conditional on four discharge hypotheses. Those hypotheses govern beta substitution preservation, application-argument codomain stability, lambda-domain preservation, and Pi-domain preservation. The interface is mapped in chapter 9377.

This is the exact point where the closed-normal theorem would have to become a full closed consistency theorem. A closed proof term of False must be normalised, and the displayed false type must remain attached throughout the reduction path. Without that preservation step, the normal-form theorem cannot be applied to an arbitrary closed proof term.

9375.3.2 The closed reduction obstruction

The substrate proves the closed reduction obstruction:

```
↪variant BEDC.MetaCIC.closed consistency reduction obstruction not available
```

. This theorem establishes that closed-term subject reduction is not directly available on the present substrate. Consequently unconditional closed-term consistency via the standard subject-reduction path is blocked at that node.

The obstruction does not weaken the positive closed-normal theorem. It locates the missing lift. The available consistency theorem applies once beta-strong normality is already part of the input; the unavailable theorem would justify transporting arbitrary closed proofs to that input form.

9375.4 The assembly diagram

The dependency map is:

```
Closed-term SN
  status: AVAILABLE
  witnesses:
    BEDC.MetaCIC.closed_typed_term_sn_from_candidate
    BEDC.MetaCIC.closed_typed_term_sn_from_closedCandidate
    BEDC.MetaCIC.closed_typed_term_sn_from_candidateSet

No closed-normal proof of False
  status: AVAILABLE
  witness:
    BEDC.MetaCIC.no_closed_normal_proof_of_false

Closed-normal consistency
  status: AVAILABLE
  witness:
    BEDC.MetaCIC.closed_normal_consistency_assembly

Closed reduction by subject reduction
  status: BLOCKED
  obstruction:
    BEDC.MetaCIC.closed_consistency_reduction_obstruction_not_available

Full closed consistency
  required inputs:
    Closed-normal consistency
    Closed reduction by subject reduction
  status: BLOCKED
  reason:
    the subject-reduction discharge is blocked
```

The assembled node is therefore closed-normal consistency, not full closed consistency. BEDC.MetaCIC establishes the normal-form sub-consistency unconditionally. It cannot lift that statement to arbitrary closed proofs of False without discharging the subject-reduction obligations.

Concretized in §6162: Closed-consistency reduction obstruction packets realize the blocked lift from arbitrary closed false proofs to beta-strong endpoints as finite endpoint, discharge, obstruction, transport, replay, provenance, and NameCert rows.

9375.5 What this partial closure does establish

The partial closure that already holds is strong. Any closed proof term that is beta-strong cannot inhabit the internal False encoding. Equivalently, the substrate rules out a closed false proof inside the normal-form fragment.

This is a non-trivial statement about normal-form inhabitants of False. The substrate has established not no-consistency-at-all but consistency on the normal-form fragment. The positive

theorem is narrow because its input includes beta-strong normality, and it is sharp because its conclusion is contradiction from a closed false proof under exactly that input.

9375.6 What discharge would buy

Discharging all four subject-reduction obligations would buy the lift from closed-normal consistency to unconditional closed consistency. The lift would have the following shape:

$$\mathsf{HasType}([], t, \mathsf{False}) \wedge \mathsf{Closed}(t) \Rightarrow \mathsf{HasType}([], n, \mathsf{False}) \wedge \mathsf{Closed}(n) \wedge \mathsf{BetaStrong}(n)$$

for a normal endpoint n reached from t. The closed-normal consistency assembly would then eliminate the right-hand side. The discharge would have to traverse the dependent-codomain boundary identified in chapter 9377.

9375.7 Apophatic framing

The partial closure is itself an apophatic name. The substrate names what it has and what it does not have, sharply. The unassembled frontier is not hidden behind a proof hole; it is documented as four named hypotheses and an explicit obstruction theorem.

This is the BEDC discipline applied to its own meta-theory: name the open cells, and do not cover them with an informal appeal to the intended calculus. The reader can see the positive assembled theorem, the blocked subject-reduction node, and the exact reason full closed consistency is not claimed.

Concretized in §733: Closed-normal MetaCIC consistency is realized as a finite boundary packet separating beta-strong consistency from the blocked subject-reduction lift.

9375.8 Boundary

This chapter records the present assembly state, not a proposal for discharging the four obligations. The discharge problem is open and resides at the dependent-codomain frontier identified in chapter 9377.

Concretized in §732: The normal-form false-proof exclusion is exposed as a concrete NameCert packet without claiming full closed consistency.

Concretized in §736: Closed-normal consistency is represented as a finite NameCert boundary separated from the subject-reduction obstruction.

Concretized in §738: Closed-consistency reduction-boundary packets realize the frontier between closed-normal consistency and full closed consistency as finite subject-reduction, normal-endpoint, obstruction, and NameCert rows.

Concretized in §739: Closed-normal consistency packets realize the MetaCIC assembly boundary as finite closedness, typing, beta-strong normality, contradiction, and subject-reduction obstruction rows.

Concretized in §740: The closed-normal consistency assembly is realized as a finite normal-form seal packet with an explicit subject-reduction boundary.

Concretized in §1177: Closed-MetaCIC consistency assembly is realized as a finite composite NameCert packet binding normal-form exclusion, subject-reduction boundary, obstruction, ledger, and local naming rows.

Chapter 9376

Closed-normal consistency: BEDC's first unconditional main result

9376.1 The result

The BEDC project uses the closed-CIC substrate as its internal metatheoretic base. Within that substrate, the strongest presently established unconditional consistency result is closed-normal consistency. If t is a closed term, t has the internal false encoding as its type, and t is beta-strong, then t is impossible:

↪ variant `BEDC.MetaCIC.closed normal consistency assembly`

.

The checked statement has the following shape:

$$\mathsf{HasType}([], t, \mathsf{falseEncoding}) \wedge \mathsf{ClosedAt}(0, t) \wedge \mathsf{BetaStrong}(t) \Rightarrow \bot.$$

The three hypotheses are not interchangeable. The typing row says that the term is displayed at the internal false encoding. The closedness row says that the term is not depending on an external context entry. The beta-strong row says that no beta step can still be taken from the displayed term. The conclusion is contradiction inside the substrate's Lean formalisation.

Equivalently, the substrate has no closed beta-normal proof of its internal false type:

↪ variant `BEDC.MetaCIC.no closed normal proof of false`

. The target is not merely a line in the assembly map of chapter 9375; following the operational priority in chapter 9386, this chapter treats that node as a first-class BEDC main result.

The proposition that full closed consistency would target is separately named:

Lean4 (definition) `BEDC.MetaCIC.no closed proof of false`

. That definition removes the beta-strong input. The distinction between the two statements is the central boundary of this chapter. Closed-normal consistency is checked as a theorem. Full closed consistency is a stronger proposition whose missing transport step is documented elsewhere.

9376.2 Why this is a first-class main result

The result is non-trivial for exactly the reason that full closed consistency is not claimed. It is not a corollary of closed subject reduction. Closed subject reduction is documented as unavailable on the present substrate in chapter 9377. The dependent-codomain obstruction prevents an arbitrary

closed proof term from being transported through beta reduction while preserving the displayed false type.

Closed-normal consistency bypasses that blocked lift. It works directly at the normal-form boundary. Its input already contains beta-strong normality, so the proof does not consume the four subject-reduction discharge hypotheses, does not require dependent-codomain inversion, and does not import a quotient or Church–Rosser theorem to repair the missing transport step.

This is why the result deserves main-result status rather than being treated as a minor helper lemma. It is the largest consistency statement that the present closed-CIC substrate supports without additional setup fields. The theorem touches the object of interest, the internal false encoding, and it eliminates that object under exactly the normal-form hypotheses that the substrate can audit.

The result also has the right failure behaviour. If a reader asks for arbitrary closed consistency, the chapter can point to the missing subject-reduction transport. If a reader asks what is already established without that transport, the chapter can point to a single Lean theorem. The paper therefore has a central positive statement and a central boundary statement, instead of an ambiguous promise that depends on informal CIC intuition.

This makes the theorem an unconditional positive result of the current BEDC.MetaCIC substrate. The substrate cannot yet say that every closed proof of false is impossible. It can say, without any additional logical commitment, that a closed proof already in beta-normal form cannot inhabit false.

9376.3 Constructive content

The result has a concrete audit reading. Given a represented closed term t, the decidability layer supplies the mechanical typing surface described in chapter 9379. In particular, the `inferTypeCtxClosed` interface is sound and complete for empty-context typing at the stated `HasType` relation.

The checker contribution is intentionally only a typing contribution. A successful checker run exposes a type judgement for the represented relation, and the completeness theorem says that represented typing judgements are seen by the checker. This is enough for the first row of the main result. It does not decide every semantic question about the term, and it does not decide the full conversion theory of the substrate.

Given a well-typed closed term t, the normalisation layer supplies candidate-mediated strong normalisation when the relevant candidate evidence is present:

```
↪variant  BEDC.MetaCIC.closed typed term sn from candidate
```

. The audit map in chapter 9383 keeps that evidence visible. It is not erased into a global theorem over every closed typed term.

The normalisation contribution is likewise exact. Candidate evidence gives a strong-normalisation witness. A beta-strong endpoint is already at the normal-form boundary required by the consistency theorem. In the cases where the audit chain supplies candidate evidence and a beta-strong endpoint, the theorem closes the false-inhabitation question at once.

Given a closed beta-strong well-typed term t, the present main result rules out inhabitation of the false encoding. The pipeline is therefore:

1. use the checker layer to expose the empty-context typing judgement;
2. use candidate-mediated normalisation when the candidate witness is part of the audited input;
3. apply the closed-normal consistency theorem at the beta-strong boundary;

4. keep every Lean marker tied to a kernel-checked BEDC.MetaCIC declaration.

This constructive content is deliberately narrow. It is Lean-kernel verified, and the BEDC audit discipline requires it to remain independent of forbidden stdlib logical dependencies. It is also explicit about its inputs: typing, closedness, and beta-strong normality are separate rows, not prose assumptions hidden inside a single word such as consistency.

This separation is important for reproducibility. A consumer can inspect which row is being supplied by a checker theorem, which row is supplied by closedness evidence, which row is supplied by normal-form evidence, and which row is discharged by the consistency theorem. No row is silently converted into another. The proof is therefore useful even when the surrounding metatheory is still being audited, because it tells the reader exactly what data reaches the contradiction.

9376.4 Relation to classical results

Classical CIC consistency is usually read through a three-part route: strong normalisation, Church–Rosser or subject reduction, and a no-false-inhabitant argument for normal forms. That route eliminates arbitrary proof terms by reducing them to a normal endpoint while preserving the relevant type.

BEDC's closed-normal statement is the normal-form version of that route. It contains the no-false-inhabitant endpoint, and it can be paired with the candidate-mediated normalisation facts where their evidence is available. It does not contain the subject-reduction transport from arbitrary closed proofs to typed normal endpoints.

The comparison can be read as a factorisation:

$$\text{arbitrary closed proof} \longrightarrow \text{typed normal endpoint} \longrightarrow \bot.$$

Classical presentations often package the first arrow through subject reduction, confluence, and normalisation. BEDC's theorem establishes the second arrow for the closed beta-strong endpoint. The first arrow is not available unconditionally in the present substrate.

The result is therefore weaker than full classical closed consistency, but it is strictly stronger than having no consistency theorem. The subject-reduction counterexample prevents the paper from elevating arbitrary closed consistency on the current substrate. The closed-normal theorem is the maximal positive consistency claim available without crossing that obstruction.

The word "maximal" is used here only relative to the stated substrate and the stated obstruction. It does not mean that stronger metatheorems are mathematically impossible. It means that the paper has a checked theorem at the normal boundary and a checked reason not to erase the reduction boundary. That is exactly the main-result shape that BEDC can honestly export.

9376.5 What it does not claim

The theorem does not claim full closed consistency:
Lean4(definition) `BEDC.MetaCIC.no closed proof of false`

. That proposition is the stronger statement excluding every closed proof of false, whether or not it is already beta-strong. The present chapter does not mark it as checked.

It does not claim that every closed proof term has a displayed false type preserved along every beta path. Such a statement would be a subject-reduction or typed-normal-endpoint theorem. The current closed-normal theorem starts after that transport problem has already been resolved in the input.

It also does not claim a global theorem that all closed typed terms reduce to normal form without candidate-mediated evidence. The normalisation audit map records checked projections from candidate evidence, closed-candidate evidence, and candidate-set membership. Those projections are central to the positive pipeline, but they are not a blanket closed-term strong-normalisation theorem.

It does not claim unrestricted closed beta-conversion decidability. The bounded normal-equality checker described in chapter 9379 has its own finished-normalisation boundary. That checker is part of the audit surface, not a replacement for the missing closed-consistency transport.

Finally, the result does not solve the dependent-codomain obstruction. The four subject-reduction discharge hypotheses remain exactly where chapter 9377 and chapter 9386 place them. Closed-normal consistency is a main result because it is clean at its boundary, not because it hides the boundary.

These non-claims are not qualifications that weaken the theorem. They are the conditions that make the theorem readable. A full consistency claim would need different hypotheses and different Lean evidence. The closed-normal claim has the evidence it needs and stops there.

9376.6 The role of the BEDC project

BEDC's current mature metatheoretic deliverable is this closed-normal consistency theorem. It is produced by the MetaCIC substrate, the normal-form audit chain, the explicit decidability surface for represented typing, and the apophatic discipline that refuses to blur open obligations into finished proofs.

The project role is therefore not merely documentary. BEDC turns a blocked classical route into a precise theorem plus a precise boundary. The theorem is not an announcement that all conventional consistency infrastructure has been internalised. It is the part of that infrastructure that the present substrate can state, check, and maintain as a public result.

This also gives the surrounding audit chapters a common endpoint. The subject-reduction chapter explains why arbitrary closed consistency is blocked. The normalisation chapter explains what evidence supplies termination. The decidability chapter explains the typing-checker surface. The assembly chapter shows the route. The present chapter names the resulting theorem as a main BEDC deliverable.

The role of chapter 9400 is positive here. By naming the missing subject-reduction lift and the candidate-mediated normalisation boundary, the paper can elevate the unconditional theorem without overstating it. The negative names make room for the positive result: closed-normal consistency is visible precisely because full closed consistency is not silently claimed.

In that sense, closed-normal consistency is the first main result with the right BEDC shape. It is mathematically specific, Lean-linked, substrate-local, and bounded by named non-claims. A reader can cite it without inheriting an unstated subject-reduction promise.

9376.7 Boundary

This chapter elevates no statement through a proof hole. It does not pretend that the subject-reduction obstruction has been discharged. It does not identify normal-form consistency with full closed consistency. It records BEDC's first-class main consistency result at its exact checked strength: closed, typed, beta-strong terms do not inhabit the internal false encoding.

The boundary can be summarised as:

$$\text{closed} + \text{typed at false} + \text{beta-strong} \Rightarrow \bot,$$
$$\text{closed} + \text{typed at false} \not\Rightarrow_{\text{present substrate}} \bot.$$

The first line is the main result of this chapter. The second line is the refused overclaim. Keeping both lines visible is the point of the closed-normal consistency elevation.

Concretized in §764: NameCert surface for the closed-normal consistency main-result boundary.

Concretized in §799: Closed-normal canonicity certificate for the false-endpoint exclusion boundary.

Concretized in §837: Endpoint-ledger NameCert for the closed beta-strong false-exclusion boundary.

Concretized in §858: Closed-normal route certificates realize the main-result normal endpoint as a finite NameCert route through false exclusion, candidate evidence, and subject-reduction obstruction rows.

Concretized in §916: Closed-normal endpoint transport is realized as a finite NameCert packet for source proof rows, beta-route rows, typed normal endpoints, false-type preservation sockets, subject-reduction obstruction, and non-escape ledgers.

Concretized in §936: ZNormal normal-form predicates are realized as finite BHist, hsame, Cont, Pkg, and NameCert rows supporting the closed-normal consistency boundary.

Concretized in §3661: Closed-normal false-exclusion witnesses are realized as finite MetaCIC typing, closedness, beta-strong endpoint, and false-encoding rows.

Concretized in §5780: MetaCIC normal endpoint comparators realize the closed-normal consistency comparator surface as finite closed-endpoint, false-exclusion, determinacy, transport, replay, provenance, and local NameCert rows.

Concretized in §6844: finite consistency-observation budgets are represented as BEDC NameCert rows

Chapter 9377

MetaCIC subject-reduction obstruction: an audit map

9377.1 The setup

The BEDC.MetaCIC formalisation aims at a closed-term consistency theorem for the substrate's internal CIC fragment. The path is the canonical one: subject reduction, strong normalisation on closed terms, and no closed normal proof of False. This chapter records the present audit state of that path, both what is already discharged and what remains as an explicit obligation.

The audit point is narrow. BEDC does not hide the subject-reduction gap behind a silent proof hole. It exposes a parameterised theorem, names the four discharge hypotheses, records the partial closed-term normalisation and closed-normal consistency facts that are already checked, and proves an explicit obstruction theorem for the stronger closed subject-reduction statement in the current substrate.

9377.2 What is already proven

The checked inventory has four parts.

- Closed-term strong normalisation is available through the candidate-mediated closed-term interface. A closed typed term is shown strongly normalising when the corresponding candidate, closed candidate, or candidate-set membership witness is supplied:

  ↪ variant BEDC.MetaCIC.closed typed term sn from candidate

  ↪ variant BEDC.MetaCIC.closed typed term sn from closedCandidate

  ↪ variant BEDC.MetaCIC.closed typed term sn from candidateSet

  .

- No closed-normal proof of False is available for closed terms whose proof term is already beta-strong:

  ↪ variant BEDC.MetaCIC.no closed normal proof of false

  .

- Closed-normal consistency assembly is checked from empty-context typing, closedness, and beta-strong normality:

```
↪ variant BEDC.MetaCIC.closed normal consistency assembly
```

.

- Subject reduction is checked as a parameterised theorem conditional on the four discharge hypotheses:

```
↪ variant BEDC.MetaCIC.subject reduction
```

.

Thus the substrate already closes the normal-form contradiction side and the parameterised preservation theorem. It does not close the unparameterised closed subject-reduction theorem.

9377.3 The four discharge obligations

The four hypotheses are not decorative assumptions. They are the named discharge obligations of the represented reduction system.

Definition 9377.1 (BetaSubstitutionPreservation)**.** BetaSubstitutionPreservation *is the beta-redex obligation. It says that if a body has type cod in the context extended by the shifted domain, and the argument has the unshifted domain type in the original context, then substituting the argument into the body has the substituted codomain type in the original context.*

This is the only obligation consumed by the direct beta case of the parameterised subject-reduction theorem. It is the place where substitution must preserve typing across the binder boundary.

Definition 9377.2 (AppArgTypeStable)**.** AppArgTypeStable *is the application-argument congruence obligation. It says that for a typed function* $f : \Pi dom.\, cod$*, a typed argument* $a : dom$*, and a reduct* $a' : dom$*, substituting* a' *into cod gives the same codomain as substituting* a *into cod.*

This obligation is consumed when reduction steps inside the argument of an application. The function type remains the same, so the target application can be typed at the original displayed result type only if the codomain readback is stable under replacing the argument by its reduct.

Definition 9377.3 (LamDomainSubjectReduction)**.** LamDomainSubjectReduction *is the lambda-domain congruence obligation. It says that if* $\lambda d.\, b$ *has a type* A *in a context* Γ*, and the displayed domain* d *takes one beta step to* d'*, then* $\lambda d'.\, b$ *still has type* A *in the same context.*

This obligation is consumed by the lambda-domain reduction constructor. It is separate because reducing the displayed domain changes the binder annotation while leaving the body and the claimed external type fixed.

Definition 9377.4 (PiDomainSubjectReduction)**.** PiDomainSubjectReduction *is the Pi-domain congruence obligation. It says that if* $\Pi d.\, c$ *has a type* A *in a context* Γ*, and the displayed domain* d *takes one beta step to* d'*, then* $\Pi d'.\, c$ *still has type* A *in the same context.*

This obligation is consumed by the Pi-domain reduction constructor. It is separate because reducing a Pi domain changes the context against which the codomain was originally checked.

9377.4 The explicit obstruction theorem

Principle 9377.5 (Closed subject reduction is documented as not available in the present substrate)**.** *The current substrate proves that the closed subject-reduction statement is not available. The theorem is a checked negation of the closed consistency reduction obstruction proposition, whose content is the closed subject-reduction statement itself:*
Lean4✓ `BEDC.MetaCIC.closed consistency reduction obstruction not available`

The obstruction is not a prose caution. It is a Lean theorem. Consequently the manuscript must not cite a blanket closed subject-reduction theorem for BEDC.MetaCIC. The available preservation theorem is the parameterised theorem, and the unparameterised closed statement is blocked by the checked obstruction.

9377.5 Critical path

Discharging any one of the four obligations does not unblock full subject reduction. All four are needed simultaneously. The four cover the reduction shapes that remain open at the subject-reduction interface:

- the beta step, governed by BetaSubstitutionPreservation;
- congruence into the App argument, governed by AppArgTypeStable;
- congruence into the Lam domain, governed by LamDomainSubjectReduction;
- congruence into the Π domain, governed by PiDomainSubjectReduction.

The parameterised theorem consumes exactly these four inputs. The obstruction theorem says that the project cannot replace that four-input interface by the closed subject-reduction statement in the present substrate.

9377.6 Where this fits in BEDC's apophatic framing

BEDC names the unknown rather than hides it. The four hypotheses, the parameterised subject-reduction theorem, and the explicit no-go obstruction theorem together form an apophatic name for the closed-term subject-reduction discharge problem: the substrate names what it cannot yet prove and audits where the proof would need to land.

This is the same discipline described in chapter 9400 and chapter 9389. An unresolved discharge obligation is not converted into an axiom, a hidden host theorem, or an informal appeal to the intended calculus. It remains a named boundary with a precise interface.

9377.7 The dependent-codomain frontier

The closed application case has a checked positive side. If the function is typed at $\Pi dom.\, cod$, the original argument and its reduct are both typed at dom, the function and original argument are closed, and the codomain itself is closed independently of the argument, then the reduced application keeps the original displayed result type:
Lean4✓ `BEDC.MetaCIC.subject reduction closed app independent codomain`

The dependent side is different. There is a closed function, a closed reducing argument, and a closed application beta step for which the original application has a type A, the reduct exists, and the reduct does not have type A:

Lean4✓ `BEDC.MetaCIC.subject reduction closed app counterexample`

Thus the obstruction is not brute failure of closed application preservation. It is a precise frontier. Closed application subject reduction is discharged in the independent-codomain regime, where substituting the reduct argument into the codomain reads back the same result type. It fails in the dependent-codomain regime when the codomain observes the argument strongly enough for substitution after reduction to change the displayed type.

This frontier places the four discharge obligations on the dependent side of the boundary. AppArgTypeStable must supply the missing codomain-readback stability for argument congruence. BetaSubstitutionPreservation must carry typing through the beta-redex binder. LamDomainSubjectReduction and PiDomainSubjectReduction must preserve the displayed binder annotations when reduction enters domains. Without those inputs, the dependent-codomain counterexample blocks any unconditional closed subject-reduction theorem for the present substrate.

9377.8 Boundary

This chapter does not claim a proof of any of the four hypotheses. It claims only that the audit map is complete at the current interface and that the critical path is sharply identified. The work of discharging the hypotheses is the substrate's outstanding meta-theoretic obligation.

Concretized in §716: Beta-substitution preservation is realized as a finite NameCert packet for the beta-redex typing boundary consumed by the MetaCIC subject-reduction interface.

Concretized in §717: MetaCIC discharge-obligation ledgers realize the four subject-reduction hypotheses and checked obstruction boundary as a finite NameCert audit packet.

Concretized in §718: SubjectReductionDischargeUp realizes the four MetaCIC subject-reduction discharge obligations as a finite NameCert packet with an explicit obstruction boundary.

Concretized in §719: Finite NameCert socket for the four MetaCIC subject-reduction discharge obligations and the checked obstruction boundary.

Concretized in §723: The MetaCIC subject-reduction obstruction is realized as a finite NameCert packet for the parameterized theorem, four discharge obligations, checked obstruction row, and non-escape ledger.

Concretized in §720: Subject-reduction discharge ledgers realize the four MetaCIC preservation obligations as finite BHist, hsame, Cont, Pkg, and NameCert rows consumed by SubjectReductionUp.

Concretized in §712: The four MetaCIC subject-reduction discharge obligations are realized as a finite NameCert packet separating parameterised preservation, obstruction, replay, and non-escape rows.

Concretized in §724: Packages the four MetaCIC subject-reduction discharge obligations as a finite NameCert carrier.

Concretized in §725: The four MetaCIC subject-reduction discharge obligations are represented as a finite NameCert obligation packet.

Concretized in §726: The MetaCIC subject-reduction obstruction is realized as a finite ledger NameCert packet linking the four discharge obligations to subject-reduction and generator-audit rows.

Concretized in §727: BetaSubstitutionDischargeUp isolates the beta-redex discharge row named by the subject-reduction obstruction interface.

Concretized in §729: Subject-reduction obligation ledgers realize the four MetaCIC discharge rows as a finite NameCert packet with obstruction non-escape.

Concretized in §730: Names the four MetaCIC subject-reduction discharge obligations as a finite NameCert frontier.

Concretized in §731: The four-obligation MetaCIC subject-reduction obstruction is realized as a finite NameCert boundary packet.

Concretized in §722: Closed-term context seals realize the MetaCIC subject-reduction obstruction as finite closedness, membership, reduction-handoff, obstruction, and NameCert rows.

Concretized in §6321: The residual-context cut packet realizes the subject-reduction obstruction as finite typed-context, residual, candidate-normalization, and provenance rows.

Concretized in §6474: The dependent-codomain application frontier is realized as a finite NameCert ledger for argument-type stability, discharge compatibility, closed-substitution readback, and non-escape.

Concretized in §6834: The four MetaCIC subject-reduction discharge sockets and checked obstruction are realized as a finite socket-cut NameCert packet.

Concretized in §7096: Beta-substitution preservation frontier packets realize the beta-redex discharge row of the MetaCIC subject-reduction obstruction as finite NameCert data.

Concretized in §7825: Subject-reduction residual-gap packets realize the dependent-codomain obstruction as finite obligation, residual, candidate-normalization, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §6922: The four MetaCIC subject-reduction discharge rows are realized as a finite matrix packet separating beta substitution, application-argument stability, lambda-domain stability, Pi-domain stability, obstruction, replay, provenance, and local naming.

Concretized in §8379: MetaCIC subject-reduction residual fences realize the dependent-codomain obstruction as finite discharge, residual, candidate-normalization, obstruction-retention, transport, replay, provenance, and NameCert rows.

Chapter 9378

MetaCIC Confluence partial-closure audit map

9378.1 The setup

The BEDC.MetaCIC confluence module is split across six sibling files: `AtomJoin`, `AtomShape`, `ClosedGeneral`, `ClosedUnconditional`, `Core`, and `Diamond`. The split is not cosmetic. The files separate raw reduction infrastructure, atom-shape facts, componentwise diamond lemmas, substitution-sensitive diamond assembly, closed-term bridge statements, and the unconditional fragments that are already available for specific closed sources.

Confluence is therefore not presented as a single hidden theorem. The Lean side exposes the exact state: a full parallel diamond follows from a substitution compatibility input, closed multi-step confluence follows from a closed parallel-diamond input, and a smaller set of closed source shapes is discharged without that input.

The operative relations are the multi-step closure BetaStarStep and the Tait–Martin-Löf style parallel relation BetaParallel. The ordinary proof route is also visible in the file structure: prove a diamond for parallel reduction, transport parallel steps into multi-step beta reduction, derive a strip lemma, and then derive Church–Rosser for the star relation. The current substrate has checked much of this route, but the point where parallel beta redexes require residual substitution compatibility remains an explicit input.

9378.2 What is established

The checked inventory has six parts.

- `Diamond.lean` contains the substitution-sensitive assembly. The full parallel diamond is proved from the explicit substitution compatibility proposition, and the unclosed substitution commutation obstruction is named:

  ```
  ↪ variant BEDC.MetaCIC.betaParallel diamond from substitution
  ↪ variant BEDC.MetaCIC.betaParallel app shape diamond from substitution
  ↪ variant BEDC.MetaCIC.substitute commutation unclosed obstruction
  ```

  .

- `ClosedGeneral.lean` turns a closed parallel diamond into closed strip and closed multi-step confluence. It also records the imported unclosed substitution counterexample next to the closed-substitution compatibility interface:

  ```
  ↪ variant BEDC.MetaCIC.betaParallel closed strip from diamond
  ↪ variant BEDC.MetaCIC.betaStarStep confluence general of parallel diamond closed
  ↪ variant BEDC.MetaCIC.betaParallel closed substitution compatibility obstruction
  ```

  .

- `ClosedUnconditional.lean` proves unconditional closed confluence for normal sources and the atom cases that reduce to normality. The theorem family is shape-limited, not a blanket closed confluence theorem:

  ```
  ↪ variant BEDC.MetaCIC.betaParallel diamond closed normal
  ↪ variant BEDC.MetaCIC.betaStarStep confluence closed normal
  ↪ variant BEDC.MetaCIC.betaStarStep confluence closed sort
  ↪ variant BEDC.MetaCIC.betaStarStep confluence closed var impossible
  ```

  .

- `Core.lean` supplies the reduction algebra: multi-step concatenation, parallel-to-star transport, atom diamonds, and componentwise diamonds for application, lambda, and Pi shapes:

  ```
  ↪ variant BEDC.MetaCIC.betaParallel to betaStar
  ↪ variant BEDC.MetaCIC.betaParallel app diamond of components
  ↪ variant BEDC.MetaCIC.betaParallel lam shape diamond
  ↪ variant BEDC.MetaCIC.betaParallel pi shape diamond
  ```

  .

- `AtomShape.lean` proves the case analysis needed to keep atoms and non-lambda applications from silently entering the beta-redex branch:

  ```
  ↪ variant BEDC.MetaCIC.betaStep app cases
  ↪ variant BEDC.MetaCIC.betaStarStep app non lam shape
  ↪ variant BEDC.MetaCIC.betaParallel betaStarStep atom coincide
  ↪ variant BEDC.MetaCIC.betaStar sort join
  ```

  .

- `AtomJoin.lean` exposes the small join and inversion wrappers used by the later confluence files. The atom joins are unconditional, while the application shape result separates congruence targets from beta-redex targets:

  ```
  ↪ variant BEDC.MetaCIC.betaStarStep diamond sort
  ↪ variant BEDC.MetaCIC.betaStarStep diamond var
  ↪ variant BEDC.MetaCIC.betaParallel app target shape
  ↪ variant BEDC.MetaCIC.betaParallel app no beta
  ```

  .

This is a genuine checked layer. The manuscript may cite componentwise diamonds, atom joins, parallel-to-star transport, closed normal confluence, and the conditional bridges from parallel diamond to closed star confluence.

The inventory also fixes what cannot be inferred by proximity. The presence of `BetaParallelDiamondClosed` as a proposition does not itself discharge that proposition. The theorem `betaStarStep_confluence_general_of_p` consumes such a diamond as an input; it is not the diamond. Likewise, the theorem `betaParallel_diamond_from_s` consumes BetaParallelSubstitutionCompatibility; it does not prove that compatibility proposition.

9378.3 What is conditional

The boundary is the substitution input. `Diamond.lean` defines BetaParallelSubstitutionCompatibility and proves full parallel diamond from it. `ClosedGeneral.lean` defines BetaParallelDiamondClosed and proves closed multi-step confluence from that input. These are parameterised results, not closed-source unconditional discharge.

The unconditional part is narrower. Closed normal sources are confluent; sort sources are confluent; closed variable sources are handled through an impossible closedness premise; atom and non-lambda application shape lemmas prevent false beta-redex cases. None of these statements is the full closed Church–Rosser theorem for arbitrary closed terms.

The sharp reading is therefore:

- full parallel diamond is conditional on BetaParallelSubstitutionCompatibility;
- full closed star confluence is conditional on BetaParallelDiamondClosed;
- closed normal, sort, and impossible closed-variable source cases are unconditional;
- application, lambda, Pi, and atom shape lemmas are infrastructure, not final closed confluence claims.

This conditional shape is constructive and useful. If the substitution compatibility input is later supplied inside the same first-principles substrate, the existing bridge theorems already specify how the result flows to the parallel diamond and then to closed star confluence. Until that input is supplied, the bridge remains a bridge from a named premise, not a closure certificate for the endpoint.

9378.4 Comparison with the SR obstruction

The subject-reduction map in chapter 9377 isolates a dependent-codomain obstruction: typing preservation across beta and binder congruence needs four named hypotheses. The confluence map has a different shape. It is not blocked by a displayed codomain that must be retyped after a reduction. It is blocked at the residual-substitution algebra needed to join parallel beta branches.

That difference matters. The confluence side already proves a large amount of syntax-directed reduction geometry without invoking typing. The remaining boundary is the substitution compatibility interface that makes the application beta branch commute with the componentwise join. Thus the confluence obstruction is algebraic over terms, while the subject-reduction obstruction is type-preservation across dependent codomains.

The two maps also differ in their positive fragments. Subject reduction already has a parameterised theorem whose four inputs are typing-specific. Confluence has a parameterised theorem whose central input is substitution compatibility, plus unconditional results for closed normal sources and for atom cases. A reader should therefore not merge the two boundaries into one

generic "MetaCIC gap". They name different interfaces and would be discharged by different proofs.

9378.5 Apophatic framing

This chapter applies the same apophatic discipline as chapter 9377. BEDC names the open cell instead of silently promoting a conditional theorem into an unconditional claim. The audit map is not a confluence proof. It is a paper-side handle for the exact proof state exported by the Lean substrate.

Concretized in §7405: Residual substitution comparison is realized as finite typed-window, local-join, obstruction-retention, bounded-checker, transport, replay, provenance, and NameCert rows.

Concretized in §8595: The residual sector nerve realizes the confluence audit boundary as finite residual-branch, candidate-join, obstruction-retention, transport, replay, provenance, and NameCert rows.

The positive content is still substantial: the module names the missing input, proves the bridges that would consume it, and proves the available closed normal and atom fragments. The negative content is equally binding: a full closed Church–Rosser theorem for arbitrary closed terms is not claimed here.

This is why the chapter belongs in the visions layer rather than in a proof obligations chapter. It does not introduce a new axiom, a new rule of the calculus, or a new proof principle. It gives the paper a stable handle for reading the checked confluence files without inflating a conditional theorem into a public closure claim.

9378.6 Boundary

This chapter does not solve MetaCIC confluence. It records the partial closure state of the confluence files and forbids the manuscript from citing a theorem stronger than the Lean interface supplies. The available claims are the checked component lemmas, the substitution-conditional parallel diamond, the closed-diamond-to-star-confluence bridge, and the unconditional closed normal and atom cases.

In particular, this chapter does not claim BetaParallelSubstitutionCompatibility, does not claim BetaParallelDiamondClosed, and does not claim arbitrary closed-term Church–Rosser for BetaStarStep. Those are the boundary names that must remain visible when the confluence module is cited elsewhere in the manuscript.

Concretized in §737: The checked closed-normal and atom confluence fragments are realized as a finite NameCert packet with conditional-boundary non-escape.

Concretized in §741: Closed-normal confluence is realized as a finite seal packet separating available normal-source joins from the substitution-compatibility boundary.

Concretized in §735: Finite NameCert packet for the confluence audit-map boundary.

Concretized in §743: The conditional confluence audit map is realized as a finite NameCert packet separating checked fragments from named remaining inputs.

Concretized in §744: The conditional parallel-diamond bridge, closed-star handoff, atom fragments, and substitution-compatibility boundary are packaged as a finite NameCert carrier.

Concretized in §745: Finite audit-witness packet for the conditional MetaCIC confluence boundary.

Concretized in §2181: The residual-substitution compatibility boundary is realized as a finite NameCert packet for conditional confluence handoff.

Concretized in §2212: The confluence critical-pair boundary is realized as finite MetaCIC redex-frontier and common-reduct NameCert data.

Concretized in §2325: The closed parallel diamond premise is realized as a finite ledger boundary consumed by the conditional MetaCIC confluence bridge.

Concretized in §2382: MetaCIC frontier critical-pair packets realize the confluence audit-map boundary as finite redex-frontier, local-join, bounded-checker, substitution-boundary, transport, replay, provenance, and NameCert rows.

Concretized in §3595: Local peaks and candidate joins are recorded as finite BEDC confluence witnesses.

Concretized in §3791: The substitution-sensitive conditional confluence boundary is realized as finite typed-window, redex-frontier, substitution-boundary, local-join, obstruction, TasteGate, replay, provenance, and NameCert rows.

Concretized in §3827: The residual checker realizes the substitution-sensitive confluence frontier as finite typed-window, redex-frontier, bounded-checker, local-join, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §3921: The confluence residual envelope realizes the conditional substitution boundary as finite MetaCIC NameCert data.

Concretized in §4082: Local peaks, candidate joins, residual frontiers, substitution boundaries, bounded checks, and obstruction rows are realized as a finite confluence-diamond boundary NameCert packet.

Concretized in §4061: The finite residual-budget and candidate-join rows for the conditional MetaCIC diamond route are realized as NameCert data.

Concretized in §4126: The residual-substitution local-join ledger is realized as finite peak, candidate-join, bounded-checker, obstruction, TasteGate, replay, provenance, and NameCert rows.

Concretized in §4238: The parallel-diamond frontier chapter realizes the confluence audit map's residual-premise, critical-pair, local-join, closed-checker, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §7608: Critical-pair residual streams realize the confluence audit map as finite parallel-diamond frontier, normalization frontier, residual-window, candidate-join, stream-order, failure, transport, replay, provenance, and NameCert rows.

Concretized in §6433: Typed parallel-diamond boundary packets realize the confluence audit map's typed-window, residual-substitution, critical-pair, local-join, checker, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §4370: The residual-substitution compatibility boundary is realized as finite MetaCIC confluence packet data.

Concretized in §5126: The residual local-join packet realizes the confluence audit boundary before the conditional parallel-diamond bridge.

Concretized in §5174: The confluence audit route is realized as finite typed-window, residual-budget, candidate-join, sibling-handoff, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §5970: Residual-join determinacy realizes the confluence audit map's finite residual-substitution boundary as a budgeted local join packet.

Concretized in §6063: The confluence audit boundary is realized as a finite residual-window diamond envelope.

Concretized in §6547: The confluence diamond ledger realizes residual-substitution, local-join, bounded-checker, and obstruction rows as finite NameCert data.

Concretized in §6547: The finite local-diamond ledger realizes the confluence audit-map branch through residual-frontier, candidate-join, bounded-checker, transport, replay, provenance, and NameCert rows.

Concretized in §6663: The closed parallel substitution-budget packet realizes the confluence audit map's named substitution-compatibility boundary as finite NameCert data.

Concretized in §6802: The MetaCIC confluence audit map is realized as a finite inventory packet separating checked fragments from retained conditional confluence premises.

Concretized in §6833: Closed-normal and atom confluence fragments are realized as a finite NameCert packet retaining the substitution-compatibility boundary.

Concretized in §8360: Residual peak schedulers realize the confluence audit boundary as finite local-peak, residual-row, candidate-join, blocked-edge, transport, replay, provenance, and NameCert data.

Concretized in §7114: Closed-normal and atom confluence joins are realized as a finite proof-relevant NameCert packet separated from the full substitution-compatibility boundary.

Concretized in §8262: The confluence-fork certificate realizes the MetaCIC parallel-diamond audit fork as finite source, branch, candidate-join, residual-boundary, and NameCert rows.

Concretized in §8021: Finite residual-join windows realize the conditional MetaCIC confluence boundary as retained premise, local join, obstruction, bounded checker, transport, provenance, and NameCert rows.

Concretized in §7977: The residual-substitution commutation boundary is realized as finite residual-window, substitution-site, candidate-join, conditional-handoff, transport, replay, provenance, and NameCert rows.

Concretized in §7879: Residual-pair lattices realize the confluence audit map as finite local-pair, candidate-join, bounded-checker, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §8317: Critical-pair residual schedulers realize the bounded residual and local diamond route as finite NameCert rows.

Concretized in §7042: A finite residual-pair local-diamond witness packet realizes the confluence audit frontier through displayed candidate-join and substitution rows.

Concretized in §7220: Critical overlap envelopes realize bounded MetaCIC confluence overlap rows as finite NameCert data.

Concretized in §7258: finite residual-join-grid NameCert carrier for the confluence audit route

Concretized in §7291: Residual critical-pair packets realize the confluence audit map as finite residual-substitution, local-join, closed-checker, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §8134: finite residual-join matrix for MetaCIC confluence audit boundaries

Concretized in §7709: Residual critical-pair budgets realize the confluence audit map as finite residual-frontier budget, candidate-join, closed-check, obstruction, TasteGate, transport, replay, provenance, and NameCert rows.

Concretized in §8368: Candidate residual-join budgets realize the confluence audit map as finite typed-window, residual-substitution, budget, candidate-join, guard, obstruction, TasteGate-instance, transport, replay, provenance, and NameCert rows.

Concretized in §7346: The local confluence frontier is realized as finite critical-pair, conditional-join, substitution-premise, obstruction, hsame, Cont, Pkg, and NameCert rows.

Concretized in §7422: Residual candidate selectors realize the bounded residual-confluence frontier as finite candidate, checker, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §7632: Parallel diamond scheduling is realized as finite component-diamond, residual-boundary, atom-join, closed-source guard, and star-confluence handoff rows.

Concretized in §5547: The candidate-normalization handoff realizes the confluence audit map's guarded route from candidate evidence through normalization frontier, residual envelope, decidable-boundary, blocked-edge retention, transport, replay, provenance, and NameCert rows.

Concretized in §7744: MetaCIC extraction-normalization sockets realize the confluence audit boundary as finite extraction, candidate-normalization, residual-substitution, local-join, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §7752: Finite residual confluence windows realize bounded local join evidence as NameCert rows.

Concretized in §7966: Residual confluence fuel packets realize bounded critical-pair and residual-substitution inspection for the MetaCIC confluence boundary.

Concretized in §8111: The residual-diamond frontier is realized as finite critical-pair, residual-substitution, candidate-join, bounded-checker, obstruction, transport, replay, provenance, and NameCert data.

Concretized in §8126: Critical-pair residual matrices realize the MetaCIC confluence audit map as finite typed-redex, residual-row, join-candidate, closedness, substitution, provenance, and NameCert data.

Concretized in §8254: The residual frontier packet realizes the confluence audit map as finite retained-premise, candidate-join, obstruction, and closed-fragment NameCert data.

Concretized in §8275: Proof-trace confluence is realized as finite MetaCIC reduction, residual-substitution, closed-normal, and conditional-diamond NameCert data.

Concretized in §8316: Residual critical-pair sieve packets realize the MetaCIC confluence audit map as finite candidate, residual-window, blocked-edge, decidable-boundary, hsame, Cont, Pkg, and NameCert rows.

Concretized in §8560: The bounded Church-Rosser fragment realizes the confluence audit boundary as finite atom, normal-source, conditional-diamond, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §8739: Residual local-confluence matrices realize the bounded local-join frontier as finite typed-window, residual-pair, checker, obstruction, transport, replay, provenance, and NameCert rows.

Chapter 9379

MetaCIC Decidability partial-closure audit map

9379.1 The setup

The BEDC.MetaCIC decidability submodule records the mechanical checking layer for the internal CIC fragment. It is split across five sibling files: `CheckClosed`, `CheckClosedAtom`, `CheckCompleteness`, `GalleryTests`, and `NormalEqDecide`. The split separates syntax equality, type inference, completeness wrappers, gallery checks, and a bounded normal-equality checker.

The central checker is `inferTypeCtx`. It maps a context and a term to an optional inferred type. Its closed-term wrapper is `inferTypeCtxClosed`. The equality atom is `Term.eq`, a Boolean structural equality on represented terms, with `checkSameTerm` as the option-valued interface used by the typing checker. The normal-equality side uses `normalizeBounded` and `decideClosedBetaConv`; this is a fuel-bounded normal-form comparison, not an unrestricted beta-conversion oracle.

The audit question is therefore precise. The submodule does not assert a single informal statement saying that MetaCIC is decidable. It provides checked Boolean and option procedures, then proves the soundness and completeness properties that are available for those procedures. This chapter maps exactly which part is closed and which part remains conditional on normalisation or on a particular term shape.

9379.2 What is established

The checked inventory has five parts.

- `CheckClosedAtom.lean` gives structural equality for terms. The Boolean equality is reflexive, converts true results into propositional equality, converts propositional equality into true results, and exposes the full iff statement:

  ```
  ↪ variant BEDC.MetaCIC.Term.eq refl
  ↪ variant BEDC.MetaCIC.Term.eq true to eq
  ↪ variant BEDC.MetaCIC.Term.eq eq to true
  ↪ variant BEDC.MetaCIC.Term.eq correct
  ```

  .

- The option-valued same-term checker is also bidirectional. A successful check gives equality, and equality gives a successful check:

  ↪ variant BEDC.MetaCIC.checkSameTerm sound

  ↪ variant BEDC.MetaCIC.checkSameTerm complete

  .

- The first type-inference checker `inferType` is sound and complete for the inductive `HasType` relation, both in arbitrary contexts and in the empty context wrapper:

  ↪ variant BEDC.MetaCIC.inferType sound

  ↪ variant BEDC.MetaCIC.inferType complete

  ↪ variant BEDC.MetaCIC.inferTypeClosed sound

  ↪ variant BEDC.MetaCIC.inferTypeClosed complete

  .

- `CheckClosed.lean` repeats the checker through `inferTypeCtx`, with explicit recognisers for sort and Pi types. The context-indexed and closed wrappers are again sound and complete through `inferTypeCtx_sound`, `inferTypeCtx_complete`, `inferTypeCtxClosed_sound`, and `inferTypeCtxClosed_com`

- `CheckCompleteness.lean` records a shape-organised completeness surface. Its raw, total-exists, and strict exported wrappers are checked, and the direct Pi, lambda, and application cases expose the main compound shapes:

  ↪ variant BEDC.MetaCIC.CheckCompleteness.inferTypeCtx complete pi direct

  ↪ variant BEDC.MetaCIC.CheckCompleteness.inferTypeCtx complete lam direct

  ↪ variant BEDC.MetaCIC.CheckCompleteness.inferTypeCtx complete app direct

  .

This is a strong positive layer. For represented syntax equality, the Boolean procedure is correct. For typing, the option-valued inference procedure is not merely a recogniser for gallery examples; it is proved sound and complete against the inductive `HasType` relation exported by the substrate.

The gallery file supplies executable sanity rows for the closed example surface. Boolean, natural-number, pair, option, list, sum, and polymorphic witnesses all pass the `inferTypeCtx []` non-`none` test:

↪ variant BEDC.MetaCIC.gallery sanity bool witnesses
↪ variant BEDC.MetaCIC.gallery sanity nat witnesses
↪ variant BEDC.MetaCIC.gallery sanity pair witnesses
↪ variant BEDC.MetaCIC.gallery sanity option witnesses
↪ variant BEDC.MetaCIC.gallery sanity list witnesses
↪ variant BEDC.MetaCIC.gallery sanity sum witnesses
↪ variant BEDC.MetaCIC.gallery sanity polymorphic witnesses
↪ variant BEDC.MetaCIC.gallery sanity all typed witnesses

.

The gallery rows are not the source of the general typing theorem. Their role is audit-facing: they show that the same checker surface used in the soundness and completeness theorems also accepts the main Church-encoded example families.

9379.3 Normal equality and bounded beta conversion

`NormalEqDecide.lean` adds a separate equality surface. It defines a bounded normalizer and compares the bounded normal forms with `Term.eq`. The basic structural facts are checked:

```
↪ variant BEDC.MetaCIC.normalizeBounded zero
↪ variant BEDC.MetaCIC.normalizeBounded sort
↪ variant BEDC.MetaCIC.normalizeBounded var
↪ variant BEDC.MetaCIC.normalizeBounded lam succ
↪ variant BEDC.MetaCIC.normalizeBounded pi succ
↪ variant BEDC.MetaCIC.normalizeBounded app succ
```

.

The decision procedure is reflexive at every fuel value, and a true Boolean result implies equality of the two bounded normalizer outputs:

```
↪ variant BEDC.MetaCIC.decideClosedBetaConv refl
↪ variant BEDC.MetaCIC.decideClosedBetaConv true eq normalized
```

.

It also yields beta-convertibility between the bounded normalizer outputs:

```
↪ variant BEDC.MetaCIC.decideClosedBetaConv true betaConv normalized
```

.

The stronger finished-normalisation interface is explicitly conditional. If both terms have closed finished normalisation witnesses at the same fuel, then a true result from `decideClosedBetaConv` gives equality of the named normal forms, beta-convertibility of those normal forms, and preservation of the closed normal-form witnesses:

```
↪ variant BEDC.MetaCIC.decideClosedBetaConv sound finished
↪ variant BEDC.MetaCIC.decideClosedBetaConv sound finished betaConv
↪ variant BEDC.MetaCIC.decideClosedBetaConv sound finished eq
```

.

This file is therefore a bounded normal-equality checker plus a conditional soundness bridge for the case where the fuel is known to finish on closed normal forms. It is not a theorem that arbitrary closed terms have a computed finished normal form at some fuel, and it is not an unrestricted decision procedure for beta conversion over all closed terms.

9379.4 What remains conditional

Three boundaries must remain visible.

- Typing is closed at the checker interface. For the represented `HasType` relation, `inferTypeCtx` has soundness and completeness theorems. The paper may cite this as a checked typing decision surface for the encoded relation.
- Closedness itself is represented by the inductive predicate `ClosedAt`. The decidability submodule consumes closedness in places such as `inferTypeCtxClosed_sound` and `ClosedFinishedNormalizes`; it does not provide a separate theorem named `Decidable (ClosedAt n t)`.
- Beta-conversion equality is conditional on bounded normalisation data. The Boolean checker is proved sound for equality of bounded normalizer outputs and for finished closed normal forms. It is not a global closed-term beta-conversion decider unless the missing normalisation endpoint data is supplied.

The first boundary is positive closure. The second is a naming boundary: the closedness predicate is an inductive relation with many checked preservation facts elsewhere in MetaCIC, but this submodule does not export a dedicated closedness-decision theorem. The third boundary links directly to normalisation: full conversion decidability would require a bridge from typed closed terms to finished bounded normal forms at a specified fuel or to an equivalent fuel-erased normalisation theorem.

9379.5 Comparison with other audit maps

The subject-reduction audit map in chapter 9377 is blocked by dependent-codomain preservation. It names four typing-preservation obligations and records an obstruction to an unconditional closed subject-reduction theorem. The decidability map has a different shape. Typing inference itself is not the obstruction; it is already checked as sound and complete for the encoded `HasType` relation.

The confluence audit map in chapter 9378 is blocked at residual substitution compatibility for joining parallel beta branches. The decidability map uses substitution through typing and normal comparison, but its open edge is not the parallel diamond. Its open edge is the endpoint data needed to promote bounded normal equality into global closed-term conversion decidability.

The normalisation layer is the closest neighbour. The bounded normalizer in `NormalEqDecide` supplies a computable comparison surface. Strong normalisation supplies the kind of endpoint guarantee that would make such a surface public for all typed closed terms. Without that connection, the normal-equality checker remains a bounded and conditionally sound procedure.

Concretized in §749: MetaCIC decidability boundaries are realized as finite checker, bounded-normal comparison, refusal, provenance, and local NameCert rows.

Concretized in §751: The concrete witness packages typing-checker exactness and bounded-conversion non-escape as finite NameCert rows.

Concretized in §752: Bounded normal-equality checkers are realized as finite BHist packets over bounded normalizer output rows, structural Term.eq readback, finished-normalization witnesses, closedness rows, hsame transport, Cont replay, Pkg provenance, and local NameCert rows.

Concretized in §2236: Finite observation folds realize the bounded MetaCIC checker-output packet as finite NameCert data.

Concretized in §3616: The decidable typing frontier is realized as finite checker, structural equality, bounded-normal comparison, refusal, provenance, and local NameCert rows.

Concretized in §3714: Typed normal-form deciders realize the MetaCIC decidability audit map as finite typing-checker, bounded-normal-comparison, finished-normalization, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §3747: The recognizer-to-carrier boundary is realized as a seven-row finite NameCert obstruction packet.

Concretized in §3889: MetaCIC fuel traces realize bounded normalizer fuel, finished-normalization evidence, equality-check rows, refusal rows, transport, replay, provenance, and NameCert data.

Concretized in §3909: The neutral-spine packet realizes MetaCIC decidability as finite typing-checker, same-term, bounded-normal comparison, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §4097: The decidable conversion frontier realizes the bounded normal-conversion boundary as finite checker, normalization-frontier, bridge, seal, obstruction, provenance, and local NameCert rows.

Concretized in §5780: The normal endpoint comparator realizes the bounded-conversion endpoint bridge as finite typed-term, endpoint trace, bridge, frontier, seal, critical-path, provenance, and NameCert rows.

Concretized in §4098: The closedness decision boundary realizes the decidability audit warning as finite audit, bounded-checker, fuel-trace, closed-type-checker, refusal, provenance, and NameCert rows.

Concretized in §5962: Bounded normalisation fuel realizes the MetaCIC decidability endpoint boundary as finite checker, fuel, finished-normal, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §6179: Bounded normalization frontiers realize MetaCIC decidability as finite fuel, finished-normal, bounded-comparison, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §6917: The bounded decidable fragment packages closed checker, bounded normal comparison, endpoint refusal, transport, replay, provenance, and NameCert rows.

Concretized in §6947: Bounded normal-equality frontier packets realize the decidability audit boundary as finite normalizer fuel, closedness, finished-normal-form, equality-checker, transport, replay, provenance, and NameCert rows.

Concretized in §8057: The bounded normal-equality budget realizes normalizeBounded and decideClosedBetaConv as finite fuel, endpoint, comparison, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §8400: Bounded conversion frontiers realize the decidability audit map as finite checker, normalization-endpoint, comparison, refusal, transport, replay, provenance, and NameCert rows.

Thus the three maps should not be read as one generic MetaCIC deficit. Subject reduction needs preservation across dependent typing, confluence needs substitution compatibility for joins, and decidability needs the exact bridge from bounded computation to finished normal forms when beta conversion is the target. The typing-checker part of decidability is already closed; the conversion-checker part is intentionally narrower.

9379.6 Apophatic framing

The apophatic discipline is the same as in the subject-reduction and confluence chapters. BEDC names what the checker proves and refuses to let a Boolean procedure become a stronger theorem by prose. A successful `inferTypeCtx` result carries a checked `HasType` witness by soundness. A `HasType` witness is accepted by the checker by completeness. A successful bounded beta-conversion result carries only the bounded-normal equality and the finished-normalisation consequences stated by the corresponding theorems.

This is why the word "decidable" has to be read at the level of the exported theorem. For syntax equality and typing inference, the checked theorems give a closed decision surface. For closedness and global beta conversion, this chapter records the absence of a named theorem at that strength in the decidability submodule. The absence is not repaired by gallery success or by the existence of a bounded normalizer.

9379.7 Boundary

This chapter records the partial closure state of the MetaCIC decidability files. It may be cited for structural term equality, same-term checking, typing-inference soundness and completeness, the shape-organised completeness wrappers, gallery acceptance rows, and the bounded normal-equality soundness facts listed above.

It does not claim a theorem named `Decidable (ClosedAt n t)`. It does not claim an unrestricted closed-term beta-conversion decider. It does not claim that `decideClosedBetaConv` is complete for beta conversion at arbitrary fuel. Those stronger readings require explicit Lean targets before they can enter the paper as closure claims.

Concretized in §746: MetaCIC decidability is realized as a finite audit packet separating checked typing inference from bounded conversion soundness.

Concretized in §748: Bounded beta comparison is realized as a finite checker packet with an explicit finished-normalisation boundary.

Concretized in §747: The checker seal packages typing, same-term, and bounded normal-equality rows as a finite NameCert surface.

Concretized in §5949: Bounded typechecking budgets realize the MetaCIC decidability audit map as finite checker rows with refusal boundaries.

Concretized in §6412: Candidate decidability traces realize finite MetaCIC local-checker schedules, rejection ledgers, and SN/confluence handoff rows.

Concretized in §8083: MetaCIC decidable typechecking handoffs realize the inferTypeCtx soundness-completeness row and the bounded normal-equality boundary as one finite NameCert packet.

Concretized in §8104: Type-check trace deciders realize the MetaCIC decidability audit map as finite checker, same-term, bounded-normal comparison, refusal, transport, replay, provenance, and NameCert rows.

Chapter 9380

MetaCIC Substitution module audit map

9380.1 The setup

The BEDC.MetaCIC substitution submodule is the syntax layer that supports movement across binders. It is split across five sibling files: `Basic`, `ClosedComposition`, `Core`, `NatShift`, and `Statements`. The split exposes a useful audit shape. Arithmetic facts about de Bruijn indices are kept separate from raw substitution facts, closedness facts, and higher substitution statements.

The operations are `shift` and `substitute`. The first raises free indices at or above a cutoff. The second replaces the variable at a depth and adjusts indices around the removed binder. Both are ordinary recursive operations on the closed `Term` generator. The audit question is therefore not whether the operations exist, but which classifier boundary they preserve and under which hypotheses.

The current closure state is exact. Closedness at a boundary makes both operations inert at that boundary. Closed source and closed payload hypotheses also support a small family of closed composition laws. The module also names larger target shapes for shift–substitute and substitute–substitute interaction, while the closed composition file provides the checked fragment that is available without a general unclosed commutation theorem.

9380.2 Core operations

9380.2.1 `shift_closed`

The boundary theorem for shift is

↪ variant `BEDC.MetaCIC.shift closed`

. It says that if a term is closed at cutoff n, then shifting at n by one leaves the term unchanged:

$$\mathsf{ClosedAt}(n, t) \Rightarrow \mathsf{shift}(n, 1, t) = t.$$

This is a classifier-preservation fact in its strongest local form. The term has no free index reaching the cutoff, so the shift branch has no occurrence to act on. The binder cases are not hidden semantic assumptions; they are the recursive cases of the `ClosedAt` witness, where the boundary advances under lambda and Pi.

The theorem is intentionally narrow. It does not state that arbitrary shifting preserves every typing or reduction property. It states only that a term already closed below the cutoff is syntactically fixed by the shift attempted at that cutoff.

9380.2.2 `substitute_closed`

The matching boundary theorem for substitution is

↪variant `BEDC.MetaCIC.substitute closed`

. It says that if a term is closed at depth d, then substituting any payload at d leaves the term unchanged:

$$\mathsf{ClosedAt}(d, t) \Rightarrow \mathsf{substitute}(d, v, t) = t.$$

The payload v is arbitrary because the replacement site is absent. For every variable index visible in t, the closedness witness supplies the inequality placing that index below d. Hence the equality branch does not fire, and the decrement branch does not fire. The recursive cases carry the same argument through application, lambda, Pi, and sort.

This is the main closed-substitution closure law used by the paper side. It is not a beta-substitution typing theorem. It is a syntactic boundary theorem: substitution at a boundary cannot alter a term whose free-variable budget is already below that boundary.

9380.2.3 Closed composition

The closed composition file supplies the checked fragment of substitution composition that is available under closed payload and closed source hypotheses. The central theorem is

↪variant `BEDC.MetaCIC.substitute compose closed both`

. It specialises the depth-indexed theorem

↪variant `BEDC.MetaCIC.substitute compose closed both at depth`

to depth 0:

$$\begin{aligned}&\mathsf{ClosedAt}(0, v) \wedge \mathsf{ClosedAt}(0, u) \wedge \mathsf{ClosedAt}(1, t)\\ &\Rightarrow \mathsf{substitute}(0, v, \mathsf{substitute}(0, u, t)) = \mathsf{substitute}(0, \mathsf{substitute}(0, v, u), t).\end{aligned}$$

The same file also records a closed swap law

↪variant `BEDC.MetaCIC.substitute swap closed`

and a shift-after- substitution bridge

↪variant `BEDC.MetaCIC.substitute after shift one closed`

. These are closed-fragment algebra, not unrestricted substitution calculus.

The audit distinction matters. `Statements.lean` names broad target shapes, including

Lean4 (definition) `BEDC.MetaCIC.ShiftSubstituteStatement`

and

Lean4 (definition) `BEDC.MetaCIC.SubstituteSubstituteStatement`

. The checked composition theorems above are the current closed slice of that algebra. The manuscript may cite the closed slice, but it must not cite an unrestricted substitute–substitute commutation theorem unless such a theorem exists under the same Lean namespace.

Concretized in §6103: The closed substitution, shift, and composition audit surface is realized as finite NameCert spine data.

9380.3 Connection to subject reduction

Substitution is one of the necessary ingredients for MetaCIC subject reduction. The subject-reduction obstruction map in chapter 9377 isolates the beta-redex obligation as BetaSubstitutionPreservation: typing must survive when an argument is substituted into a binder body and the codomain is read back through the same substitution.

The substitution module audited here is lower-level. It proves syntactic closedness and closed composition facts about `Term`. Those facts are necessary for a disciplined beta case, but they are not the whole beta typing obligation. The typing obligation also mentions context lookup, body typing, argument typing, codomain substitution, and the dependent type assigned after the beta step.

Thus the connection is a handoff, not an identification. The substitution module supplies the syntax-side closure laws that any subject-reduction discharge must respect. The subject-reduction boundary remains the four-input interface described in chapter 9377. Closing syntactic substitution does not by itself close dependent typing preservation.

9380.4 Connection to GeneratorClosureClassifier

The same closure state has a certificate-theoretic reading. In Definition 9389.7, a generator-closure classifier records that a generator action preserves a classifier. The concrete MetaCIC instances are

```
↪variant BEDC.MetaCIC.closed under shift classifier
```

and

```
↪variant BEDC.MetaCIC.closed under substitute classifier
```

.

These two instances read the `shift` and `substitute` operations as authorized generators over the closed-term carrier. Their classifier is `ClosedAt` at the relevant boundary. The closure field says that when the operation is applied inside the admitted slice, the result stays inside that slice.

The algebra of Definition 9389.8 then explains why these local facts compose with the wider BEDC audit machinery. Identity, sequential composition, alternation, sub-generator restriction, and finite iteration preserve classifier closure once the corresponding local classifier witnesses are present. The substitution module provides concrete local witnesses for two important MetaCIC generators; the algebra explains how such witnesses can be routed through larger certificate networks without changing their scope.

9380.5 Apophatic framing

This chapter names a positive closure layer without turning it into a larger claim. BEDC can say exactly what the substitution module supplies: boundary inertness for shift and substitution, closed-source composition fragments, and classifier instances for the two generator actions. It also says what the module does not supply: unrestricted substitution commutation, closed subject reduction, or a hidden semantic equality principle for terms.

The apophatic point is methodological. The manuscript must not fill a missing dependent-typing bridge by appealing to the existence of syntactic substitution lemmas. The available lemmas are real, checked, and useful, but their scope is the closed syntactic layer.

9380.6 Boundary

This chapter records the present closure state of `BEDC.MetaCIC.Substitution`. It may be used to cite the checked boundary theorems `shift_closed` and `substitute_closed`, the closed composition theorems in `ClosedComposition.lean`, the named statement shapes in `Statements.lean`, and the concrete GeneratorClosureClassifier instances for shift and substitution.

It does not claim an unrestricted substitution calculus. It does not claim that BetaSubstitutionPreservation is discharged. It does not claim the full closed subject-reduction theorem excluded by chapter 9377. The substitution closure state is a necessary building block for those routes, not their endpoint.

Concretized in §??: Substitution audit rows are realized as a finite NameCert packet for closed syntax movement and subject-reduction handoff boundaries.

Concretized in §779: The closed substitution audit map is realized as a finite NameCert packet over ClosedAt, shift, substitute, closed-composition, and generator-closure rows.

Concretized in §824: Substitution audit window routes realize the closed shift, substitute, composition, generator-closure, and subject-reduction handoff rows as a finite NameCert packet.

Concretized in §840: Context-indexed substitution audit rows are realized as a finite NameCert packet over closed-boundary, binder-seal, beta-preservation, and typed-normal-form handoff surfaces.

Concretized in §910: Substitution generator-audit packets realize closed shift, closed substitution, closed composition, and generator-route replay as a finite NameCert carrier.

Concretized in §1102: The substitution audit map is realized by a finite NameCert carrier for closed shift and substitution audit routes.

Concretized in §6990: Closed shift, substitution, composition, and binder-seal audit rows are realized as finite NameCert spine data.

Concretized in §??: The MetaCIC substitution audit packet realizes the closed movement, generator-closure, and subject-reduction handoff boundary as finite NameCert rows.

Concretized in §7519: Typed substitution windows realize the MetaCIC substitution audit boundary as finite typed-context, closedness, substitution, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §7856: The residual-substitution spine realizes the closed substitution audit boundary as finite residual-window, binder-seal, obstruction, transport, replay, provenance, and NameCert rows.

Chapter 9381

MetaCIC ClosurePreservation module audit map

9381.1 The setup

`ClosurePreservation.lean` is a single-file module inside `BEDC.MetaCIC`. It records the closedness-preservation layer for the core syntax operations that later appear in beta reduction and its finite closures. The file is deliberately narrower than subject reduction: its classifier is `ClosedAt`, not `HasType`.

The public surface is a five-theorem chain. It starts with shift at one successor depth, passes through variable substitution and full term substitution at an arbitrary closedness boundary, and then lifts the result to one-step beta reduction and finite beta-step chains. Each theorem is an ordinary structural fact about MetaCIC terms and the closedness predicate.

This gives a useful contrast with the subject-reduction obstruction in chapter 9377. Closure preservation is available without extra typing hypotheses because no dependent codomain is being transported. Subject reduction is blocked at the typing layer, where application arguments, binder domains, and beta substitution must preserve displayed types.

9381.2 Established theorems

9381.2.1 `shift_one_preserves_closed_succ`

The shift theorem is

```
↪variant  BEDC.MetaCIC.shift one preserves closed succ
```

. It says that shifting by one at depth n preserves closedness at the successor boundary. In schematic form:

$$\mathsf{ClosedAt}(n, t) \Rightarrow \mathsf{ClosedAt}(n + 1, \mathsf{shift}(n, 1, t)).$$

The theorem is the local shift witness needed by substitution and beta closure. Under binders, the closedness boundary advances in the same way as the term recursion. The proof obligation is therefore structural: every free index that was already below the source boundary remains below the target boundary after the one-step lift.

9381.2.2 substitute_var_preserves_closed_at

The variable-level substitution theorem is

↪variant BEDC.MetaCIC.substitute var preserves closed at

. It is the pointwise closedness fact for the variable branch of substitution. The theorem separates the arithmetic cases that full substitution later uses: the replaced variable, indices below the replacement depth, and indices above the replacement depth.

This theorem is not a typing statement. It does not assign a type to a replacement payload and does not read back a substituted codomain. It only says that the variable operation used by substitution respects the relevant closedness boundary when its closedness inputs are present.

9381.2.3 substitute_preserves_closed_at

The full substitution theorem is

↪variant BEDC.MetaCIC.substitute preserves closed at

. It lifts the variable theorem through the full `Term` recursion. In schematic form:

$$\mathsf{ClosedAt}(n+1,t) \wedge \mathsf{ClosedAt}(n,v) \Rightarrow \mathsf{ClosedAt}(n,\mathsf{substitute}(n,v,t)).$$

The displayed form records the usual binder budget: the substituted term is closed one level deeper, and the payload is closed at the receiving boundary. After substitution removes the selected variable, the result is closed at the receiving boundary.

This is the main closure-preservation lemma for syntactic substitution. It is strong enough to support beta-redex closure, because beta contraction is implemented by `substitute`. It is not strong enough to give beta subject reduction, because subject reduction also requires the type assigned to the contractum to be the substituted codomain.

9381.2.4 betaStep_preserves_closed

The one-step beta theorem is

↪variant BEDC.MetaCIC.betaStep preserves closed

. It states that a single beta step preserves `ClosedAt` at any depth:

$$\mathsf{BetaStep}(t,t') \wedge \mathsf{ClosedAt}(n,t) \Rightarrow \mathsf{ClosedAt}(n,t').$$

The beta-redex constructor uses `substitute_preserves_closed_at`. The congruence constructors use the corresponding recursive closedness components for applications, lambdas, and Pi types. No typing context is inspected, and no conversion rule is introduced.

This theorem is a genuine building block for any typed route through beta reduction. It guarantees that beta movement does not leave the closed-term slice. Its scope stops exactly there: preserving the closedness classifier is not preserving the `HasType` relation.

9381.2.5 betaStarStep_preserves_closed

The finite beta-chain theorem is

↪variant BEDC.MetaCIC.betaStarStep preserves closed

. It lifts one-step closedness preservation from `BetaStep` to `BetaStarStep`. In schematic form:

$$\mathsf{BetaStarStep}(t,t') \wedge \mathsf{ClosedAt}(n,t) \Rightarrow \mathsf{ClosedAt}(n,t').$$

The theorem is the finite-iteration closure fact for beta reduction. A zero-step chain is immediate, and a nonzero chain composes the one-step theorem with the induction hypothesis for the remaining chain.

This is the exact closure fact consumed by closed-normal and conversion-facing arguments: a closed term remains closed along any finite beta path. It does not say that the term remains typed, normalizing, confluent, or convertible under an unrestricted typing rule.

9381.3 Why ClosurePreservation is unconditional while SR is not

The distinction is the classifier. ClosurePreservation works over `ClosedAt`, a structural predicate on the syntax tree. The proof cases follow the constructors of terms, beta steps, and finite beta chains. When the operation descends under a binder, the closedness index advances. When beta contracts a redex, the substitution theorem supplies the closedness budget for the body and argument.

Subject reduction works over `HasType`. Its input is not just a term but a typing derivation in a context with a displayed type. The dependent-codomain cases record information that closedness cannot see. Reducing an argument can change the codomain read through that argument. Reducing a displayed binder domain can change the type annotation that a typing derivation depends on. Contracting a beta redex requires the body type and codomain to be transported through substitution.

Therefore the closure layer is unconditional, while the subject-reduction layer remains conditional at the interface named in chapter 9377. The two statements do not compete. They live over different classifiers.

9381.4 Role within MetaCIC

ClosurePreservation supplies the closed-term invariant used around subject reduction, confluence, normalization, beta conversion, and closed consistency. It says that the syntax operations used by beta reduction do not escape the closed slice once their inputs are closed at the required boundary.

For subject-reduction routes, this removes one possible source of failure. A typed proof term that is already closed does not become open merely because a beta step or a finite beta path is taken. The remaining obstruction is not free-variable escape. It is the dependent typing transport described by the subject-reduction map.

For confluence and normalization routes, the same invariant lets the paper keep closed-term hypotheses stable while it discusses common reducts, normal forms, and beta-strong fragments. A finite beta path may be followed without rechecking the closedness boundary from scratch at each endpoint.

9381.5 Connection to GeneratorClosureClassifier

The substitution and shift theorems instantiate the generator-closure reading of Definition 9389.7. A generator is authorized only relative to a classifier, and its closure field records that admitted inputs remain inside the classifier after the generator acts.

For MetaCIC closedness, the relevant classifier is `ClosedAt`. The concrete generator witnesses are `closed_under_shift_classifier` and `closed_under_substitute_classifier`. The shift

and substitution preservation theorems are exactly the local facts that make those witnesses meaningful.

Beta preservation then reads as a composed generator story. The beta redex case uses substitution, the congruence cases recurse through term constructors, and the beta-star theorem applies finite iteration. The classifier stays closed under those authorized moves, but the classifier is still closedness rather than typing.

9381.6 Boundary

This chapter records the closure state of `BEDC.MetaCIC.ClosurePreservation`. It may be used to cite the five checked preservation theorems named above and the concrete GeneratorClosureClassifier witnesses for shift and substitution.

It does not claim that closure preservation implies typing preservation. It does not claim that `betaStarStep_preserves_closed` implies typed subject reduction for closed terms. It does not supply a conversion rule for typing or a discharge of the dependent-codomain, binder-domain, or beta substitution obligations isolated in chapter 9377.

Concretized in §786: Closure-preservation audit witnesses are realized as finite BEDC NameCert packets for the MetaCIC ClosedAt theorem chain.

Concretized in §791: Closure preservation is realized as a finite audit packet for closedness-preserving shift, substitution, beta-step, and beta-star routes.

Concretized in §792: The concrete audit trace records the closedness-preservation theorem chain as a finite NameCert packet.

Concretized in §794: ClosurePreservation traces realize the unconditional ClosedAt-preservation chain as finite BHist, hsame, Cont, Pkg, and NameCert rows.

Concretized in §795: MetaCIC closure-preservation audit traces are realized as finite BHist, generator-closure, kernel-acceptance, hsame, Cont, Pkg, and NameCert rows.

Concretized in §788: Finite NameCert packet for the ClosurePreservation theorem chain.

Concretized in §797: The closed beta path packet realizes the closure-preservation audit map as a finite NameCert route object.

Concretized in §800: Closure-preservation theorem rows are realized as a finite NameCert audit seal for shift, substitution, beta-step, and beta-star closedness routes.

Concretized in §801: Closure-preservation classifier packets realize the MetaCIC ClosedAt generator-closure audit as a concrete NameCert surface.

Concretized in §802: finite ClosurePreservation audit packet

Concretized in §803: ClosurePreservation is realized as a finite audit packet over shift, substitution, beta-step, beta-star, closedness, transport, route, provenance, and NameCert rows.

Concretized in §804: The dependent-codomain closure-preservation packet records the finite transport boundary consumed by subject-reduction routes.

Concretized in §805: Closure-preservation route ledgers realize the MetaCIC closedness-preservation chain as finite BHist, hsame, Cont, Pkg, and NameCert rows.

Concretized in §6692: Closed beta trace envelopes realize the ClosurePreservation audit map as finite beta-chain, substitution, and ClosedAt replay data.

Concretized in §6876: Finite beta-chain closedness iteration realizes the BetaStarStep closedness route as a finite NameCert packet without subject-reduction or confluence claims.

Chapter 9382

MetaCIC TypedExamples module audit map

9382.1 The setup

The BEDC.MetaCIC `TypedExamples` submodule is a worked-example gallery for the internal CIC fragment. Its files collect Church encodings, dependent identity terms, polymorphic identity terms, application forms, beta redexes, projection forms, Pi forms, constants, and sort-indexed context examples.

This chapter reads the gallery as an audit surface. Unlike the subject reduction, confluence, normalisation, substitution, and decidability audit maps, the submodule is not primarily a metatheory module. It does not provide the general proof that typing is preserved by every beta step or that every closed typed term normalises. It supplies concrete typed terms whose elaboration and typing witnesses exercise the substrate on representative programs.

The closure state is therefore gallery-level. Each cited target says that a particular encoded term has the displayed type, closedness witness, beta computation, or checker acceptance result. The collection is useful precisely because the terms are ordinary objects of the represented syntax rather than external examples.

9382.2 Inventory

The module has four broad strata.

- `ChurchGallery.lean` and the `ChurchGallery/` directory provide the base Church encodings for booleans, natural numbers, pairs, and options. They expose the shared terms `churchBoolTy`, `churchTrueTm`, `churchFalseTm`, `churchNatTy`, `churchZeroTm`, `churchOneTm`, and `churchSuccTm`, plus typed constructors and eliminators for pair and option witnesses.
- The sibling files `ChurchBoolLogic`, `ChurchNatRec`, `ChurchNatArith`, `ChurchNatPred`, `ChurchEquality`, `ChurchList`, and `ChurchSum` extend the gallery with boolean connectives, arithmetic operations, predecessor-style examples, Leibniz equality encodings, Church lists, and Church sums.
- `Identity.lean` and `Polymorphic.lean` contain identity, dependent identity, polymorphic identity, constant, apply, flip, and compose forms. These examples check binder discipline and universe-like sort movement inside the represented calculus.

- `AppForms.lean`, `Applications.lean`, `ApplicationTail.lean`, `BasicApplications.lean`, `BetaRedex.lean`, `ConstForms.lean`, `PiForms.lean`, `Projections.lean`, and `Sorts.lean` cover application, beta-redex, constant, Pi, projection, and context lookup shapes.

This inventory is intentionally heterogeneous. Some files demonstrate direct `HasType` derivations. Some use `inferTypeCtx_sound` to turn a checker result into a typing witness. Some record beta computation rows or closedness rows that make later examples admissible. Together they form a ground-truth set for the represented syntax.

The file-level audit reading is similarly explicit.

- The gallery root imports the base boolean, natural-number, pair, and option files and gives shared names to the recurring Church terms. Those shared names are the vocabulary consumed by the later arithmetic, equality, and list files.
- `BoolNat.lean` is the smallest Church-encoding source. It proves the boolean and natural-number type formers, their constructors, and small identity and constant examples.
- `Pair.lean` and `Option.lean` add product-like and maybe-like data. Their role is not merely to add more examples, but to force the checker through multi-argument constructors and eliminator-style terms.
- `ChurchBoolLogic.lean` and the arithmetic files move from typing rows to computation rows. They record how boolean connectives and natural number operations reduce on selected inputs under the closedness hypotheses displayed in the theorem statements.
- `ChurchEquality.lean` is the dependent proof-object branch. It checks Leibniz equality types, reflexivity proofs, closedness rows, and normal-equality checker rows for selected equality examples.
- `ChurchList.lean` and `ChurchSum.lean` are the larger binder-stress files. They combine nested type formers, constructors, eliminators, closedness support, and computation rows for folds and case analysis.
- The non-Church files remain important because they isolate syntax forms without the surrounding encoding burden. They are the local probes for sort contexts, Pi formation, projection behavior, constants, ordinary applications, application tails, and beta redexes.

Thus the inventory should not be read as a flat list of examples. It is a layered gallery: atoms and binders first, then identity and application patterns, then Church data, then eliminators and computation rows over that data. The order matters for audit use because a later failure in a Church file can often be compared against the smaller non-Church probes to locate whether the issue is basic typing, binder shifting, eliminator typing, or beta computation.

9382.3 Representative theorems

The base Church boolean and Church natural-number rows are the smallest public examples. The boolean type and constructors are typed in the empty context:

```
↪ variant  BEDC.MetaCIC.church bool type
↪ variant  BEDC.MetaCIC.church true
↪ variant  BEDC.MetaCIC.church false
```

. The natural-number encoding and its first constructors are likewise typed:

```
↪ variant  BEDC.MetaCIC.church nat type
```

```
↪ variant BEDC.MetaCIC.church zero
↪ variant BEDC.MetaCIC.church one
↪ variant BEDC.MetaCIC.church succ
```

. These targets establish that the gallery's basic numerals and booleans are not paper-only conventions; they are terms accepted by the encoded typing relation.

The list gallery checks a type former, constructors, and a fold operator:

```
↪ variant BEDC.MetaCIC.church list type typed
↪ variant BEDC.MetaCIC.church nil typed
↪ variant BEDC.MetaCIC.church cons typed
↪ variant BEDC.MetaCIC.church fold typed
```

. This group exercises nested Pi structure, shifted element types, and eliminator typing. It is a compact stress test for binder indices because the encoded list type moves an element type through several binders.

The sum gallery records the either type, both injections, and case analysis:

```
↪ variant BEDC.MetaCIC.church either type typed
↪ variant BEDC.MetaCIC.church inl typed
↪ variant BEDC.MetaCIC.church inr typed
↪ variant BEDC.MetaCIC.church case either typed
```

. The accompanying beta rows, such as

```
↪ variant BEDC.MetaCIC.church case inl
↪ variant BEDC.MetaCIC.church case inr
```

, show that the eliminator computes on both injection branches under the displayed closedness inputs.

The equality gallery uses a Leibniz-style encoding:

```
↪ variant BEDC.MetaCIC.leibniz eq type
↪ variant BEDC.MetaCIC.leibniz refl type
↪ variant BEDC.MetaCIC.refl zero proof
↪ variant BEDC.MetaCIC.refl true proof
```

. These rows show a dependent proof object, not merely first-order data. They are useful witnesses that the same typed-example layer includes proposition-shaped programs.

The dependent and polymorphic identity examples give a separate binder-focused surface:

```
↪ variant BEDC.MetaCIC.lam dependent identity
↪ variant BEDC.MetaCIC.polymorphic identity
↪ variant BEDC.MetaCIC.poly identity type
↪ variant BEDC.MetaCIC.poly identity at sort type
```

. They test the common identity pattern in both direct dependent and explicitly polymorphic forms.

The application and beta-redex files make the gallery operational rather than only declarative:

```
↪ variant BEDC.MetaCIC.app id sort in empty ctx
↪ variant BEDC.MetaCIC.dep id applied to arg in sort ctx
↪ variant BEDC.MetaCIC.id sort redex
↪ variant BEDC.MetaCIC.id sort redex typed
```

. These examples connect the typing gallery to the beta relation used elsewhere in MetaCIC.

9382.4 Role within MetaCIC

The submodule functions as the typing relation's ground-truth gallery. A change to the typing implementation, closedness infrastructure, substitution helpers, or beta evaluator should preserve these examples unless the represented calculus itself has changed. In that sense the gallery is a regression surface for concrete syntax, binder shifting, context lookup, application typing, and closed Church-encoded programs.

The gallery also keeps the manuscript honest about examples. When the paper mentions Church booleans, naturals, lists, sums, equality, or identity programs inside MetaCIC, the cited rows above are the Lean-side witnesses that the terms exist with the stated typing or computation behavior.

9382.5 Connection to other audit maps

The closest neighbour is the decidability map in chapter 9379. Its `GalleryTests` layer checks that the type inference surface accepts the main closed example families. The present chapter records the worked examples themselves. The two layers should be read together: `TypedExamples` supplies the concrete programs, while the decidability gallery checks the option-valued inference interface on those program families.

The subject-reduction map in chapter 9377 has a different role. TypedExample terms that take beta steps should preserve typing along the expected route, but the audit map cannot promote that expectation into an unconditional subject-reduction theorem. The SR chapter names the preservation obligations that would be needed for that stronger claim.

The normalisation and confluence maps are also adjacent but not identical. The Church examples include concrete beta computations and some normalisation-style rows. They are witnesses that the reduction machinery runs on selected terms, not a proof of arbitrary closed-term normalisation or arbitrary closed-term Church–Rosser.

9382.6 Boundary

This chapter is an audit map for a worked-example collection. It may be cited for the displayed typed Church encodings, dependent identity examples, polymorphic identity examples, application examples, beta-redex rows, and selected computation rows.

It does not prove subject reduction, strong normalisation, confluence, or global conversion decidability. It does not claim that every Church-style encoding has all expected algebraic laws inside MetaCIC. It records the examples whose Lean targets are present and keeps their role at gallery level.

Concretized in §775: TypedExamples gallery rows are represented as a finite NameCert regression surface.

Concretized in §756: Typed example gallery rows are packaged as a finite NameCert carrier with checker, closedness, beta, and regression-surface obligations.

Concretized in §753: TypedExamples gallery rows are realized as a finite worked-example seal.

Concretized in §880: Typed example audit budgets realize the TypedExamples audit map as finite regression-spend NameCert rows.

Concretized in §922: Application-form examples are realized as finite typed-application route packets.

Concretized in §923: Typed example coverage matrices realize gallery, checker, beta, and regression-spend coverage as finite NameCert rows.

Concretized in §924: Church eliminator regression matrices realize bool, nat, list, and sum eliminator gallery rows as one finite checker and beta-regression NameCert packet.

Concretized in §2330: Typed-example reduction traces are realized as finite MetaCIC NameCert rows linking typed term, reduction step, checker result, closedness, transport, replay, and provenance.

Concretized in §6175: Typed gallery context probes realize sort contexts, binder shapes, applications, beta redexes, and Church examples as finite NameCert rows.

Concretized in §8235: Typed equality eliminator packets realize the Leibniz equality gallery as finite checker, closedness, reduction, transport, replay, provenance, and NameCert rows.

Chapter 9383

MetaCIC Normalization partial-closure audit map

9383.1 The setup

BEDC.MetaCIC's normalisation submodule is laid out across four sibling files: `AppAdequacy`, `ClosedSN`, `PiAdequacy`, and `Reducibility`. Together they aim at strong normalisation on closed terms via the candidate-mediated reducibility path.

The operative endpoint is StrongNormalizable(t). The module does not present that endpoint as a hidden global oracle. It exposes a reducibility candidate layer, a closed-candidate layer, candidate-set wrappers, Pi and application adequacy lemmas, and closed typed term projections from those witnesses.

This chapter records the exact reading discipline for that interface. The normalisation files contain many checked termination facts, but the public closed-term route is candidate-mediated. A manuscript citation must therefore name the supplied candidate evidence, closed candidate evidence, or candidate-set membership evidence; it must not silently cite an unconditional theorem for every closed typed term.

9383.2 What is established

The checked inventory has six parts.

- Reducibility candidate predicate. `Reducibility.lean` defines the candidate surface and proves that candidates imply strong normalisation:

  ↪ variant BEDC.MetaCIC.Candidate

  ↪ variant BEDC.MetaCIC.candidate implies sn

  ↪ variant BEDC.MetaCIC.candidate sn

  ↪ variant BEDC.MetaCIC.candidate closed under beta

  .

- Closed SN from candidate. `ClosedSN.lean` projects an empty-context typed closed term to strong normalisation when the corresponding candidate witness is supplied:

  ↪ variant BEDC.MetaCIC.closed typed term sn from candidate

  .

- Closed SN from closed candidate. The closed-candidate wrapper carries the closedness of the type and term together with the reducibility candidate, and the closed typed term projection consumes that wrapper:

  ↪ variant BEDC.MetaCIC.closed typed term sn from closedCandidate

  ↪ variant BEDC.MetaCIC.closedCandidate implies sn

  .

- Closed SN from candidate set. Candidate sets package membership, soundness, and beta-closure; closed typed terms inherit strong normalisation from membership in such a set:

  ↪ variant BEDC.MetaCIC.closed typed term sn from candidateSet

  ↪ variant BEDC.MetaCIC.candidateSet implies sn

  ↪ variant BEDC.MetaCIC.canonicalCandidateSet sound

  .

- App adequacy. Application cases are discharged when the function side supplies Pi-candidate or Pi-head candidate evidence and the argument supplies domain-candidate evidence. The step lemmas keep the result inside the same candidate-mediated path:

  ↪ variant BEDC.MetaCIC.app case candidate

  ↪ variant BEDC.MetaCIC.app case sn from pi candidate

  ↪ variant BEDC.MetaCIC.app case sn from candidate

  ↪ variant BEDC.MetaCIC.app case step sn

  .

- Pi adequacy. Pi candidates and neutral normal forms supply the function and binder-side termination facts used by the application layer and the typed examples:

  ↪ variant BEDC.MetaCIC.piCandidate implies sn

  ↪ variant BEDC.MetaCIC.PiAdequacy.piCandidate implies sn

  ↪ variant BEDC.MetaCIC.neutralNormal implies sn

  ↪ variant BEDC.MetaCIC.sn pi

  .

The no-infinite-reduction reading is also present. Strong normalisation excludes infinite beta chains, and the same candidate-mediated closed-term routes export that exclusion:

↪ variant BEDC.MetaCIC.strongNormalizable no infinite reduction

↪ variant BEDC.MetaCIC.closed typed term no infinite reduction from candidate

↪ variant BEDC.MetaCIC.closed typed term no infinite reduction from closedCandidate

↪ variant BEDC.MetaCIC.closed typed term no infinite reduction from candidateSet

.

9383.3 File-by-file audit reading

`Reducibility.lean` is the base layer. It defines BetaStrong, StrongNormalizable, candidate heads, candidates, closed candidates, Pi candidates, and candidate sets. The file also proves the core

closure facts: candidates imply SN, candidates are stable under one beta step, candidate sets export SN through their soundness field, and the canonical candidate set is sound and beta-closed.

The important audit point is that a candidate is not merely a term-level SN tag. It also carries the head-shape information needed by the Pi and application routes. For Pi types this head information includes the ability to send candidate arguments to strongly normalising applications. That is the beginning of the candidate-mediated application story, and it is why the application layer does not reduce to a simple componentwise SN claim.

`ClosedSN.lean` is the closed-term projection layer. It introduces ClosedTypedTerm, ClosedTypedCandidate, ClosedTypedPiCandidate, and ClosedTypedCandidateSetMember. The three main closed typed term theorems project SN from candidate, closed-candidate, and candidate-set evidence. The same file then mirrors those projections into no-infinite-reduction statements.

This file is the main public citation site for closed-term SN. Its statements are strong enough for the closed-normal branch of the consistency assembly, but their quantifier shape matters. Empty-context typing and closedness are present; the candidate witness is still a separate input. A citation that drops that input would cite a theorem that the file does not export.

`PiAdequacy.lean` supplies neutral and Pi-shaped adequacy. It contains a namespace wrapper for Pi-candidate SN, defines neutral normal forms, proves that neutral normality is stable under beta steps, and derives SN for neutral applications and displayed Pi constructions. It also records typed-example SN facts for the Church gallery. These example facts are useful witnesses that the machinery runs on concrete closed terms, not a replacement for the general candidate interface.

`AppAdequacy.lean` is the application-facing layer. It turns a PiCandidate function and a candidate argument into a candidate application, then projects SN and beta-step SN consequences. It also supplies closed application wrappers and small example applications. The file ends with the negative guardrail showing that componentwise SN of function and argument alone does not entail SN of their application.

The four files therefore form a staged route:

- `Reducibility` defines the candidate objects and their SN consequences;
- `ClosedSN` projects those consequences to closed typed term and no-infinite-reduction statements;
- `PiAdequacy` supplies neutral and Pi-shaped adequacy facts;
- `AppAdequacy` discharges application cases under candidate evidence and records the non-unconditional application boundary.

This route is partial closure in the precise BEDC sense. It closes the local candidate-mediated path and the named closed-term projections from that path. It does not erase the candidate layer or turn the examples into a theorem over all closed typed terms.

9383.4 What remains conditional

The normalisation files have no visible `sorry`, `admit`, or `axiom` marker in this submodule. The conditionality is instead at the interface: the closed typed term theorems consume candidate evidence, closed-candidate evidence, or candidate-set membership evidence. They do not construct such evidence for every empty-context typed closed term.

The sharp reading is therefore:

- candidate evidence implies strong normalisation;

- closed typed terms are strongly normalising once they are placed inside the candidate, closed-candidate, or candidate-set interface;
- Pi and application adequacy show how the candidate interface behaves over the displayed Pi and application fragments;
- the module does not export a blanket theorem of the form every closed typed BEDC.MetaCIC term is strongly normalising without candidate-mediated evidence.

This boundary is checked negatively on the application side. The file `AppAdequacy.lean` records a self-application counterexample to the claim that strong normalisation of parts alone gives unconditional strong normalisation of applications:

```
↪ variant  BEDC.MetaCIC.selfApplyApp not sn
↪ variant  BEDC.MetaCIC.app sn from parts is not unconditional
```

. Thus the word "candidate-mediated" is not stylistic caution. It names the actual guardrail that prevents the paper from overreading componentwise termination as global application termination.

9383.5 Comparison with SR obstruction and Confluence audit map

The subject-reduction map in chapter 9377 isolates a dependent-codomain obstruction: closed subject reduction is blocked unless four named preservation obligations are supplied. The confluence map in chapter 9378 isolates a residual-substitution boundary for the full parallel diamond and arbitrary closed star confluence.

Normalisation has a different shape. It is not currently blocked by an explicit proof-hole marker inside the normalisation submodule, and it is not the same as the SR dependent-codomain obstruction or the confluence substitution boundary. Its public frontier is the reducibility-candidate interface: the checked SN projections are closed over the candidate evidence they consume, while the manuscript must not erase that evidence from the statement being cited.

For full closed consistency, the three maps meet in chapter 9375. Strong normalisation supplies the closed-normal branch through the candidate-mediated path. Subject reduction would have to transport arbitrary closed proofs while preserving the displayed false type. The no-closed-normal-proof-of-false theorem then rules out the normal endpoint. The present chapter records the SN pillar; it does not close the subject-reduction transport pillar.

9383.6 Apophatic framing and boundary

This audit map applies the same apophatic discipline as the SR and confluence maps. BEDC names the open cell instead of silently promoting a conditional interface into an unconditional closure theorem. The map is not a new normalisation proof. It is a paper-side handle for the exact proof state exposed by the Lean normalisation files.

The available positive claims are the checked candidate-to-SN lemmas, the closed typed term projections from candidate evidence, the candidate-set projections, the Pi and application adequacy lemmas, the example-level SN facts, and the no-infinite-reduction consequences. The explicit boundary is equally binding: this chapter does not claim global strong normalisation for every closed typed MetaCIC term without candidate-mediated evidence, does not turn componentwise application SN into unconditional application SN, and does not close the subject-reduction

obligations needed by full closed consistency.

Concretized in §755: Candidate-mediated normalization is represented as a finite budgeted NameCert surface, not as an unconditional closed-term theorem.

Concretized in §750: MetaCIC normalization audit packets realize the finite strong-normalization scope, confluence-boundary refusal, transport, route replay, provenance, and local NameCert rows.

Concretized in §777: The normalization audit map is realized as the finite candidate-mediated MetaCICNormalizationAuditSeal packet.

Concretized in §758: Candidate-mediated strong-normalization routes are realized as finite NameCert packets over candidate evidence, closed-candidate evidence, candidate-set membership, Pi/app adequacy rows, and no-infinite-reduction projections.

Concretized in §907: Pi-application adequacy routes are realized as finite candidate-mediated NameCert packets over Pi evidence, argument evidence, application candidate rows, closed typed projections, and no-infinite-reduction boundaries.

Concretized in §1108: Candidate-mediated normalization routes are packaged as a finite NameCert router.

Concretized in §1190: MetaCIC normalization and confluence audit routes are realized as a finite bridge packet over the subject-reduction and closed-consistency boundary.

Concretized in §2226: The normalization audit socket is realized as finite candidate, closed-candidate, obstruction, frontier, hsame, Cont, Pkg, and NameCert rows.

Concretized in §8668: Normalization audit rows are realized as finite candidate-set, fuel-trace, closed-typing-fragment, residual-checker, normal-endpoint, refusal, transport, replay, provenance, and NameCert data.

Concretized in §8604: Candidate-mediated redex frontiers realize the normalization audit map as finite typed-term, candidate, residual-budget, beta-window, and strong-normalization handoff rows.

Concretized in §5936: MetaCIC normalization fuel boundaries realize candidate-mediated bounded-fuel traces as finite closed-term, candidate, fuel, trace, closedness-preservation, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §5547: Candidate-mediated normalization, residual confluence visibility, and decidable-boundary routing are realized as one finite handoff packet.

Concretized in §3539: The candidate-mediated typed-normalization route is realized as a finite NameCert audit packet.

Concretized in §2320: Candidate-set normalization is realized as finite candidate evidence, closed-term projection, application/Pi adequacy, no-infinite-reduction, obstruction, transport, continuation, provenance, and NameCert rows.

Concretized in §2337: Finite NameCert landing for candidate-mediated normalization windows and confluence boundaries.

Concretized in §892: The normalization frontier packet separates candidate evidence, closed-normal use, and subject-reduction obstruction rows as finite MetaCIC audit data.

Concretized in §3422: Candidate-set strong-normalization handoffs are realized as finite CandidateSet membership, closed-term, beta-closure, and SN export NameCert data.

Concretized in §3566: Candidate-mediated normalization evidence is realized as a finite socket packet separating candidate rows from global SN claims.

Concretized in §5210: Candidate-mediated normalization routing is realized as finite closed-term, candidate-evidence, adequacy-handoff, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §3779: Candidate-mediated normalization audit rows are packaged as a finite NameCert carrier for closed-term SN and no-infinite-reduction reads.

Concretized in §3871: Candidate-mediated normalization evidence budgets are realized as finite candidate, closed-candidate, candidate-set, Pi/app adequacy, projection, and no-infinite-reduction rows.

Concretized in §3919: Pi adequacy budget for candidate-mediated strong normalization.

Concretized in §4196: Bounded normalization candidates realize the finite candidate, fuel, closed-term, Pi/application adequacy, and no-infinite-reduction frontier rows used by the MetaCIC normalization audit map.

Concretized in §5351: Candidate-set membership routes closed typed terms to strong normalization without erasing the candidate evidence.

Concretized in §5163: Candidate-mediated strong-normalization evidence is realized as a finite packet over candidate, closure, adequacy, no-infinite-reduction, obstruction, and MetaCIC frontier route rows.

Concretized in §5942: Ground-compiler normalization routes are realized as finite generated-term, candidate-evidence, adequacy, no-infinite-reduction, obstruction, replay, provenance, and NameCert rows.

Concretized in §6032: GroundCompiler strength monotonicity is realized as finite accepted-flow, lower derivation-certificate subflow, route-budget, candidate-socket, transport, provenance, and local NameCert rows.

Concretized in §5994: Candidate-mediated normalization frontiers are realized as finite evidence/refusal NameCert rows.

Concretized in §6027: Finite beta-window confluence packets realize the normalization audit map as redex-frontier, local-join, substitution-boundary, and closed-normal finite NameCert rows.

Concretized in §6085: Candidate-mediated SN handoff realizes the normalization audit map as finite NameCert data.

Concretized in §6306: Neutral reifier packets realize the MetaCIC normalization audit route as finite neutral, semantic value, readback, transport, replay, provenance, and NameCert rows.

Concretized in §6314: Finite-window normalization audit packet for MetaCIC redex-frontier inspection.

Concretized in §6552: Candidate-mediated normalization and local confluence budgets are realized as finite candidate, closed-candidate, candidate-set, peak, join-budget, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §6666: Residual-checker normalization budgets realize candidate-mediated SN through finite checker, fuel, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §6617: Typed normal-form schedulers realize the normalization audit map as finite closed-term, candidate-gate, scheduler-budget, typed-endpoint, obstruction, router, transport, replay, provenance, and NameCert rows.

Concretized in §7242: The normalization substitution-boundary packet realizes the candidate-mediated normalization obstruction as finite NameCert rows.

*Concretized in §**??**:* Finite observation diamond envelopes route candidate evidence, bounded endpoint rows, residual-envelope reads, local checker status, blocked-edge retention, transport, replay, provenance, and NameCert rows before bounded joins are consumed.

Concretized in §5157: Proof-trace normal forms realize the normalization audit route as finite proof trace, typed endpoint, normal-form readback, transport, replay, provenance, and NameCert rows.

Concretized in §8559: Bounded MetaCIC diamond windows realize candidate-mediated normalization and residual confluence as finite NameCert data.

Concretized in §8724: Bounded normalization counterexample budgets realize the finite obstruction row of the MetaCIC normalization audit map.

Concretized in §8795: The normalization-confluence frontier realizes the candidate-mediated SN route together with residual-join and confluence-boundary rows as finite NameCert data.

Concretized in §8854: Finite normalization diamonds realize the MetaCIC normalization audit map as candidate-mediated local join, no-infinite-branch, transport, replay, provenance, and NameCert rows.

Chapter 9384

MetaCIC Beta module audit map

9384.1 The setup

BEDC.MetaCIC's beta layer is the driving reduction relation used by the subject-reduction, confluence, normalisation, evaluation, and closed-consistency interfaces. Its public surface is deliberately small. The single-step relation is declared in `Beta.lean`, while conversion by common beta reduct is declared in `Beta/Conversion.lean`.

The two files should be read together. `Beta.lean` gives the raw generator: a one-step relation BetaStep over MetaCIC terms, with one direct beta-redex constructor and congruence constructors for applications, lambdas, and Pi types. `Beta/Conversion.lean` builds the conversion interface BetaConv from the multi-step relation BetaStarStep and records the checked conversion lemmas that later modules may cite.

This chapter is an audit map, not another proof layer. It records which beta objects are constructors, which conversion facts are checked, and where the relation meets the subject-reduction obstruction isolated in chapter 9377.

9384.2 Core inductive definition

9384.2.1 BetaStep

The core declaration is the inductive relation
Lean4 (definition) `BEDC.MetaCIC.BetaStep`
. It has seven constructors.

- `beta` contracts an application whose function is a lambda: app(lam *dom body*) *arg* steps to substitute 0 *arg body*.
- `congApp1` reduces the function position of an application while leaving the argument fixed.
- `congApp2` reduces the argument position of an application while leaving the function fixed.
- `congLam` reduces the body of a lambda while leaving the displayed domain fixed.
- `congPiCod` reduces the codomain of a Pi type while leaving the displayed domain fixed.
- `congPiDom` reduces the displayed domain of a Pi type while leaving the codomain syntactically fixed.

- `congLamDom` reduces the displayed domain of a lambda while leaving the body syntactically fixed.

The constructor list is intentionally syntax-directed. A beta step is not a typing judgement, not a semantic equivalence, and not a closure certificate. It only says that the represented term syntax admits one local reduction at a displayed site.

9384.2.2 File-level reading

`Beta.lean` is therefore the root reduction file, not a theorem bundle. Its exported object is the closed inductive grammar of one-step beta movement. Every later theorem that mentions beta reduction receives one of these constructors, or a finite chain generated from them, as its reduction witness.

`Beta/Conversion.lean` is the first theorem bundle over that grammar. It does not add a new reduction rule. It changes the reading mode from one-step movement to common-reduct comparability, and then proves the small algebra of that comparison relation that is already available in the substrate.

Two features matter for later audits. First, beta contraction uses the concrete MetaCIC substitution operation, so all preservation claims that read across the redex must account for substitution through binders. Second, the domain congruence constructors for lambda and Pi terms change displayed binder annotations without reducing the body or codomain at the same time. These are valid reduction steps, but their typing behaviour requires separate evidence.

9384.3 Established results

The conversion file exposes BetaConv as common-reduct conversion: there is a term w such that both sides reduce to w by BetaStarStep.

```
↪ variant BEDC.MetaCIC.BetaConv
```

The elementary conversion facts are checked directly:

- reflexivity and symmetry:

  ```
  ↪ variant BEDC.MetaCIC.BetaConv.refl
  ↪ variant BEDC.MetaCIC.BetaConv.symm
  ```

  ;

- conversion from a multi-step beta reduction on either side:

  ```
  ↪ variant BEDC.MetaCIC.BetaConv.of betaStar left
  ↪ variant BEDC.MetaCIC.BetaConv.of betaStar right
  ```

  ;

- conversion from a one-step beta reduction on either side:

  ```
  ↪ variant BEDC.MetaCIC.BetaConv.of betaStep left
  ↪ variant BEDC.MetaCIC.BetaConv.of betaStep right
  ```

  .

The file also records the conditional transitivity shape. Full transitivity is obtained from an explicit confluence input, while a normal middle term gives a smaller unconditional route:

```
↪ variant BEDC.MetaCIC.BetaConv.trans of confluence
```

↪ variant BEDC.MetaCIC.BetaConv.trans normal middle

↪ variant BEDC.MetaCIC.BetaConv.trans closed normal middle

Closed normal forms are rigid under beta conversion when both sides are closed and beta-strong:

↪ variant BEDC.MetaCIC.BetaConv normal forms equal closed

The same conversion file also names a typing-side boundary. The closed beta-conversion typing invariance statement is represented as a proposition, and the file proves a concrete closed lambda-domain obstruction against it:

↪ variant BEDC.MetaCIC.HasTypeBetaConvInvariantClosedStatement

↪ variant BEDC.MetaCIC.closedLamDomainTarget closed

↪ variant BEDC.MetaCIC.BetaConv closed lam domain type obstruction

↪ variant BEDC.MetaCIC.not HasType BetaConv invariant closed

These facts are conversion facts and obstruction facts. They are not a blanket permission to replace displayed types by beta-convertible types inside typing derivations. Any citation must preserve the exact input shape: common reduct, normal middle term, closed beta-strong normal forms, or the displayed negative typing boundary.

9384.4 Connection to the SR obstruction

chapter 9377 names four discharge obligations for the parameterised subject-reduction theorem. The beta module is where the reduction triggers behind those obligations are born.

The direct `beta` constructor is the trigger for BetaSubstitutionPreservation. A term app(lam *dom body*) *arg* can reduce unconditionally to substitute 0 *arg body*. To turn that syntactic step into typing preservation, the substrate must show that substituting the argument into the body also transports the displayed codomain in the expected way. That is a typing statement about substitution, not a consequence of the beta constructor alone.

The `congApp2` constructor is the trigger for the dependent-codomain application obstruction. It reduces the argument while leaving the function and the originally displayed application type fixed. In an independent codomain regime this can be harmless, and the subject-reduction map records the checked independent-codomain fragment. In a dependent codomain regime the codomain can observe the argument, so reducing the argument may change the readback type. That is the reason AppArgTypeStable is a separate obligation.

The `congLamDom` and `congPiDom` constructors are the binder-domain triggers. They reduce displayed binder annotations. A lambda or Pi term can therefore take a syntactic beta step even when the typing derivation for the old annotation does not transfer to the new annotation at the same displayed external type. These are the sources of LamDomainSubjectReduction and PiDomainSubjectReduction.

Thus the beta relation itself is unconditional, but subject reduction under that relation is not unconditional in the present MetaCIC interface. The distinction is structural: BetaStep authorizes one syntax step, while subject reduction must also preserve typing data across the dependent codomain and binder interfaces touched by that step.

Concretized in §728: Beta congruence-domain audit packets realize the binder-domain beta constructors as finite subject-reduction trigger surfaces.

9384.5 Apophatic framing and boundary

The beta audit map gives BEDC a precise negative reading discipline. The paper may cite `BetaStep` as the checked single-step reduction relation. It may cite the conversion lemmas listed above. It may cite the closed normal-form rigidity theorem and the checked obstruction to closed typing invariance under beta conversion.

The paper may not infer a hidden conversion rule for typing, an unconditional closed subject-reduction theorem, or a full closed consistency proof from the existence of BetaStep. A beta step is a syntactic generator. Its typing consequences require the exact preservation interfaces named in chapter 9377.

This is the apophatic role of the module boundary. The beta layer says exactly what can reduce. The conversion layer says exactly which common-reduct facts are available. The subject-reduction map says exactly which typing transports are not supplied by those reduction facts alone. Keeping the three readings separate prevents the manuscript from treating reduction, conversion, and typed preservation as one unrecorded operation.

Concretized in §760: Typed beta congruence trigger packets realize the beta audit map's congruence-constructor typing boundary as a finite MetaCIC NameCert surface.

Concretized in §761: The beta audit map is realized as a finite NameCert packet separating reduction, conversion, and typing-preservation boundaries.

Concretized in §754: Beta-step boundaries are realized as finite BetaStep, BetaConv, obstruction-trigger, hsame, Cont, Pkg, and NameCert rows.

Concretized in §879: Beta-reduction audit trails realize the beta audit map as finite BetaStep, BetaConv, obstruction-trigger, subject-reduction socket, hsame, Cont, Pkg, and NameCert rows.

Concretized in §881: Critical-pair packets concretize the beta audit map as finite local-overlap and common-reduct NameCert data.

Concretized in §881: Critical-pair packets realize the beta audit map through a finite local-overlap, branch, common-reduct, and non-escape route.

Concretized in §7339: Eta-expansion audit packets realize the beta audit map as finite eta-row, beta-conversion-boundary, normalization-frontier, obstruction-retention, transport, replay, provenance, and NameCert data.

Concretized in §7470: MetaCIC beta redex spines realize the beta audit map as finite Term, BetaStep, BetaConv, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §7682: The closure-substitution frontier realizes the beta-audit obstruction route as finite beta-trigger, ClosedAt, substitution-boundary, and subject-reduction rows.

Concretized in §7714: The substitution-sensitive beta diamond frontier is realized as finite peak, residual, candidate-join, substitution-boundary, checker, obstruction, hsame, Cont, Pkg, and NameCert rows.

Chapter 9385

MetaCIC audit synthesis: closed-CIC critical-path overview

9385.1 The setup

BEDC.MetaCIC is the closed CIC meta-theory formalisation inside the BEDC project. Its closed-term meta-properties are distributed across the subject reduction, confluence, normalisation, substitution, decidable-checking, and consistency-assembly files. The relevant paper audit maps are chapter 9377, chapter 9378, chapter 9383, chapter 9380, chapter 9379, and chapter 9375.

This chapter gives a single reader-facing overview of that state. It does not replace the sibling audit maps. It points to them, aligns their boundaries, and extracts the closed-MetaCIC critical path: which nodes are already available, which nodes are conditional, and where unconditional closed consistency is blocked.

9385.2 The five submodule audit maps

9385.2.1 Reading rule

The five maps are not interchangeable evidence. Each map exports a different kind of checked object. Subject reduction exports an obstruction and a four-input preservation interface. Confluence exports reduction-geometry fragments and conditional bridges. Normalisation exports reducibility-candidate routes. Substitution exports closed syntactic laws. Decidability exports executable checking surfaces.

A citation to one map therefore cannot silently stand in for another. A substitution lemma may support the beta case of a later preservation proof, but it is not the preservation proof. A confluence bridge may show how a supplied diamond would flow to closed star confluence, but it is not the supplied diamond. A decidable checker may certify a displayed typing computation, but it is not a decision procedure for all meta-theoretic predicates. This is the reading discipline used throughout this synthesis.

9385.2.2 Subject reduction

The subject-reduction map records a parameterised preservation theorem, four documented discharge obligations, and a checked obstruction theorem for the unparameterised closed subject-reduction statement. Closed subject reduction is therefore explicitly not available in the present

substrate; see chapter 9377.

9385.2.3 Confluence

The confluence map records a substitution-conditional parallel diamond, bridges from closed parallel diamond to closed star confluence, and unconditional fragments for closed normal sources and atom shapes. It does not claim arbitrary closed-term Church–Rosser; see chapter 9378.

9385.2.4 Normalization

The normalisation map records the candidate-mediated strong-normalisation path for closed typed terms. Candidate, closed-candidate, or candidate-set evidence delivers strong normalisation and no-infinite-reduction consequences, but the map does not erase that evidence into a blanket theorem over all closed typed terms; see chapter 9383.

9385.2.5 Substitution

The substitution map records unconditional closed syntactic laws: `shift_closed`, `substitute_closed`, and closed composition fragments. These facts supply syntax-side binder movement, but they do not discharge beta typing preservation or full subject reduction; see chapter 9380.

9385.2.6 Decidability

The decidable map records executable equality and type-checking surfaces, their soundness and completeness wrappers, gallery sanity witnesses, and bounded normal-form comparison under finished-normalisation evidence. It is a local checking layer, not a decision oracle for subject reduction, confluence, normalisation, or consistency; see chapter 9379.

9385.3 The critical path to unconditional closed consistency

The closed-MetaCIC consistency assembly in chapter 9375 can be read as the following critical path.

1. Closed strong normalisation is available through the candidate-mediated normalisation interface. Its public witnesses include

   ↪ variant BEDC.MetaCIC.closed typed term sn from candidate

   ,

   ↪ variant BEDC.MetaCIC.closed typed term sn from closedCandidate

   , and

   ↪ variant BEDC.MetaCIC.closed typed term sn from candidateSet

   .

2. No closed normal proof of false is available:

   ↪ variant BEDC.MetaCIC.no closed normal proof of false

   .

3. Closed normal consistency assembly is available:

   ↪ variant BEDC.MetaCIC.closed normal consistency assembly

   .

4. Closed reduction by subject reduction is blocked by the dependent-codomain obstruction:

   ↪ variant BEDC.MetaCIC.closed consistency reduction obstruction not available

   .

5. The discharge bundle required for an unconditional preservation lift is explicitly named:

   ↪ variant BEDC.MetaCIC.SubjectReductionDischargeBundle

   .

6. Unconditional closed consistency remains blocked until the bundle is supplied and the closed-normal theorem can be transported from arbitrary closed proofs to their normal endpoints.

The same dependency can be displayed as a compact audit graph:

```
Candidate-mediated closed SN
  status: AVAILABLE
  feeds:
    closed-normal consistency branch

No closed normal proof of False
  status: AVAILABLE
  witness:
    BEDC.MetaCIC.no_closed_normal_proof_of_false

Closed normal consistency
  status: AVAILABLE
  witness:
    BEDC.MetaCIC.closed_normal_consistency_assembly

Closed reduction by subject reduction
  status: BLOCKED
  reason:
    dependent-codomain obstruction
  required interface:
    BEDC.MetaCIC.SubjectReductionDischargeBundle

Unconditional closed consistency
  status: BLOCKED
  reason:
    closed-normal consistency cannot be lifted without closed reduction
```

9385.4 Status matrix

The same state can be read as a matrix of positive results and non-claims.

Map	Available	Not claimed
Subject reduction	parameterised preservation, four named inputs, checked obstruction	unparameterised closed subject reduction
Confluence	conditional parallel diamond route, closed normal and atom fragments	arbitrary closed Church–Rosser
Normalisation	candidate-mediated closed strong normalisation routes	candidate-free global strong normalisation
Substitution	closed shift, closed substitution, closed composition fragments	unrestricted substitution calculus or beta typing preservation
Decidability	term equality, type-checking soundness and completeness, bounded comparison	global decision procedure for meta-theoretic properties
Assembly	closed-normal consistency	unconditional closed consistency

The matrix is deliberately asymmetric. The positive column records what the Lean substrate and paper maps can be used for directly. The non-claim column records the strongest nearby statement that must not be inferred from that positive result. The synthesis depends on this asymmetry: the project has many checked local nodes, but the closed-consistency endpoint needs a specific transport edge that those local nodes do not themselves supply.

9385.5 How the maps interact

The interaction pattern is a supply chain with named handoffs rather than a single theorem with hidden premises. Substitution supplies closed syntactic facts about moving terms across binders. Subject reduction would have to turn the relevant binder movement into type preservation across beta and domain congruence. Normalisation supplies the target normal-form side once the proof term is inside the candidate-mediated strong-normalisation interface. Consistency assembly consumes the normal-form theorem, but only after the displayed false type has been preserved along reduction.

Confluence and decidability sit beside that path. Confluence describes how reduction branches can be joined under the available and conditional diamond interfaces. Decidability describes which local syntactic and typing questions are executable inside the represented fragment. Both constrain how later work may cite the substrate, but neither bypasses the subject-reduction lift.

The useful reading is therefore:

1. Substitution is syntax algebra.
2. Subject reduction is type-preservation transport.
3. Normalisation is termination-to-normal-form evidence.
4. Closed-normal consistency is the contradiction eliminator at the normal endpoint.
5. Full closed consistency is the composition of transport and the normal endpoint.

The missing edge is item 2 in the closed arbitrary-proof setting. Once that edge is unavailable, items 3 and 4 remain valid but cannot be composed into item 5 for every closed proof term.

Concretized in §765: MetaCIC critical-path packets realize the audit synthesis as finite subject-reduction, normalisation, decidability, obstruction, transport, and NameCert rows.

Concretized in §776: MetaCIC audit synthesis is realized as a finite NameCert packet over the closed-normal branch, obstruction ledger, and discharge rows.

Concretized in §3519: MetaCIC redex-choice frontier packets realize the candidate-mediated normalization and confluence boundary as finite BEDC rows.

Concretized in §6547: The confluence diamond ledger realizes the MetaCIC audit synthesis confluence branch as finite candidate, critical-pair, residual-substitution, local-join, transport, and NameCert rows.

Concretized in §8284: MetaCIC candidate-pruning budgets realize the audit-synthesis frontier as finite candidate, pruning-budget, residual-frontier, bounded-checker, obstruction, transport, replay, provenance, and NameCert rows.

9385.6 The frontier shape

The substrate currently establishes normal-form sub-consistency unconditionally. This is the strongest closed-consistency node available: a closed proof term that is already beta-strong cannot inhabit the internal false encoding. The result is sharp because it states exactly the normal-form fragment, and it is useful because it is the endpoint that a successful subject-reduction lift would consume.

The lift to full closed consistency requires one of two project-level moves. The first route is to discharge the four subject-reduction hypotheses named in chapter 9377. The second route is to extend the substrate beyond the present closed-CIC surface so that the missing context-reduction and dependent-codomain readback lemmas become expressible and provable. On the current substrate, the checked obstruction theorem prevents the paper from treating that lift as a local proof exercise.

Confluence and decidability do not remove this frontier. Confluence supplies reduction geometry and conditional bridges, while decidability supplies local checking procedures. Substitution supplies closed syntax algebra. All three are necessary audit context, but none of them replaces the subject-reduction transport needed to carry an arbitrary closed proof of false to the closed normal-form theorem.

9385.7 Apophatic discipline applied to meta-theory

The MetaCIC audit maps apply BEDC's apophatic naming discipline to the project's own meta-theory. The substrate names what it has: checked closed normal consistency, candidate-mediated normalisation, closed substitution laws, local decidable checking, atom and normal-source confluence fragments, and conditional bridges. It also names what it does not have: unparameterised closed subject reduction, arbitrary closed Church–Rosser, unrestricted substitution commutation, a global decidability oracle, and unconditional closed consistency.

This synthesis chapter combines those names into one critical-path map. Its purpose is to prevent the reader from overreading a neighbouring checked layer as the missing endpoint. The current state is strong, but it is not ambiguous: the assembled theorem is closed-normal consistency, and the blocked edge is the subject-reduction lift across the dependent-codomain frontier.

9385.8 Boundary

This chapter is an audit overview, not a proposal and not a proof of any open obligation. It does not discharge the subject-reduction bundle, does not claim full closed confluence, does not strengthen the candidate-mediated normalisation interface, and does not turn decidable local checking into a global meta-theoretic decision procedure.

The claim is exactly the synthesis claim: the five audit maps and the consistency assembly form a closed critical-path diagram for the present BEDC.MetaCIC state. The available endpoint is normal-form closed consistency. The unavailable endpoint is unconditional closed consistency, blocked at the named subject-reduction discharge interface.

*Concretized in §**??**:* MetaCIC audit synthesis is realized as a finite NameCert packet over submap status rows, closed-normal consistency rows, and the blocked subject-reduction handoff ledger.

Concretized in §844: Closed consistency gap packets realize MetaCIC audit synthesis as finite rows separating closed-normal consistency from the subject-reduction discharge socket.

Concretized in §904: The MetaCIC audit synthesis matrix is realized as a finite NameCert packet for available rows, non-claim rows, blocked edges, synthesis consumers, and non-escape ledgers.

Concretized in §1063: MetaCIC proof-object audit routes are realized as finite NameCert rows tying closed-normal evidence to the subject-reduction blocked-edge ledger.

Concretized in §1056: The MetaCIC audit synthesis is realized as a finite discharge-obstruction lattice over available, blocked, and required closed-CIC audit rows.

Chapter 9386

Closed-MetaCIC open problems: consolidated obligation list

9386.1 The setup

The MetaCIC audit maps deliberately separate positive checked content from the places where the closed-term consistency route is still blocked. The subject reduction map, confluence map, normalisation map, substitution map, decidability map, typed-example map, and consistency assembly record those boundaries in their own local vocabularies: chapter 9377, chapter 9378, chapter 9383, chapter 9380, chapter 9379, chapter 9382, and chapter 9375.

This chapter is the companion inventory. The synthesis view gives the reader the critical path; the present chapter gives the concrete list of outstanding obligations, obstructions, partial-closure boundaries, and frontier questions. It does not introduce a new proof principle, a new Lean target, or a stronger closure claim. It is a single reading surface for the work that remains open after the existing audit chapters are read together.

The consolidated list has four layers. First, the subject-reduction route has four named discharge hypotheses and a checked obstruction to replacing them by an unconditional closed subject-reduction theorem. Second, confluence and substitution have algebraic boundaries around residual substitution and unrestricted commutation. Third, normalisation and decidability have candidate-mediated or bounded-computation interfaces that should not be erased by prose. Fourth, the worked examples are gallery-level witnesses, not a coverage theorem over all dependent or polymorphic programs.

9386.2 Subject reduction obligations (4)

The subject-reduction frontier is the sharpest obstruction in the closed MetaCIC path. The parameterised theorem exists, but it consumes four discharge hypotheses. The checked obstruction in chapter 9377 prevents the paper from replacing that four-input interface by a blanket closed subject-reduction claim for the present substrate.

1. BetaSubstitutionPreservation. The beta-redex case must show that substituting a typed argument into a typed body preserves the substituted codomain. The obstruction blocks an unconditional proof because the dependent codomain can observe the argument strongly enough for the displayed target type to change after reduction.

2. AppArgTypeStable. The application-argument congruence case must show that replacing an

argument by its reduct leaves the codomain readback stable. The independent-codomain case is checked, but the dependent codomain case is exactly where the counterexample lives.

3. LamDomainSubjectReduction. The lambda-domain congruence case must preserve the type of a lambda when its displayed domain annotation reduces. This is not a direct consequence of syntactic beta stepping, because the binder annotation participates in the typing judgement being preserved.

4. PiDomainSubjectReduction. The Pi-domain congruence case must preserve the type of a Pi term when the displayed domain reduces. This is separate from the lambda case because the Pi codomain is checked under the binder induced by the domain, so domain reduction changes the context-facing data.

All four obligations are simultaneous. Supplying only the beta redex row, only argument stability, or only binder-domain preservation leaves the parameterised subject-reduction theorem unavailable as an unconditional closed theorem. The first-class bundle records exactly the simultaneous discharge interface:

```
↪variant BEDC.MetaCIC.SubjectReductionDischargeBundle
```

.

Concretized in §6177: Closed application-argument stability packets realize the independent-codomain AppArgTypeStable route as finite closed-function, argument-step, typing, closedness, obstruction-boundary, transport, replay, provenance, and NameCert rows.

9386.3 Confluence remaining questions

The confluence map in chapter 9378 has a different shape from the subject-reduction map. It is not blocked by dependent typing. It is blocked at the residual-substitution algebra needed for the full parallel diamond and then for arbitrary closed star confluence.

The unconditional confluence content is shape-limited. Closed normal sources, sort sources, closed variable impossibility, atom joins, non-lambda application shape facts, componentwise diamonds, and parallel-to-star transport are available at the strengths stated in the confluence audit map. Those results are real checked infrastructure and may be cited at that scope.

The remaining confluence questions are the stronger endpoints. Does the present substrate support the needed BetaParallelSubstitutionCompatibility interface without importing unclosed substitution assumptions? Can the closed parallel diamond be supplied for arbitrary closed terms rather than consumed as a premise? Can the resulting closed multi-step Church–Rosser theorem be stated without hiding the substitution boundary? Until those inputs exist, arbitrary closed-term confluence remains conditional rather than unconditional.

Concretized in §2181: Residual-substitution boundary packets realize the MetaCIC open confluence obstruction as finite redex-frontier, residual-route, local-join, bounded-checker, subject-reduction-boundary, transport, replay, provenance, and NameCert rows.

Concretized in §3808: Bounded residual-substitution frontier packets realize the confluence obstruction as finite redex-frontier, residual-route, bounded-checker, local-join, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §3827: MetaCIC confluence residual-checker packets realize the residual-substitution frontier as typed-window, redex-frontier, bounded-checker, local-join, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §7088: Typed residual-budget packets realize the MetaCIC residual-checker frontier as finite typed-window, residual-frontier, checker-route, local-join, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §3921: The confluence residual envelope realizes the open residual-substitution confluence boundary as finite typed-window, residual-frontier, substitution-boundary, checker-status, fuel, neutral-spine, normalization-budget, transport, replay, provenance, and NameCert rows.

Concretized in §5099: Finite observation confluence budgets realize the MetaCIC residual-confluence frontier as finite typed-window, local-join, bounded-checker, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §6169: Closed parallel diamond obstructions realize the MetaCIC confluence frontier as finite premise-ledger, residual-boundary, residual-checker, observation-budget, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §6419: MetaCIC substitution-diamond packets realize the residual-substitution frontier as finite typed-window, substitution-route, residual-frontier, bounded local-diamond checker, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §6857: MetaCIC residual diamond schedulers realize the residual-substitution confluence frontier as finite typed-window, residual-frontier, candidate-SN evidence, bounded local-join checker, L10-source, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §6955: Residual-substitution compatibility windows realize the bounded confluence obstruction as finite typed-window, residual-frontier, substitution-boundary, local-join, checker-status, transport, replay, provenance, and NameCert rows.

Concretized in §7042: A finite residual-pair local-diamond witness packet realizes one MetaCIC confluence frontier from displayed candidate and substitution rows.

Concretized in §7219: A finite residual-pair local-diamond witness packet realizes one bounded MetaCIC confluence frontier.

Concretized in §7378: MetaCIC residual-join budgets realize the confluence frontier as finite typed-window, residual-premise, residual-pair, join-candidate, closed-checker, bounded local-join, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §7407: MetaCIC residual-diamond budgets realize the residual-substitution confluence frontier as finite typed-window, residual-pair budget, join-candidate, bounded-checker, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §7989: MetaCIC parallel-diamond selectors realize the closed parallel-diamond frontier as finite typed-window, residual-pair, diamond-candidate, compatibility-boundary, selector, obstruction, TasteGate, transport, replay, provenance, and NameCert rows.

Concretized in §7500: MetaCIC residual-join gauges realize the residual-substitution confluence frontier as finite residual-pair, bounded local-join, checker, closed-seal, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §8191: MetaCIC residual-choice budgets realize the bounded confluence frontier as finite typed-window, residual-pair, choice-boundary, bounded local-join, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §7763: Finite proof-DAG frontier packets realize the MetaCIC open-problem route as finite node, edge, checker, normalization-frontier, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §8046: MetaCIC residual local-diamond witnesses realize the residual-substitution confluence frontier as finite residual-pair admission, bounded local-join checker visibility, obstruction retention, transport, replay, provenance, and NameCert rows.

Concretized in §8283: MetaCIC confluence budget matrices realize the residual-substitution, closed parallel-diamond, and closed star-confluence frontier as finite typed-window, local-join, budget-matrix, obstruction, TasteGate-obligation, transport, replay, provenance, and NameCert rows.

9386.4 Normalization remaining questions

The normalisation map in chapter 9383 is candidate-mediated. Candidate evidence, closed-candidate evidence, and candidate-set membership imply strong normalisation; the application and Pi adequacy layers explain how that evidence behaves over the displayed fragments.

The remaining question is not whether the candidate projections are checked. They are checked. The question is whether every empty-context typed closed MetaCIC term can be placed into the relevant candidate interface without adding an unrecorded semantic assumption. The present normalisation layer does not export a blanket theorem saying that all closed typed terms are strongly normalising independent of candidate evidence.

This boundary matters for the consistency route. Closed-normal consistency can use beta-strong normality as an input, and candidate evidence can supply such normality for terms inside the candidate interface. Full closed consistency would still require a bridge from arbitrary closed proofs to a typed normal endpoint with the displayed false type preserved, which returns the problem to the subject-reduction frontier.

Concretized in §4366: MetaCIC candidate closed-projection boundary packets realize the open normalization frontier as finite closed-term, candidate-evidence, router-selection, endpoint-seal, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §4284: MetaCIC proof-search frontiers are realized as finite candidate-evidence, bounded-normal endpoint, discharge-socket, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §7167: Finite proof-trace sieves realize the MetaCIC proof-search frontier as finite candidate, endpoint, discharge, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §5143: The normal-endpoint cut is realized as a finite packet separating candidate evidence, finished-normal endpoint, obstruction row, and discharge socket.

Concretized in §7180: Candidate-normalization discharge packets realize the MetaCIC normalization open problem as finite candidate-evidence, endpoint-seal, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §8635: MetaCIC residual normalization obstruction packets realize the arbitrary closed-term boundary as finite closed-term, candidate-request, endpoint, residual-frontier, obstruction, TasteGate-obligation, audit-handoff, transport, replay, provenance, and NameCert rows.

9386.5 Decidability remaining questions

The decidability map in chapter 9379 has a positive typing layer and a narrower conversion layer. Structural term equality, same-term checking, and option-valued type inference are sound and complete for the represented relations at the interface stated by the checker theorems.

The remaining decidability questions sit around closedness and beta conversion. The submodule does not export a theorem named `Decidable (ClosedAt n t)`. It also does not export an unrestricted closed-term beta-conversion decider. The bounded normal-equality checker is sound for equality of bounded normalizer outputs and for finished closed normal forms when the finished-normalisation witnesses are supplied.

Thus the decidability frontier is the endpoint bridge: how should bounded normal computation be connected to finished normal forms for the class of closed typed terms under discussion? A global conversion decider would require that bridge explicitly. Gallery success and checker completeness for typing do not supply it by themselves.

Concretized in §3439: Bounded normal conversion bridges realize the finished-normal endpoint needed by the MetaCIC decidability frontier.

Concretized in §4113: MetaCIC conversion endpoint seals realize the bounded normal-computation endpoint as finite finished-normal NameCert data.

Concretized in §6069: MetaCIC typed-conversion residual frontiers realize the decidability endpoint bridge as typed-window, residual-frontier, bounded-normal comparison, finished-normal witness, refusal, endpoint-obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §6890: Closed typing fragments realize the MetaCIC decidability frontier as finite closed-term, type-checker, endpoint, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §7645: ClosedAt decision refusal boundaries are realized as finite checker, bounded-normal, refusal, transport, replay, provenance, and NameCert rows.

9386.6 TypedExamples coverage questions

The typed-examples map in chapter 9382 supplies a worked gallery: Church booleans, naturals, pairs, options, lists, sums, Leibniz equality, dependent identity, polymorphic identity, applications, beta-redexes, constants, Pi forms, projections, and sort-indexed context examples. These examples are Lean-side witnesses for concrete represented terms.

The open question is coverage, not existence. The gallery demonstrates many typical dependent, polymorphic, Church-encoded, and application-shaped terms, but it does not claim exhaustive coverage of all dependent-program forms or all expected algebraic laws of every Church encoding inside MetaCIC. The examples therefore remain a regression and audit surface rather than a general metatheorem.

The practical frontier is to decide which example families should be treated as representative enough for the paper's public narrative. Dependent codomains, polymorphic instantiation, eliminator computation, nested binder movement, and conversion-sensitive examples are the highest-value families because they touch the same boundaries as subject reduction, normalisation, and decidable conversion.

Concretized in §6650: Dependent eliminator coverage packets realize the typed-examples coverage frontier as finite typed-window, eliminator-family, conversion-boundary, gallery-status, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §6883: Polymorphic-instantiation coverage packets realize the typed-example frontier as finite universe-instantiation, typed-window, conversion-boundary, obstruction, transport, replay, provenance, and NameCert rows.

9386.7 Cross-cutting frontier questions

9386.7.1 Dependent-codomain barrier

Subject reduction is not unconditionally available in the dependent-codomain case. The independent-codomain application case is checked, while the dependent case has a counterexample in the present substrate. This is the obstruction that prevents the closed-normal consistency result from automatically becoming full closed consistency.

There are three coherent routes through the barrier. One can change the substrate so that a context-reduction lemma is available. One can weaken the subject-reduction statement so that it accepts the typing reorganisation forced by dependent codomains. One can also expose dependent-codomain inversion as a setup field or axiom-set-shaped interface rather than as an internal theorem. Each route changes the public meaning of the substrate, and none is taken here.

9386.7.2 Bundle discharge route

The discharge-bundle route is conceptually clean. A value of SubjectReductionDischargeBundle packages the four subject-reduction inputs, and the corresponding wrapper lifts the parameterised theorem to an unconditional theorem relative to that bundle. This makes the discharge interface first-class without spreading the four hypotheses through every downstream citation.

The same route also states the obstruction sharply. On the present closed-term substrate, inhabiting the bundle at the required strength is incompatible with the documented obstruction. The bundle is therefore a marker for a paper-side discharge path or for a substrate extension, not evidence that the closed-term substrate already contains the missing proof.

9386.7.3 Normal-form-only consistency

chapter 9375 establishes the positive closed-normal node. A closed proof term that is already beta-strong cannot inhabit the internal false encoding. This result is unconditional at its stated input shape and does not depend on discharging subject reduction.

The open judgement is presentational and strategic. The paper can treat normal-form consistency as a first-class BEDC deliverable, because it is a real closed theorem at the normal-form boundary. Doing so would avoid overstating full closed consistency while still making the checked positive result visible as a central endpoint.

9386.7.4 Substrate extension for dependent-codomain closure

The strongest design decision is whether to extend the closed-CIC substrate so that dependent-codomain reduction can be closed internally. Such an extension could make the conventional subject-reduction route possible, but it would also change the substrate interface and the audit obligations that downstream chapters must respect.

The conservative alternative is to keep the present substrate and report the closed-normal theorem as the main internal result. The expansive alternative is to add the exact context-reduction or setup-class field needed by the dependent-codomain cases, then re-audit subject reduction, confluence, normalisation, decidability, and examples against that enlarged interface.

9386.8 Operational priorities

The apophatic naming discipline of chapter 9400 is binding here. The paper should not pretend that the obligations above are solved. They are named open problems with exact interfaces.

The reader-facing priority order is:

1. Treat closed-normal consistency as a first-class deliverable. It is the strongest presently assembled consistency node and it does not require subject-reduction discharge.
2. Explore a setup-class field route for dependent-codomain inversion. This keeps the additional input explicit and avoids converting the obstruction into an untracked theorem claim.
3. Keep the subject-reduction obstruction documented. It should not be hidden behind a proof placeholder, an informal appeal to CIC intuition, or an overbroad citation of the parameterised theorem.

This priority order also constrains citations. The paper may cite the checked normal-form result, the parameterised subject-reduction theorem, the shape-limited confluence fragments, the candidate-mediated normalisation projections, the typing checker, the bounded normal-equality facts, and the typed-example gallery. It may not cite any of those as full closed consistency, arbitrary closed subject reduction, arbitrary closed Church–Rosser, global closed-term strong normalisation, or unrestricted beta-conversion decidability.

9386.9 Boundary

This chapter is an inventory, not a discharge. It consolidates the open MetaCIC work exposed by the existing audit maps and the consistency assembly. It does not prove any of the four subject-reduction obligations. It does not prove residual substitution compatibility for full confluence. It does not erase candidate evidence from normalisation, finished-normalisation evidence from bounded conversion, or gallery scope from typed examples.

The boundary is therefore simple: the chapter names the remaining problems and the available design routes, while leaving the proof state exactly where the Lean and paper audit maps place it.

Concretized in §763: finite ledger carrier for the MetaCIC open-obligation boundary

Concretized in §762: The MetaCIC open-problem inventory is realized as a finite frontier ledger over subject-reduction, confluence, normalization, decidability, typed-example, and consistency-boundary rows.

Concretized in §780: MetaCIC open problems are realized as a finite NameCert ledger for remaining subject-reduction, confluence, normalization, substitution, decidability, typed-example, and blocker rows.

Concretized in §781: The dependent-codomain barrier is realized as a finite NameCert packet for codomain readback, discharge handoff, and obstruction-boundary rows.

Concretized in §892: The normalization frontier is realized as a finite NameCert packet separating candidate evidence, finished-normal evidence, closed-normal use, and subject-reduction obstruction rows.

Concretized in §1008: The MetaCIC beta-redex frontier is realized as a finite NameCert packet for discharge-row coverage, beta-boundary routing, and obstruction non-escape.

Concretized in §3434: The decidable beta frontier realizes bounded MetaCIC beta-audit windows as finite NameCert data.

Concretized in §1100: The consolidated open-problem surface is realized as a finite frontier-witness NameCert packet.

Concretized in §2274: Candidate-mediated strong-normalization and confluence-boundary rows are realized as one finite MetaCIC NameCert packet.

Concretized in §3626: The dependent-codomain stability boundary is realized as a finite MetaCIC NameCert packet.

Proposition 9386.1 (Lambda-domain discharge row is mandatory)**.** *Consider a MetaCIC subject-reduction discharge route through the explicit bundle interface* SubjectReductionDischargeBundle *of chapter 9374. If that route is used to make the parameterised subject-reduction theorem available for the represented reduction relation, then its finite discharge packet contains a distinct row LD satisfying* LamDomainSubjectReduction*. This row is the lambda-domain congruence obligation of Definition 9377.3; it cannot be supplied by the beta-substitution row, the application-argument row, the Pi-domain row, transport, continuation replay, package provenance, or local naming.*

Proof. The four-obligation audit of section 9377.3 separates the reduction shapes consumed by the parameterised subject-reduction theorem. The lambda-domain shape is named by Definition 9377.3: if $\lambda d.\, b$ has type A in Γ and d steps to d', the target lambda $\lambda d'.\, b$ must still have type A in the same context. This is a binder-annotation preservation requirement, not a beta-redex substitution requirement and not an application-codomain stability requirement.

Read the explicit bundle route from subsection 9374.2.1. The bundle has four discharge fields, and one of them is the lambda-domain field. Therefore any use of the bundle route carries the lambda-domain row as a named component of the finite packet.

The finite ledger form gives the same conclusion at the BEDC packet surface. In Definition 720.1 an accepted SubjectReductionDischargeLedger$^{\uparrow}$ carrier is displayed as

$$L = (B, A, LD, PD, R, H, C, P, N),$$

where LD is the lambda-domain subject-reduction row and R is the route that consumes exactly B, A, LD, PD. The handoff theorem Definition 720.3 confines subject-reduction consumption to those four obligation rows through R, and the non-escape theorem Definition 720.4 confines downstream reads to the displayed packet. Hence H, C, P, N can transport, replay, authenticate, and name the route, but none of them can create or replace the missing lambda-domain preservation row.

Consequently, whenever the MetaCIC subject-reduction discharge interface is used, LamDomainSubjectReducti is a required finite discharge obligation row. Supplying the other rows without LD leaves the discharge interface incomplete for the lambda-domain congruence case. □

Proposition 9386.2 (Application-argument stability is a required discharge row)**.** *Let a MetaCIC subject-reduction consumer use the discharge interface through a* SubjectReductionDischargeBundle *as described in chapter 9374. Suppose the consumer reads a finite discharge socket*

$$O = (B, A, L, P, H, C, Q, N)$$

as in Definition 719.1. If the consumed reduction branch is application-argument congruence, then the required discharge input is exactly the row A matching AppArgTypeStable *of Definition 9377.2. It cannot be replaced by the beta row B, the lambda-domain row L, the Pi-domain row P, the independent-codomain application theorem, or the closed-obstruction row recorded in Q.*

Proof. Read the four-obligation interface of section 9377.3. The application-argument congruence branch is governed there by AppArgTypeStable, while BetaSubstitutionPreservation, LamDomainSubjectReductio and PiDomainSubjectReduction govern the beta, lambda-domain, and Pi-domain branches. Thus the branch classifier already separates the application-argument input from the other three discharge rows.

Now read the socket carrier. In

$$O = (B, A, L, P, H, C, Q, N),$$

row A is the application-argument stability row, and the remaining rows have distinct roles: B is beta substitution preservation, L is lambda-domain preservation, P is Pi-domain preservation, H transports displayed rows, C replays displayed routes, Q records provenance together with the parameterised subject-reduction row and the closed-obstruction boundary, and N names the local certificate. Therefore a socket read for the application-argument branch has only one matching discharge coordinate, namely A.

The bundle route does not change that payload. By chapter 9374, a SubjectReductionDischargeBundle is the four-field packet for the same four hypotheses. Therefore route consumption cannot remove the application-argument row or identify it with one of the other three fields.

Finally separate the positive narrow case from the full discharge interface. The independent-codomain application theorem applies only where the codomain readback is already stable because the codomain is independent of the argument. The present proposition concerns the subject-reduction discharge interface used for the application-argument congruence branch in general, including the dependent-codomain boundary identified in section 9377.7. At that boundary, the codomain can observe the reducing argument, so the interface must carry the explicit AppArgTypeStable row. The obstruction row in Q records the absence of a closed theorem and is not one of the four discharge inputs. Thus A is an explicit finite discharge obligation whenever the interface is consumed for the application-argument branch. □

Proposition 9386.3 (Beta-substitution preservation is a mandatory discharge row)**.** *Any use of the MetaCIC subject-reduction discharge interface must expose* BetaSubstitutionPreservation *as a finite discharge obligation. More precisely, a subject-reduction call that follows the explicit* SubjectReductionDischargeBundle *route has a distinguished beta row whose content is exactly the obligation of Definition 9377.1. That row is not supplied by* AppArgTypeStable*,* LamDomainSubjectReduction*,* PiDomainSubjectReduction*, the dependent-codomain obstruction theorem, or the closed-normal consistency assembly.*

Proof. Read the four-obligation interface from section 9377.3. The first field is BetaSubstitutionPreservation, and Definition 9377.1 identifies its content: body typing under the shifted-domain context and argument typing at the unshifted domain must yield typing of the substituted body at the substituted codomain. This is the beta-redex preservation case, not an application-argument stability case and not a binder-domain congruence case.

Now read the public discharge route. In the bundle route of section 9374.2, SubjectReductionDischargeBundle is the four-field packet consumed by the subject-reduction wrapper. Since the beta field is one of those four fields, constructing the packet requires a beta-substitution preservation row before the wrapper can be invoked.

The remaining three rows have disjoint jobs. AppArgTypeStable stabilizes codomain readback when reduction enters an application argument, while LamDomainSubjectReduction and PiDomainSubjectReduction preserve displayed binder annotations when reduction enters lambda

and Pi domains. None of those statements contains the beta-redex premise-conclusion shape from Definition 9377.1. They therefore cannot fill the beta field of the bundle packet.

Finally, the obstruction material in chapter 9377 has the opposite polarity: it blocks replacing the four-input interface by a blanket closed subject-reduction theorem for the present substrate. It does not discharge any field. Hence a consumer that uses the MetaCIC subject-reduction discharge interface must carry BetaSubstitutionPreservation explicitly as the finite beta discharge row, and the interface remains unavailable as a closed subject-reduction theorem until that row is supplied together with the other three discharge rows. □

Proposition 9386.4 (Pi-domain discharge row is mandatory)**.** *Consider a MetaCIC subject-reduction discharge route through the explicit bundle interface* SubjectReductionDischargeBundle *of chapter 9374. If that route is used to make the parameterised subject-reduction theorem available for the represented reduction relation, then its finite discharge packet contains a distinct Pi-domain row satisfying* PiDomainSubjectReduction*. This row is the Pi-domain congruence obligation of Definition 9377.4; it cannot be supplied by the beta-substitution row, the application-argument row, the lambda-domain row, transport, continuation replay, package provenance, or local naming.*

Proof. Read the four-obligation audit of section 9377.3. The Pi-domain branch is named by Definition 9377.4: if $\Pi d.\, c$ has type A in Γ and the displayed domain d steps to d', the target Pi term $\Pi d'.\, c$ must still have type A in the same context. This is the Pi-binder domain preservation case. It is not the beta-redex substitution case, not the application-argument codomain-readback case, and not the lambda-domain binder-annotation case.

The public route preserves that separation. In the explicit route of subsection 9374.2.1, SubjectReductionDischargeBundle is the four-field packet for the four subject-reduction hypotheses, including the Pi-domain field. Thus route consumption cannot remove the Pi-domain coordinate or identify it with any other coordinate.

The socket and ledger surfaces display the same finite row. In Definition 719.1 an accepted socket is

$$O = (B, A, L, P, H, C, Q, N),$$

where P is the Pi-domain subject-reduction row. The four-row exactness theorem Definition 719.8 says that the subject-reduction ledger consumes exactly B, A, L, P and may not replace one of those four rows, add a fifth discharge row, or treat the obstruction boundary as discharge evidence. Hence a socket consumer for the Pi-domain branch has only one matching discharge coordinate, namely P.

The ledger notation records the same coordinate as PD. By Definition 720.1 an accepted ledger is

$$L = (B, A, LD, PD, R, H, C, P, N),$$

where PD matches PiDomainSubjectReduction and R consumes exactly B, A, LD, PD. The handoff theorem Definition 720.3 confines subject-reduction consumption to those four obligation rows through R, and the non-escape theorem Definition 720.4 confines downstream reads to the displayed packet. Therefore H, C, P, N can transport, replay, authenticate, and name the finite route, but none of them can create or replace the missing Pi-domain preservation row.

Consequently, whenever the MetaCIC subject-reduction discharge interface is consumed for the Pi-domain congruence branch, PiDomainSubjectReduction is a required finite discharge obligation row. Supplying the beta, application-argument, and lambda-domain rows without the Pi-domain row leaves the discharge interface incomplete for that branch. □

Concretized in §2307: The MetaCIC open frontier is realized as a finite dependency matrix over discharge rows, obstruction rows, and audit-map consumers.

Concretized in §3352: The Pi-domain subject-reduction obligation is realized as a finite closed MetaCIC NameCert packet.

Concretized in §3381: The lambda-domain subject-reduction obligation is realized as a finite closed MetaCIC NameCert packet.

Concretized in §3460: Proof-obligation gap packets realize the MetaCIC subject-reduction obstruction as finite named obligation, refusal, handoff, transport, replay, provenance, and NameCert rows.

Concretized in §3567: The candidate-mediated strong-normalization frontier is realized as finite MetaCIC NameCert data.

Concretized in §4292: The MetaCIC normal-endpoint budget is realized as finite candidate evidence, bounded-normal endpoint, finished-normal seal, obstruction, transport, replay, provenance, NameCert, and TasteGate rows.

Concretized in §6111: The four subject-reduction discharge rows are realized as a finite socket-preserving NameCert boundary.

Concretized in §6577: Candidate-normalization witnesses realize the MetaCIC normalization frontier as finite candidate-evidence, endpoint, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §6617: Typed normal-form scheduler packets realize the normalization open problem as finite candidate-gate, scheduler-budget, endpoint-seal, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §6922: Subject-reduction discharge matrices realize the four simultaneous MetaCIC discharge rows as finite NameCert data.

Concretized in §8837: MetaCIC subject-reduction obstruction witnesses realize the simultaneous four-row obstruction surface as finite beta-substitution, application-argument, lambda-domain, Pi-domain, matrix, proof-obligation-gap, obstruction, socket, transport, replay, provenance, and NameCert rows.

Concretized in §8051: The residual-confluence budget packet realizes the MetaCIC confluence frontier as finite typed-window, residual-pair, local-join, bounded-checker, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §8456: Residual normal-form budget routers realize the MetaCIC residual and normalization frontier as finite typed-window, residual-budget, scheduler-budget, endpoint-seal, candidate-handoff, obstruction, transport, replay, provenance, and NameCert rows.

Concretized in §3437: finite critical-pair ledger for MetaCIC audit-map concretization

Concretized in §3519: MetaCIC redex-choice frontier packets realize candidate-mediated normalization and confluence boundaries as finite BEDC rows.

Concretized in §4238: MetaCIC parallel-diamond frontier packets realize the bounded residual and critical-pair route for candidate-mediated confluence inspection.

Concretized in §7797: MetaCIC residual-substitution socket packets connect normalization and confluence audit surfaces through finite residual source, substitution-window, candidate-boundary, and confluence socket rows.

Concretized in §7893: MetaCIC residual-diamond readback packets realize candidate-mediated residual, local witness, and L10 source-ledger routes as finite NameCert rows.

Concretized in §8369: MetaCIC audit synthesis routers realize the subject-reduction, confluence, normalization, substitution, decidability, blocker, and open-input rows as one finite NameCert packet.

Chapter 9387

Three Axiom Families, One Meta-Closure Taxonomy

This chapter gives a taxonomy for three axiom families that BEDC refuses to internalise: the axiom of choice, quotient soundness, and propositional extensionality. The taxonomy normalizes them as three shapes of unwitnessed closure rather than proving a metatheorem that the host axioms are equivalent to three ontic collapses. Choice is read as term-level acceptance of an unwitnessed selection function; quotient soundness is read through a quotient-facing classifier-to-equality shape; propositional extensionality is read as proposition-level acceptance of equality from bidirectional implication. These readings are interpretive specifications for the axiom-purity gate, not Lean-checked equivalences with Classical.choice, core Quot.sound, or propext. This chapter (i) records the three schematic readings as "accept an unwitnessed $\exists$ as argument input", (ii) states the taxonomy that places them under one meta-closure heading, (iii) pairs each reading with its BEDC effective replacement – countable and dependent choice plus the finite case via explicit recursion for choice, the typed naming certificate framework of chapter 9 with classifier-respecting transport for quotient soundness, and explicit hsame / psame transport for propositional extensionality – and (iv) records that the project's axiom-purity gate is therefore a refusal of hidden closure rather than a rejection of the application content the three axiom families serve.

9387.1 The three axiom families as taxonomy entries

Definition 9387.1 (Meta-closure operation)**.** *A* meta-closure operation *at a syntactic stratum $S \in \{term, type, proposition\}$ is a derivation step that, given a positive existential statement at stratum S together with no constructor witness, supplies a value of S as if a witness had been given. The accepted value plays the role of an oracle: it appears as input to subsequent constructions inside the kernel without being traceable to a closed inductive constructor.*

Example 9387.2 (Choice as term-level meta closure)**.** *The axiom of choice asserts: from $\forall i \in I, \exists x_i \in A_i$, conclude $\exists f : I \to \bigsqcup A_i$ with $f\, i \in A_i$. Read at the term stratum, the conclusion is a term f of function type whose body is not constructed from the existential witnesses. The axiom supplies f as an oracle; the body is unwitnessed and therefore inaccessible to kernel-level computation. In this taxonomy it is the term-level entry for Definition 9387.1.*

Example 9387.3 (Quotient soundness as type-level meta closure)**.** *The quotient-soundness reading used here is a quotient-facing specification shape: from a relation R on a type A, a consumer*

receives equality or representative behavior at the class level without displaying the classifier transport that produced it. This is not a formal account of Lean core Quot.sound*, and it is not a proof that Lean quotients supply canonical representative selectors. It is the type-level entry in the taxonomy of Definition 9387.1.*

Example 9387.4 (Propositional extensionality as proposition-level meta closure)**.** propext *asserts: from $P \Leftrightarrow Q$, conclude $P = Q$ at the proposition level. The conclusion identifies two propositions whose only relation is bidirectional implication; reading the identification at the proposition stratum,* propext *supplies an unwitnessed equality of propositions. In this taxonomy it is the proposition-level entry for Definition 9387.1.*

9387.2 The unification taxonomy

Principle 9387.5 (The three axiom families share one taxonomy)**.** *Choice (Definition 9387.2), the quotient-facing soundness shape (Definition 9387.3), and* propext *(Definition 9387.4) are classified under the meta-closure schema of Definition 9387.1. The classification is by syntactic stratum: term, type or classifier, and proposition. It licenses the refusal ledger's organization; it does not assert that a Lean metatheory has proved the three host constants equivalent to three BEDC collapse modes.*

Explanation. The three examples display a common specification pattern: an unavailable witness, equality token, or class-level bridge is treated as ordinary input to later construction. The differences across choice, the quotient-facing soundness shape, and propext are the strata at which that pattern is requested. This is enough to sort the refusal ledger stratum by stratum. The argument is not a metatheoretic equivalence proof for Lean's forbidden constants. □

Concretized in §515: Unwitnessed-existence closure is realized as a finite NameCert packet over term, type, and proposition strata, with explicit replacement and axiom-purity ledger rows.

Concretized in §566: Propext transport boundaries realize the proposition-stratum replacement as finite direction, transport, replay, and non-escape NameCert rows.

Concretized in §568: Effective replacement ledgers realize choice witnesses, quotient transport, propext transport, and axiom-purity refusal as one finite NameCert packet.

Concretized in §634: Quotient-soundness refusal is realized as a finite NameCert packet replacing representative selection by classifier-respecting psame transport and audit-visible non-escape.

Concretized in §1012: Term-stratum choice closure is realized as a finite witness-map and oracle-refusal NameCert packet.

Concretized in §6939: The three-axiom closure route is realized as finite closure, generator-induction, refusal, transport, replay, provenance, and NameCert rows.

9387.3 Effective replacements inside BEDC

Definition 9387.6 (Effective replacement for choice)**.** *The BEDC* effective replacement for choice *is the package consisting of: countable choice on $\mathbb{N}$-indexed families with explicit witness functions; dependent choice along a* Cont*-chain with explicit step functions; and finite choice via primitive recursion on a closed inductive list. Each replacement supplies a witness function whose body is constructed from the kernel-level data of the assumption.*

Definition 9387.7 (Effective replacement for `Quot`-soundness)**.** *The BEDC* effective replacement for `Quot`-soundness *is the typed naming-certificate framework of chapter 9. Two carrier elements identified by a classifier are not collapsed at the type level; instead, the certificate exposes a* psame-*transport that lets every classifier-respecting operation pass through the identification without selecting a canonical representative.*

Definition 9387.8 (Effective replacement for propext)**.** *The BEDC* effective replacement for propext *is the explicit* hsame *and* psame *transport on every certificate. Two propositions P, Q that are bidirectionally implied are not identified; instead, every kernel-level construction that consumes P receives a Q-version via the bidirectional implication, and the construction is parameterised over the chosen direction.*

Theorem 9387.9 (Replacements suffice for BEDC's certified content)**.** *Every theorem in the manuscript whose statement is supported by a Lean-checked-level marker is provable using only the replacements of Definition 9387.6, Definition 9387.7, and Definition 9387.8 in place of the three classical axioms.*

Sketch. The replacements are themselves kernel-level constructions on closed inductive carriers. A traversal of the manuscript's certified content maps each invocation of choice to countable, dependent, or finite choice; each invocation of `Quot`-soundness to certificate-level psame-transport; and each invocation of propext to a hsame-mediated rewrite. The traversal terminates because the certified content is finite and the replacement is uniform across applications of each axiom. □

9387.4 The axiom-purity gate as refusal of meta closure

Remark 9387.10 (The gate's structural meaning)**.** *The project's axiom-purity gate (`axiom-purity -strict` in `lean4/scripts/bedc_ci.py`) refuses every kernel-level theorem whose transitive dependencies include* Classical.choice*,* Quot.sound*, or* propext*. Read through the taxonomy of Definition 9387.5, the gate is organized as a refusal at three strata: term, type or classifier, and proposition. The gate is therefore not a rejection of the application content the three axiom families serve; it is a refusal of unledgered shortcuts that supply that content without constructive witnesses or displayed transport.*

9387.5 Assumed bridges and derived bridges

The taxonomy above should not be read as a claim that the classical axioms are syntactically ill-typed in their host theories. They are well-typed constants there. The BEDC diagnosis is sharper: each constant inhabits a bridge type whose source and target belong to different audit strata, but the inhabitant is assumed rather than derived from displayed constructor, classifier, ledger, transport, or NameCert data.

Definition 9387.11 (Proposition existence and data witness)**.** *For $A : \mathsf{Type}$ and $P : A \to \mathsf{Prop}$, the proposition-level existence claim is*

$$\mathsf{ExistsProp}(A, P) := \exists x : A,\ P(x),$$

while the data-level witness package is

$$\mathsf{SigmaData}(A, P) := \sum_{x:A} P(x).$$

The first expression asserts existence as a proposition. The second displays a term together with the proof carried by that term.

Definition 9387.12 (Unledgered cross-stratum bridge)**.** *A map $c : A \to B$ is an* unledgered cross-stratum bridge *when A and B are consumed at different audit strata, c is later used as an ordinary kernel input, and no constructor, definition, classifier, transport row, ledger, setup field, or* NameCert *row derives c from displayed data.*

Principle 9387.13 (The three axiom families are read as assumed bridges)**.** *In their host theories,* Classical.choice*,* Quot.sound*, and* propext *are not type errors. In BEDC's audit reading they are treated as assumed bridge shapes:*

$$\begin{aligned} \mathsf{Classical.choice} &: \mathsf{ExistsProp}(A, P) \to \mathsf{SigmaData}(A, P), \\ \mathsf{Quot.sound} &: \ x \sim y \to [x] = [y], \\ \mathsf{propext} &: \ (P \Leftrightarrow Q) \to (P = Q). \end{aligned}$$

Each bridge turns source-side relation or existence data into a kernel-consumable object without displaying the derivation of that object.

Explanation. The three displayed types are meaningful in the host environment that admits the corresponding constants. Thus the issue is not syntactic well-typedness. For choice, the bridge turns a proposition-level existential into a data-level dependent pair. For quotient soundness, it turns a classifier witness into equality at a quotient-facing point. For propositional extensionality, it turns bidirectional implication into equality of propositions. In each case, if the constant is removed, the bridge term is not supplied by the source datum alone. It is therefore an assumed bridge from the BEDC viewpoint, not a derived bridge. □

Definition 9387.14 (Type-honest fragment)**.** *A BEDC fragment is* type-honest *when it refuses unledgered bridges of the following forms:*

$$\mathsf{ExistsProp}(A, P) \to \mathsf{SigmaData}(A, P), \qquad x \sim y \to [x] = [y], \qquad (P \Leftrightarrow Q) \to (P = Q).$$

If the fragment also uses apophatic far-end language, type honesty additionally refuses any socket-to-element bridge of the form $\mathsf{T} : X$ or $\mathsf{T} \in X$.

Principle 9387.15 (Axiom-purity as type honesty)**.** *The axiom-purity gate for* Classical.choice*,* Quot.sound*, and* propext *is the mechanical face of the type-honesty taxonomy in Definition 9387.14. It rejects assumed bridges where the manuscript requires derived bridges.*

Explanation. By Definition 9387.13, the three forbidden constants inhabit the three unledgered bridge shapes. By Definition 9387.14, a type-honest fragment does not consume those bridge shapes unless a displayed replacement is provided. The gate therefore checks the same discipline at dependency level: an implementation using one of the constants has exposed an assumed bridge in its proof ancestry. □

Remark 9387.16 (`#print axioms` reports an implementation footprint)**.** *The command* `#print axioms` *reports the transitive dependencies of a particular Lean declaration. If it lists* Classical.choice*,* Quot.sound*, or* propext*, the conclusion is that this implementation consumed those bridge assumptions. The report is not a lower bound proving that every possible construction of the same mathematical object must consume them.*

Remark 9387.17 (Sibling instance: halting and reasoning by contradiction)**.** *The chapter's taxonomy (Definition 9387.5) sits in a family with the halting capstone (chapter 9368) and the reasoning-by-contradiction capstone (chapter 9458): all three identify a different audit face of meta-closure refusal. Halting names the operational-semantics face; reasoning by contradiction names the proof-theoretic face; the present chapter names the foundational-axiom face. Together they constitute the discipline side of the two-loops architecture (Definition 9461.15).*

Definition 9387.18 (Term-stratum choice closure)**.** *Fix an index carrier I, an ambient term carrier U, and a family of positive fiber predicates $A_i \subseteq U$. The* term-stratum choice closure schema *is the following instance of Definition 9387.1: from an accepted family of positive existentials*

$$H : \forall i \in I,\ \exists x : U,\ x \in A_i$$

with no displayed constructor-level selection of such terms, introduce a term $o_H : I \to U$ and membership evidence $o_H(i) \in A_i$ for each i. The term $o_H(i)$ is then available as an oracle input to later term-level constructions.

Principle 9387.19 (Choice as term-stratum meta-closure reading)**.** *For arbitrary indexed families A_i, the term-stratum choice closure schema of Definition 9387.18 is the specification shape used here to read the axiom-of-choice principle of Definition 9387.2:*

$$(\forall i \in I,\ \exists x_i,\ x_i \in A_i) \Longrightarrow \exists f : I \to \bigsqcup_{i \in I} A_i,\ \forall i \in I,\ f(i) \in A_i.$$

Here $f(i) \in A_i$ abbreviates that the value of f lies over the i-fiber of the displayed coproduct.

Explanation. Assume the term-stratum closure schema. Given $H : \forall i \in I, \exists x_i, x_i \in A_i$, the schema supplies an oracle term $o_H : I \to U$ with evidence $o_H(i) \in A_i$ for every i. Define $f(i) = (i, o_H(i))$ as an element of the displayed coproduct $\bigsqcup_{i \in I} A_i$. The fiber evidence supplied with o_H proves $f(i) \in A_i$ for each i, so f has the displayed choice-function shape.

Conversely, if the displayed axiom-of-choice principle is admitted, then for a term-stratum closure datum $H : \forall i \in I, \exists x_i, x_i \in A_i$ it produces a function $f : I \to \bigsqcup_{i \in I} A_i$ with $f(i) \in A_i$ for every i. Let $o_H(i)$ be the component of $f(i)$ in the i-fiber. The accompanying fiber proof is the evidence required to use $o_H(i)$ as the accepted value of the existential at i. Thus the schema records the same consumer-facing shape as the choice principle. The point is the audit shape, not an independent Lean theorem equating all formulations of choice. □

Definition 9387.20 (Quotient representative package)**.** *Let A be a type and let R be an equivalence relation on A. A* quotient representative package *for (A, R) is a triple (Q, π, ρ) with*

$$Q : \mathsf{Type}, \qquad \pi : A \to Q, \qquad \rho : Q \to A,$$

such that

$$\forall a\, b : A,\ R(a, b) \Longrightarrow \pi(a) = \pi(b),$$
$$\forall u : Q,\ \pi(\rho(u)) = u,$$

and

$$\forall a : A,\ R(\rho(\pi(a)), a).$$

Write $\mathsf{QRep}_{A,R}(Q, \pi, \rho)$ for this conjunction. The second displayed condition says that ρ is a section of π; the third says that the selected representative of the class of a remains in the R-class of a.

Lemma 9387.21 (Quotient representative packages are exact)**.** *Let R be an equivalence relation on A. If $\mathsf{QRep}_{A,R}(Q, \pi, \rho)$ holds, then for all $a, b : A$,*

$$\pi(a) = \pi(b) \iff R(a, b).$$

Proof. The reverse implication is the soundness field of $\mathsf{QRep}_{A,R}(Q, \pi, \rho)$. For the forward implication, assume $e : \pi(a) = \pi(b)$. Representative adequacy gives $R(\rho(\pi(a)), a)$ and $R(\rho(\pi(b)), b)$. Transport the second witness along congruence of ρ applied to e, obtaining $R(\rho(\pi(a)), b)$. Symmetry of the first witness gives $R(a, \rho(\pi(a)))$, and transitivity with the transported second witness gives $R(a, b)$. □

Definition 9387.22 (Type-stratum quotient closure)**.** *For a type A and an equivalence relation R on A, the* type-stratum quotient closure schema *is the following instance of Definition 9387.1: from the positive existential*

$$\exists Q : \mathsf{Type},\ \exists \pi : A \to Q,\ \exists \rho : Q \to A,\ \mathsf{QRep}_{A,R}(Q, \pi, \rho)$$

with no displayed constructor-level witness for Q, π, or ρ, introduce such a triple as accepted type-level data. The accepted type is read as A/R, and the accepted selector is available as an oracle input to later type-level constructions.

Principle 9387.23 (Quotient-facing soundness as type-stratum reading)**.** *At the schema level, the type-stratum quotient closure schema of Definition 9387.22 is the paper's quotient-facing proxy for the* `Quot`*-soundness refusal of Definition 9387.3. It packages the consumer-facing data as a type Q, a projection, and a representative section. This proxy is a specification device for BEDC's refusal ledger, not a statement that Lean core* Quot.sound *supplies such a selector or that the proxy has been proved equivalent to Lean's quotient implementation.*

Explanation. Assume the type-stratum quotient closure schema. Given A and R, instantiate the positive existential in Definition 9387.22. The schema supplies Q, π, and ρ satisfying $\mathsf{QRep}_{A,R}(Q, \pi, \rho)$. By Definition 9387.21, equality in Q tracks the classifier R on representatives inside this proxy package, so Q may be read as quotient-facing data for the local schema. The section and representative-adequacy fields make ρ the selected representative row of the proxy package.

Conversely, if a host-side quotient-facing package supplies a type, projection, and representative section with the displayed properties, then it fills the existential datum accepted by Definition 9387.22. The two readings therefore align at the level of this paper schema. The BEDC replacement in Definition 9387.7 refuses the selector ρ and keeps classifier-respecting psame-transport instead. □

Definition 9387.24 (Proposition-stratum propext closure)**.** *For propositions $P, Q : \mathsf{Prop}$, a* proposition-stratum closure datum *is a bidirectional implication*

$$b_{P,Q} : (P \Rightarrow Q) \wedge (Q \Rightarrow P).$$

The proposition-stratum propext closure schema *is the following instance of Definition 9387.1: from such a datum, with no displayed constructor-level inhabitant of the identity proposition $P = Q$, accept the identity proposition as inhabited by supplying an equality token*

$$\varepsilon_{P,Q} : P = Q.$$

The token is then available as input to later proposition-stratum constructions by rewrite transport in every proposition-valued context $C : \mathsf{Prop} \to \mathsf{Prop}$.

Principle 9387.25 (Propext as proposition-stratum meta-closure reading)**.** *The proposition-stratum propext closure schema of Definition 9387.24 is the specification shape used here to read propositional extensionality:*

$$\forall P, Q : \mathsf{Prop},\ (P \Leftrightarrow Q) \Rightarrow P = Q.$$

In this reading, the accepted oracle value in Definition 9387.1 is the equality token $\varepsilon_{P,Q}$. This is a specification-level identification of shape, not a separate metatheoretic proof about every formulation of propositional extensionality.

Explanation. Assume the proposition-stratum propext closure schema. Let $P, Q : \mathsf{Prop}$ and let $h : P \Leftrightarrow Q$. The datum h is a pair of implications $P \Rightarrow Q$ and $Q \Rightarrow P$. Applying the schema to this datum supplies an equality token $\varepsilon_{P,Q} : P = Q$, which has the consumer-facing shape of propositional extensionality.

Conversely, if propositional extensionality is admitted, then a proposition-stratum closure datum $b_{P,Q} : (P \Rightarrow Q) \wedge (Q \Rightarrow P)$ can be sent to an equality $P = Q$. Equality elimination along that token supplies contextual rewrite behavior for proposition-valued contexts. Thus the schema records the same consumer-facing route as the extensionality principle. The claim remains a taxonomy of route shape. □

Definition 9387.26 (Primitive-recursive countable witness map)**.** *Let $A : \mathbb{N} \to \mathsf{Type}$ and let $w : \forall n : \mathbb{N}, A(n)$. Put*

$$\Sigma A := \bigsqcup_{k:\mathbb{N}} A(k).$$

The associated primitive-recursive countable witness map *is the function*

$$\mathsf{cw}_{A,w} : \mathbb{N} \to \Sigma A$$

defined by the primitive-recursion clauses

$$\mathsf{cw}_{A,w}(0) = (0, w(0)), \qquad \mathsf{cw}_{A,w}(n+1) = (n+1, w(n+1)).$$

Equivalently,

$$\mathsf{cw}_{A,w} = \mathsf{rec}_{\mathbb{N}}\big((0, w(0))\big)\big(\lambda n\, r.\, (n+1, w(n+1))\big),$$

where the step variable r is ignored because the premise supplies the witness in the next fiber.

Theorem 9387.27 (Countable choice is realized by primitive recursion)**.** *For every family $A : \mathbb{N} \to \mathsf{Type}$ and every displayed witness family $w : \forall n : \mathbb{N}, A(n)$, the map $\mathsf{cw}_{A,w}$ of Definition 9387.26 is a fiberwise choice function:*

$$\forall n : \mathbb{N},\ \mathsf{cw}_{A,w}(n) \in A(n).$$

Here membership uses the displayed-coproduct convention of Definition 9387.19: the value lies over the n-fiber, and its second component inhabits that fiber. The construction uses only the $\mathbb{N}$ recursor and dependent-pair introduction, so it is an instance of Definition 9387.6 and does not invoke the term-stratum choice closure of Definition 9387.18.

Proof. Induct on n. At 0, the first recursion clause gives

$$\mathsf{cw}_{A,w}(0) = (0, w(0)),$$

whose first projection is 0 and whose second projection is the displayed term $w(0) : A(0)$. Hence $\mathsf{cw}_{A,w}(0)$ lies in the 0-fiber.

For the successor case, the second recursion clause gives

$$\mathsf{cw}_{A,w}(n+1) = (n+1, w(n+1)).$$

Its first projection is $n+1$, and its second projection is the displayed term $w(n+1) : A(n+1)$. Thus $\mathsf{cw}_{A,w}(n+1)$ lies in the $(n+1)$-fiber. This proves the displayed universal statement. No step eliminates an unwitnessed existential: the only fiber element used at index n is the constructor-level term $w(n)$, so no oracle selector or Classical.choice enters the construction. □

Corollary 9387.28 (Witnessed countable choice for predicates)**.** *Let $B : \mathbb{N} \to \mathsf{Type}$ and let $P : \forall n : \mathbb{N}, B(n) \to \mathsf{Prop}$. If*

$$H : \forall n : \mathbb{N}, \bigsqcup_{x:B(n)} P(n, x)$$

is a constructor-level family of existential witnesses, then there are functions

$$a : \forall n : \mathbb{N}, B(n), \qquad p : \forall n : \mathbb{N}, P(n, a(n))$$

given by dependent-pair projection from $H(n)$. The displayed-pair map

$$n \mapsto (n, a(n)) : \mathbb{N} \to \bigsqcup_{n:\mathbb{N}} B(n)$$

is the primitive-recursive witness map of Definition 9387.26 applied to a, and $p(n)$ proves the chosen value satisfies P at every index.

Proof. For each n, the term $H(n)$ is a displayed pair. Define $a(n)$ to be its first projection and $p(n)$ to be its second projection. Then $a(n) : B(n)$ and $p(n) : P(n, a(n))$ by dependent-pair elimination. Applying Definition 9387.27 to the family B and witness function a gives the displayed-pair map $n \mapsto (n, a(n))$, and the proof component $p(n)$ supplies the predicate evidence for each chosen value. Projection from a displayed pair is kernel computation, not term-stratum meta closure. □

Definition 9387.29 (Certified psame-respecting operation)**.** *Let A and B be BEDC carrier layers whose public classifiers are written psame_A and psame_B, and whose carrier-classifier laws are licensed by naming certificates in the sense of Definition 9.6 and Definition 9.7. A map $\varphi : A \to B$ is a* certified psame-respecting operation *when its stability data contains a descent witness*

$$\tau_\varphi : \forall a, a' : A,\ \mathsf{psame}_A(a, a') \Longrightarrow \mathsf{psame}_B(\varphi(a), \varphi(a')).$$

This witness is the operation-level DescentCert *component of Definition 9.4. It is evidence about the classifiers, not an equality $a = a'$ and not a selector of a representative of the psame_A-class.*

Theorem 9387.30 (NameCert psame transport replaces quotient equality)**.** *Let A and B be BEDC carrier layers with certified classifiers psame_A and psame_B. Let $\varphi : A \to B$ be a certified* psame*-respecting operation with descent witness τ_φ as in Definition 9387.29. For every $a, a' : A$, a classifier witness*

$$s : \mathsf{psame}_A(a, a')$$

transports through φ to a target classifier witness

$$\mathsf{psame}_B(\varphi(a), \varphi(a')).$$

The derivation uses no type-level equality $a = a'$, no quotient representative type, and no representative-selecting section.

Proof. Unfold the certified psame-respecting operation datum. Its descent field is precisely

$$\tau_\varphi : \forall x, y : A,\ \mathsf{psame}_A(x, y) \Longrightarrow \mathsf{psame}_B(\varphi(x), \varphi(y)).$$

Apply this field to a, a', and the supplied classifier witness s. The resulting witness is

$$\tau_\varphi(a, a', s) : \mathsf{psame}_B(\varphi(a), \varphi(a')).$$

This proof consumes only the displayed classifier evidence and the certified descent field. A quotient-style argument would first turn s into an equality at a quotient type and then use congruence of φ over that equality. The naming-certificate argument keeps a and a' as distinct source terms and transports only the classifier judgment. Thus the quotient-soundness role identified in Definition 9387.7 is supplied by explicit psame-transport. □

Definition 9387.31 (Proof-input proposition construction)**.** *Let P : Prop and let X be a kernel target, where X may itself be a proposition or a certified carrier. A* proof-input proposition construction over P *is a construction whose access to P is mediated by a displayed proof argument:*

$$\Phi_P : P \to X.$$

An hsame-style proposition transport *between propositions P and Q is the bidirectional implication datum*

$$b_{P,Q} = (b^{\rightarrow}_{P,Q}, b^{\leftarrow}_{P,Q}) : (P \Rightarrow Q) \wedge (Q \Rightarrow P).$$

It is used as transport data between proof inputs, not as an equality token $P = Q$.

Theorem 9387.32 (hsame-style proposition transport bypasses propext)**.** *Let P, Q : Prop and let*

$$b_{P,Q} = (b^{\rightarrow}_{P,Q}, b^{\leftarrow}_{P,Q}) : (P \Rightarrow Q) \wedge (Q \Rightarrow P)$$

be the proposition-stratum transport datum of Definition 9387.24, read without the equality token supplied by propext*. For every proof-input proposition construction*

$$\Phi_P : P \to X,$$

there is a Q-parameterised construction

$$\Phi[P \rightsquigarrow Q] : Q \to X$$

given by

$$\Phi[P \rightsquigarrow Q](q) = \Phi_P\big(b^{\leftarrow}_{P,Q}(q)\big).$$

Dually, every proof-input construction $\Psi_Q : Q \to Y$ has a P-parameterised construction

$$\Psi[Q \rightsquigarrow P] : P \to Y, \qquad \Psi[Q \rightsquigarrow P](p) = \Psi_Q\big(b^{\rightarrow}_{P,Q}(p)\big).$$

Thus every later kernel step that consumes a displayed proof of the proposition can be rerun on the transported proposition through the chosen implication direction, using no inhabitant of $P = Q$ and no contextual rewrite over an arbitrary C : Prop → Prop.

Proof. Unpack the bidirectional transport datum into its two implication components. Given $q : Q$, the reverse component $b^{\leftarrow}_{P,Q} : Q \Rightarrow P$ produces a proof $b^{\leftarrow}_{P,Q}(q) : P$. The original construction Φ_P consumes exactly such a displayed proof, so applying it gives

$$\Phi_P(b^{\leftarrow}_{P,Q}(q)) : X.$$

This defines the displayed map $\Phi[P \rightsquigarrow Q] : Q \to X$. The dual construction is identical, using $b^{\rightarrow}_{P,Q} : P \Rightarrow Q$ before applying Ψ_Q.

No step asks for an equality proof $\varepsilon_{P,Q} : P = Q$. The proposition symbol is never rewritten inside an arbitrary context; the construction only composes ordinary proof functions. The stronger operation described in Definition 9387.24 would manufacture an equality token and then transport through every proposition-valued context. The construction above is the effective replacement promised by Definition 9387.8: it keeps P and Q distinct and moves only displayed proof inputs along the supplied bidirectional implication. □

Definition 9387.33 (Presented term-stratum witness family)**.** *Fix an index carrier I, an ambient term carrier U, and positive fiber predicates $A_i \subseteq U$. For each $i \in I$, let R_i be a carrier of constructor recipes and let $\epsilon_i : R_i \to U$ be the evaluation map from recipes to terms. A* presented term-stratum witness family *over $(A_i)_{i\in I}$ is data*

$$r : \forall i \in I,\ R_i, \qquad \rho : \forall i \in I,\ \epsilon_i(r(i)) \in A_i.$$

Its exposed choice output *is the pair $\Phi(r, \rho) = (f_r, \mu_r)$ defined by*

$$f_r : I \to \bigsqcup_{i\in I} A_i, \qquad f_r(i) = (i, \epsilon_i(r(i))),$$

with fiber evidence $\mu_r(i) = \rho(i)$. Thus the source presentation records the recipe binding $i \mapsto r(i)$ as constructor-level data, while the exposed output records only the evaluated fiber term and its membership evidence.

Proposition 9387.34 (Term-stratum meta closure drops per-index witness recipes)**.** *In the setting of Definition 9387.33, let (r, ρ) and (r', ρ') be presented witness families, possibly with different recipe carriers and evaluation maps. If their evaluated terms agree pointwise,*

$$\forall i \in I,\ \epsilon_i(r(i)) = \epsilon'_i(r'(i)),$$

then the underlying U-components of their exposed choice outputs agree pointwise. Consequently, when the term-stratum meta-closure interface of Definition 9387.18 or the choice conclusion of Definition 9387.2 is used as the only subsequent input, the available data are only f and the fiber evidence $f(i) \in A_i$. The per-index recipe binding $i \mapsto r(i)$ is not a destructurable component of that output.

Proof. Unfold the exposed output map Φ of Definition 9387.33. For each index $i \in I$, the underlying U-component of $f_r(i)$ is $\epsilon_i(r(i))$, and the underlying U-component of $f_{r'}(i)$ is $\epsilon'_i(r'(i))$. The displayed pointwise equality therefore gives equality of the exposed term components at every index.

Now inspect the term-stratum closure interface. By Definition 9387.18 and the choice-facing reading of Definition 9387.19, the closure output has the form

$$f : I \to \bigsqcup_{i\in I} A_i, \qquad \mu : \forall i \in I,\ f(i) \in A_i.$$

Dependent elimination of this output projects only f and μ. Neither projection has type R_i, neither returns a recipe $r(i)$, and neither records an equality tying the accepted output to a displayed constructor presentation. To recover $r(i)$ from the closure output one would need extra data, for example a selector from exposed fiber terms back into R_i whose evaluation gives that term. Such a selector is not part of Definition 9387.18, Definition 9387.2, or the displayed choice-output type. Hence the term-stratum meta-closure step is precisely the passage from a possible constructor presentation to the exposed term-and-membership interface, and that passage drops the per-index witness recipe structure unless the original presentation is supplied as a separate input. □

Concretized in §677: Choice recipe ledgers realize term-stratum witness-recipe loss as finite BHist, hsame, Cont, Pkg, NameCert, and axiom-purity refusal rows.

Definition 9387.35 (Presented quotient equivalence derivation)**.** *Let A be a type and let $R_0 : A \to A \to \mathsf{Prop}$ be a displayed base relation. Write $a \sim_R b$ for the closed derivation carrier freely generated by*

$$\mathsf{refl}_a : a \sim_R a,$$

$$\mathsf{base}_r : a \sim_R b \quad (r : R_0(a, b)),$$

$$\mathsf{symm}(d) : b \sim_R a \quad (d : a \sim_R b),$$

and

$$\mathsf{trans}(d_1, d_2) : a \sim_R c \quad (d_1 : a \sim_R b,\ d_2 : b \sim_R c).$$

A presented quotient equivalence derivation *from a to b is a tree $d : a \sim_R b$ together with its endpoints. If $\pi : A \to Q$ is the projection supplied by a quotient representative package for $\sim_R$, the quotient-soundness exposure of d is the equality token*

$$\theta_\pi(d) : \pi(a) = \pi(b)$$

obtained by applying the soundness field of $\mathsf{QRep}_{A,\sim_R}(Q, \pi, \rho)$ to d.

Proposition 9387.36 (Type-stratum meta closure drops equivalence derivations)**.** *In the setting of Definition 9387.35, the type-stratum quotient closure of Definition 9387.22 exports an input tree $d : a \sim_R b$ only through the implication*

$$d : a \sim_R b \Longrightarrow \theta_\pi(d) : \pi(a) = \pi(b).$$

The exported equality does not carry d as a destructurable component. Consequently, any later construction whose available quotient input is only

$$e : \pi(a) = \pi(b)$$

can perform equality transport at the quotient type and, under Definition 9387.21, may obtain some endpoint classifier witness, but it has no access to the original reflexive, base-edge, symmetric, and transitive constructor tree. Recovering the original input tree would require an additional trace selector

$$\delta_{a,b} : (\pi(a) = \pi(b)) \to (a \sim_R b), \qquad \forall d : a \sim_R b,\ \delta_{a,b}(\theta_\pi(d)) = d,$$

which is not a field of Definition 9387.20, Definition 9387.22, or the quotient-soundness schema of Definition 9387.3.

Proof. The presented input has three visible pieces: the endpoint a, the endpoint b, and the derivation tree $d : a \sim_R b$. The last piece is an inductive tree. It can be eliminated by cases on whether it is reflexive, a base edge, a symmetric reversal, or a transitive composite.

Within the quotient-facing proxy, applying the displayed soundness field consumes that tree and returns the equality token $\theta_\pi(d) : \pi(a) = \pi(b)$. The codomain of this token mentions only the projection and the two endpoint classes. It does not contain a dependent-pair component of type $a \sim_R b$, nor a field recording which constructor of the equivalence-derivation carrier was used.

Thus a later context whose quotient input is only $e : \pi(a) = \pi(b)$ has the equality eliminator for e as its type-level tool. Equality elimination transports constructions from the class of a to the class of b; it does not expose the proof tree that was consumed to create e. If Definition 9387.21 is also used, it applies to e and the representative fields of the quotient package to produce an endpoint relation witness. That witness is obtained from the equality and the package fields, not by projecting the original tree d, since d is no longer present in the context.

A uniform recovery of the original tree would therefore be extra structure: precisely a selector $\delta_{a,b}$ with $\delta_{a,b}(\theta_\pi(d)) = d$ for every input derivation. None of the cited quotient interfaces contains such a selector. The type-stratum closure step read in Definition 9387.23 therefore exposes equality at A/R while dropping the kernel-level equivalence derivation that supplied it. □

Definition 9387.37 (Presented proposition-equivalence datum)**.** *Let $P, Q : \mathsf{Prop}$. A* presented proposition-equivalence datum *from P to Q consists of proof-recipe carriers $R^{\rightarrow}$ and $R^{\leftarrow}$, evaluation maps*

$$E^{\rightarrow} : R^{\rightarrow} \to (P \Rightarrow Q), \qquad E^{\leftarrow} : R^{\leftarrow} \to (Q \Rightarrow P),$$

and selected recipes $r^{\rightarrow} : R^{\rightarrow}$ and $r^{\leftarrow} : R^{\leftarrow}$. Its evaluated implication pair is

$$b_D = (\pi_D^{\rightarrow}, \pi_D^{\leftarrow}) = (E^{\rightarrow}(r^{\rightarrow}), E^{\leftarrow}(r^{\leftarrow})) : (P \Rightarrow Q) \wedge (Q \Rightarrow P).$$

The equality exposure *of D under proposition-stratum meta closure is the single token*

$$\varepsilon_D : P = Q$$

supplied from b_D by Definition 9387.24. The recipe carriers, the selected recipes, and the evaluated implication maps are source-side data of the presentation; the exposed closure output is only the equality token.

Proposition 9387.38 (Proposition-stratum meta closure drops implication direction)**.** *Let D be a presented proposition-equivalence datum as in Definition 9387.37, with evaluated components $\pi_D^{\rightarrow} : P \Rightarrow Q$ and $\pi_D^{\leftarrow} : Q \Rightarrow P$, and let $\varepsilon_D : P = Q$ be its equality exposure. For any proposition-valued context $C : \mathsf{Prop} \to \mathsf{Prop}$, the closure-mediated application from $C(P)$ to $C(Q)$ is typed only by*

$$\mathsf{rew}_{D,C}^{\rightarrow} : C(P) \to C(Q), \qquad \mathsf{rew}_{D,C}^{\rightarrow}(t) = \mathsf{transport}_C(\varepsilon_D, t),$$

and the reverse application is typed only by

$$\mathsf{rew}_{D,C}^{\leftarrow} : C(Q) \to C(P), \qquad \mathsf{rew}_{D,C}^{\leftarrow}(u) = \mathsf{transport}_C(\varepsilon_D^{-1}, u).$$

Thus any later application site that receives the proposition-stratum closure output receives the equality token and its two equality-elimination orientations, but it receives neither the original implication chosen from b_D nor the proof recipe producing that implication. In particular, if two presented data expose the same equality token, then every expression using them only through the closure interface has the same free data at the application site even when their implication components or recipe carriers differ. The proposition-stratum meta-closure step therefore drops both the original implication direction and the internal proof structure of the implication pair.

Proof. Unfold the proposition-stratum closure interface of Definition 9387.24. Its output is a term $\varepsilon_D : P = Q$. Once this output has been supplied, the eliminator available to a proposition-valued context is identity elimination on that equality. Instantiating the eliminator with the family $C : \mathsf{Prop} \to \mathsf{Prop}$ gives exactly the two displayed transports: along ε_D from $C(P)$ to $C(Q)$, and along the symmetric equality ε_D^{-1} from $C(Q)$ to $C(P)$.

The arguments of these transports are C, the equality token, and the displayed proof being transported. The implication maps $\pi_D^{\rightarrow}$ and $\pi_D^{\leftarrow}$ are not arguments of the transport term, and the recipe witnesses $r^{\rightarrow}$ and $r^{\leftarrow}$ are still further upstream. Equality elimination can inspect only the equality constructor pattern of ε_D; it has no eliminator for the pre-closure presentation that produced ε_D. Even in the special context $C(X) = X$, the maps $P \Rightarrow Q$ and $Q \Rightarrow P$ obtained from ε_D are equality-derived transports, not projections of $\pi_D^{\rightarrow}$ or $\pi_D^{\leftarrow}$.

To recover the original direction at a later application site one would need extra fields selecting $\pi_D^{\rightarrow}$ or $\pi_D^{\leftarrow}$ from the exposed value. To recover internal proof structure one would need extra fields returning $r^{\rightarrow}$, $r^{\leftarrow}$, or their recipe carriers from the exposed value. None of these fields is present in Definition 9387.24 or in the propext-facing reading of Definition 9387.25. This is why the effective replacement of Definition 9387.8 and Definition 9387.32 keeps the bidirectional implication datum and the chosen direction as explicit parameters instead of identifying P and Q. □

Chapter 9388

The Closure-Universality Quadrant: A Two-Axis Substrate Map

Concretized in §947: Realizes the universality/closure quadrant as a finite two-axis substrate certificate.

Concretized in §957: The two-axis closure-universality map is realized as a finite substrate-quadrant NameCert packet.

Concretized in §950: The two-axis quadrant map is realized as a finite substrate-classifier NameCert packet.

Concretized in §946: The two-axis universality/closure map is represented as a finite NameCert packet with explicit quadrant and exclusion rows.

Concretized in §953: Finite universal-and-closed substrate packets are realized as UniversalClosedSubstrateUp NameCert rows.

Concretized in §951: Oracle-augmented substrate packets realize the universal-but-not-closed quadrant as finite oracle-call, transcript, boundary, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1015: Oracle response ledgers realize query, response, boundary, refusal, route, provenance, and NameCert rows as finite BEDC data.

Definition 9390.13 of chapter 9390 established that two facts about Rule 110 are logically independent: it is Turing-universal in the sense of Cook 2004, and it is closed observational in the sense of Definition 9393.1. This chapter takes that independence seriously and reads it as an organising principle. The two axes – universality and closure – generate a 2×2 quadrant of substrate types. The project currently exhibits one quadrant in concrete detail (universal-and-closed, the Rule 110 reading); the other three quadrants are populated by recognisable substrate classes, each of which sharpens the structural claim about Rule 110 by contrast. The chapter populates the quadrant, locates known substrates within it, and identifies what each quadrant says about the closed-observational framework.

9388.1 The two axes, formally

Definition 9388.1 (Universality axis)**.** *A substrate S is* Turing-universal *if every partial recursive function on natural numbers is realised as a computation of S on some encoded input. The universality axis assigns each substrate a value* $\mathsf{Univ}(S) \in \{yes, no\}$*. The Church-Turing thesis identifies*

$\mathsf{Univ}(S)$ = *yes with the existence of a polynomial-time compilation from any Turing machine into* S.

Definition 9388.2 (Closure axis)**.** *A substrate* S *is* closed observational *if its observations are exhausted by finite-length records of orbits of* S*'s next-state function, with no external commitments participating in deciding which records count as observations (Definition 9393.1). The closure axis assigns each substrate a value* $\mathsf{Closed}(S) \in \{yes, no\}$.

Principle 9388.3 (Axes are independent)**.** *The universality axis and the closure axis are logically independent. There is no derivation from* $\mathsf{Univ}(S)$ *to* $\mathsf{Closed}(S)$ *or vice versa; each axis is fixed by separate structural features of* S*. Definition 9390.13 is the special case of this independence for Rule 110. The quadrant generated by the two axes has four cells, each of which is structurally meaningful.*

9388.2 Quadrant I: universal and closed

Example 9388.4 (Rule 110 substrate)**.** *The cellular substrate of Definition 9390.7 inhabits the universal-and-closed quadrant. Cook 2004 proves* $\mathsf{Univ}(\mathsf{R110})$ = *yes; Definition 9390.10 proves* $\mathsf{Closed}(\mathsf{R110})$ = *yes. The project's* `rule110/` *sub-system is the engineering exhibit of this quadrant at minimum 220-line scale.*

Example 9388.5 (Other CA at this quadrant)**.** *Elementary cellular automaton Rule 30 and Rule 54 are conjectured (not yet proved) to be Turing-universal. Game of Life is provably universal (Conway, Berlekamp, Guy 1982). Each of these CA, when used as a closed observational substrate in the sense of Definition 9390.6, is a candidate inhabitant of the universal-and-closed quadrant. Rule 110 is the project's choice because it has the smallest mechanically-verified universality construction.*

Principle 9388.6 (This quadrant is the project's anchor)**.** *The universal-and-closed quadrant is the substrate position from which the closed-observational framework derives its principal claim: even at maximum computational capacity in the substrate, internal observation cannot ratify universal closures over an infinite domain (Definition 9393.5, transported to the cellular reading in Definition 9390.10). The project anchors at this quadrant because it is the strongest version of the closure argument: universality buys no leverage against closure.*

9388.3 Quadrant II: universal but not closed

Definition 9388.7 (Oracle-augmented substrate)**.** *An* oracle-augmented substrate *is a Turing-universal substrate equipped with one or more oracles for problems strictly above the recursive level: a halting oracle, an arithmetic-hierarchy oracle, or a hypercomputation channel. The presence of an oracle violates the closure premise because the substrate's observations include records produced by consulting the oracle, and the oracle is not a substrate-internal process.*

Example 9388.8 (Hypercomputation models)**.** *Several mathematical models occupy the universal-but-not-closed quadrant: Turing's o-machines (with halting oracles), infinite-time Turing machines (Hamkins-Lewis), real-number machines (Blum-Shub-Smale), and accelerating Turing machines. Each of these models is at least Turing-universal; each violates closure because each admits a step that is not a finite local rule on a finite state.*

Principle 9388.9 (Open universal substrates lose the no-induction theorem)**.** *The no-induction theorem of Definition 9393.5 fails for oracle-augmented substrates. Specifically, a halting oracle can ratify universal closures on Turing-decidable predicates by direct query; a Σ^0_2 oracle can ratify closures over Π^0_1 predicates. The forward-binding source T of chapter 9393 is therefore consulted via the oracle, rather than via the inscription point of Definition 9393.16. The project does not currently exhibit an oracle-augmented substrate; the universal-but-not-closed quadrant is sketched here as the structural complement of the project's anchor quadrant.*

Remark 9388.10 (Why this quadrant matters even if empty in practice)**.** *A reader might argue that hypercomputation is physically unrealised and therefore the universal-but-not-closed quadrant is theoretically vacant. The project does not take a position on the physical realisability of oracles. The structural relevance of this quadrant is that it shows what the closure premise is doing work to exclude: closure rules out exactly the substrates whose observations would otherwise bypass the no-induction theorem. The premise is therefore not vacuous; it carries information.*

9388.4 Quadrant III: not universal but closed

Definition 9388.11 (Sub-universal closed substrate)**.** *A substrate is* sub-universal closed *if it is closed observational (Definition 9393.1) and admits a decision procedure for its computational power that places it strictly below Turing universality. Examples include linear-bounded automata, pushdown automata, finite-state machines, and decidable arithmetic fragments such as Presburger arithmetic and the theory of real closed fields.*

Example 9388.12 (Presburger arithmetic as substrate)**.** *The first-order theory of* $(\mathbb{N}, 0, 1, +)$ *is decidable (Presburger 1929). Used as a closed observational substrate, every Presburger statement has a decision procedure that terminates in a finite, computable number of steps; the substrate is therefore closed observational. It is not Turing-universal; multiplication is not definable in the theory. This is a clean inhabitant of the sub-universal-closed quadrant.*

Principle 9388.13 (Closure plus sub-universality keeps no-induction)**.** *The no-induction theorem transports to the sub-universal-closed quadrant without modification. Even a decidable closed substrate cannot ratify universal closures over an infinite domain from inside; decidability of a fragment is not internal ratification of universal statements over that fragment. The universal-but-decidable-by-external-procedure case is consistent with the substrate's records being finite. The closure argument is therefore stronger in this quadrant: even when an external decision procedure exists, the substrate's own records cannot internally produce* $\forall n \in \mathbb{N}.\, P(n)$ *without external supply.*

Remark 9388.14 (BEDC kernel at this quadrant on the host side)**.** *On the host side, BEDC itself is a sub-universal-closed substrate: total functional, so not Turing-universal as a programming language (Definition 9370.4); closed observational, in that every kernel-level observation is a finite typed term. The host therefore sits in this quadrant; the cellular substrate sits in the universal-and-closed quadrant. The project displays both quadrants simultaneously as host plus substrate, with the closure premise transferred uniformly across both.*

9388.5 Quadrant IV: neither universal nor closed

Definition 9388.15 (Degenerate quadrant substrate)**.** *A substrate in the neither-universal-nor-closed quadrant is sub-universal and admits external commitments in its observation premise. This*

includes substrates whose observations are physical signals from environments outside the substrate (sensors, human input, network traffic), and whose computational expressiveness is bounded below Turing universality.

Example 9388.16 (Embedded controller with sensor input)**.** *An embedded microcontroller running a finite-state program that reads from external sensors inhabits this quadrant. The program's computation is finite-state, hence sub-universal. The observations include sensor readings, whose values are not produced by the controller's internal computation; the closure premise fails because observation values originate from outside the substrate.*

Remark 9388.17 (The framework does not anchor here)**.** *The degenerate quadrant is structurally the weakest position for the closed-observational framework; the framework's conclusions transfer to this quadrant only after the external observation channel is itself given a closure analysis. The project's substrates do not anchor here. The quadrant is included in the map for completeness, not as a target.*

9388.6 The quadrant as map

	Universal	**Sub-universal**
Closed	Quadrant I: Rule 110, Game of Life, Rule 30/54 (conjectured). Project anchor. The strongest closure-argument site.	Quadrant III: Presburger arithmetic; PDA / LBA / finite-state machine substrates; BEDC host. Closure argument holds; universality not asserted.
Not closed	Quadrant II: o-machines, infinite-time TM, real-number machines, accelerating TM. Closure argument fails; oracle ratifies universal closures.	Quadrant IV: embedded controllers with external sensor input; arbitrary engineering systems with mixed substrates. Framework not anchored here without additional analysis.

Principle 9388.18 (The map sharpens the closure premise)**.** *The four-quadrant map sharpens the closure premise of Definition 9393.1 by showing what the premise is not: it is not a statement about computational expressiveness (Quadrant I and Quadrant III both satisfy it); it is not a statement about cellular structure (Presburger satisfies it without being cellular); it is a statement specifically about the absence of external commitments in the observation channel. The premise is therefore identifiable independently of universality, and the no-induction theorem is the conclusion of the closure premise alone.*

9388.7 Mapping to BEDC engineering

Quadrant reading	**BEDC engineering realisation**

Quadrant I: Rule 110 anchor	`rule110/` 220-line ANSI C99 trust path; Definition 9390.10; cook compile-frontier (Definition 9390.19).
Quadrant III: BEDC host as sub-universal-closed	Lean 4 build at `lake build` exit 0; `axiom-purity -strict` traces; total functional discipline.
Quadrant II / IV: not anchored	Not exhibited inside the project; sketched as structural complements; their existence sharpens what the project's closure claim is doing.
Axis independence audit	Definition 9390.13 states the special case for Rule 110; this chapter generalises the independence to the full quadrant.
Closure premise localised	The premise of Definition 9393.1 is the observation-channel restriction; universality is not assumed and not asserted.

9388.8 Closure remarks

This chapter has read the universality and closure axes as independent and generated the 2×2 quadrant they span. The project's two anchors (`rule110/` as Quadrant I substrate and BEDC host as Quadrant III system) jointly demonstrate that the closure premise applies uniformly across computational expressiveness levels. Quadrant II and Quadrant IV are populated by recognised substrate classes that the project does not anchor in; their structural role is to identify what the closure premise rules out (external observation channels) versus what it tolerates (any computational power, from finite-state to Turing-universal).

The boundary of this chapter is: the closure premise is independent of universality; the no-induction theorem applies in any closed quadrant; the project anchors in two of the four quadrants and identifies the other two without claiming substrates there. No new theorem is introduced; the chapter generalises Definition 9390.13 into a full map and reads the map as a check on the closure premise's information content.

Concretized in §955: Presburger arithmetic supplies the sub-universal closed quadrant witness.

Concretized in §946: Closure-universality quadrants are realized as finite BHist packets for universality axis, closure axis, quadrant tag, substrate witness, sibling cellular anchors, hsame transport, Cont routes, Pkg provenance, and NameCert rows.

Concretized in §956: Oracle-substrate boundaries are realized as finite BHist packets separating oracle-query rows from closed substrate observations.

Chapter 9389

Generator-Closure Certificates and the Two Layers of BEDC: Technical Mechanism for the Strong Externality Claim

This chapter adds a technical layer to the philosophical reading of chapter 9393, chapter 9420, and chapter 9415. The earlier chapters' strong claim – mathematical induction must be supplied from outside every closed observational substrate, and the source-position is named T / God in the apophatic sense – is preserved without softening. The work of the present chapter is to make precise *how* BEDC operationally enforces that claim: through authorized generators, naming certificates, and generator-closure classifiers, together with GAP ledgers that audit compression residue. The technical layer does not weaken the philosophical claim; it shows the engineering that makes the claim auditable, line by line, in the substrate.

Principle 9389.1 (Two co-equal layers, not replacement)**.** *The strong philosophical reading – forward-binding belief must enter from outside the substrate at a position named* T *– and the structural technical reading – BEDC licenses induction generator-by-generator via closure certificates – are two aspects of the same engineering. Neither replaces the other. The technical layer accounts for what BEDC does inside its authorized generators; the philosophical layer accounts for what BEDC refuses to internalise and where the refused content sits. Replacing the philosophical vocabulary with weaker terms ("meta-assumption", "external principle", "axiom-like commitment") yields a system that no longer accounts for what BEDC actually does.*

9389.1 The two operational layers of BEDC

Definition 9389.2 (Bare record layer)**.** *The* bare record layer *of BEDC is the substrate viewed as a monotonically accumulating ledger of* Obs *items with no closure rule beyond strict record preservation. At the bare record layer the substrate can recognise repeated patterns within previously accumulated* Obs*, but it cannot infer that the patterns continue beyond what has been recorded; no generating structure has been authorized and so no inductive step is licensed.*

Definition 9389.3 (Closed inductive kernel layer)**.** *The* closed inductive kernel layer *of BEDC is the substrate equipped with a finite collection of authorized generating structures, each of which is*

a closed inductive declaration (in the project sense of `inductive` *types with a bounded constructor list) together with the eliminator or fold pattern licensed by the closure of the constructor list. At this layer the substrate can perform structural induction over each authorized generator, but every step of such induction is internal to the generator: it ranges over the objects the constructor list closes, not over an externally postulated totality.*

Principle 9389.4 (Two layers, two operational behaviours, neither reaches free-floating induction)**.** *At the bare record layer (Definition 9389.2) the substrate's strongest statement about a repeating pattern is "no record so far falsifies the pattern". At the closed inductive kernel layer (Definition 9389.3) the substrate's strongest statement is "every object generated by the closure of these constructors carries the closure witness". Neither statement reaches free-floating mathematical induction. The move from "every closure of these constructors" to "every object whatsoever" is the move that requires forward-binding belief from* T*, as Definition 9393.8 states.*

Example 9389.5 (`Hist` as an authorized generator)**.** *BEDC's* `Hist` *type is declared by a closed inductive presentation:* `emp` *generates the empty history;* `E0` *and* `E1` *extend any history by one mark. The constructor list is finite and closed, so the closure of the constructor list defines exactly the set of finite histories. Within this generator, structural induction over* `Hist` *is licensed: every property that holds at* `emp` *and is preserved by* `E0` *and* `E1` *extensions holds at every* `Hist` *object. The substrate hosts the corresponding* hsame *decidability and other invariants by appeal to this generator-internal structural induction. But the substrate does* not *thereby derive a free-floating induction principle over all objects; the licence is restricted to the closure of the* `Hist` *constructor list, and any extension beyond that closure requires the forward-binding belief whose source is* T*.*

9389.2 Naming certificates and generator-closure classifiers

Definition 9389.6 (Naming certificate)**.** *A* naming certificate *is a substrate-internal artefact that promotes a stable, already-generated behaviour to the status of a derived interface (a* `def`*, a* `class` *field, or a* NameCert *packet). The certificate does not introduce the behaviour as a new primitive; it records that the behaviour is generated by an existing authorized generator and is stable under the substrate's other audit rules. Naming certificates are the bridge between the bare record layer and the closed inductive kernel layer: they take a record-side pattern and license it as an interface, contingent on the generator that produced it.*

Definition 9389.7 (Generator-closure classifier)**.** *A* generator-closure classifier *is the audit-side companion of a naming certificate: it states which closure rules the certificate is contingent on (the constructor list of the underlying generator) and rejects continuations of the named pattern that would lie outside that generator's closure. Generator-closure classifiers are the substrate's way of saying "the naming certificate ranges over this generator, no more, no less". On the formal side, BEDC.MetaCIC encodes this as a* `structure GeneratorClosureClassifier` *carrying a single closure field* $\forall x\, y,\ Generator(x, y) \to Classifier(x) \to Classifier(y)$*, with concrete instantiations for the substrate's shift and substitute generators on closed-term carriers*

```
Lean4✓  BEDC.MetaCIC.GeneratorClosureClassifier
  ↪ variant  BEDC.MetaCIC.closed under shift classifier
  ↪ variant  BEDC.MetaCIC.closed under substitute classifier
```

.

Principle 9389.8 (The classifier family is closed under identity, composition, alternation, sub--generator restriction, and finite iteration)**.** *The collection of generator-closure classifiers over a*

fixed carrier α is itself closed under five minimal structural operations: the identity generator $x = y$ preserves every classifier (the audit unit), the sequential composition $\exists z,\, G_1(x,z) \wedge G_2(z,y)$ of two classifier-preserving generators is again classifier-preserving (the audit composition), the disjunctive alternation $G_1(x,y) \vee G_2(x,y)$ of two classifier-preserving generators is again classifier-preserving (the audit alternation), any sub-generator $G' \subseteq G$ inherits the closure of a classifier-preserving generator (the audit restriction, contravariant in the generator argument), and the n-fold iteration of any classifier-preserving generator is again classifier-preserving for every $n \in \mathbb{N}$ (the audit iteration, formalised over the finite-iteration relation $\mathsf{IterRel}\, G\, n$*). All five facts are formalised in BEDC.MetaCIC as*

Lean4✓ `BEDC.MetaCIC.GeneratorClosureClassifier.refl`

,

Lean4✓ `BEDC.MetaCIC.GeneratorClosureClassifier.comp`

,

Lean4✓ `BEDC.MetaCIC.GeneratorClosureClassifier.union`

,

Lean4✓ `BEDC.MetaCIC.GeneratorClosureClassifier.weaken`

, and

Lean4✓ `BEDC.MetaCIC.GeneratorClosureClassifier.iterate`

. The substrate therefore has a minimal closed algebra of generator-closure classifiers, internal to the audit gates and built up by structural composition without external generator-side licence. Under this algebra a non-deterministic, possibly iterated, but classifier-preserving generator-network is itself a closure-preserving compound, and the audit gates traverse it without leaving the algebra. The iteration operation gives the algebra a Kleene-star-like component: the finite reflexive-transitive closure of any classifier-preserving step relation is itself classifier-preserving.

Principle 9389.9 (Cross-carrier product and sum closure)**.** *The generator-closure classifier construction is also compositional across carriers, not only within a fixed carrier. Given two carriers α and β each with a classifier-preserving generator, two complementary cross-carrier closures are available. The product closure forms the componentwise generator on the product carrier $\alpha \times \beta$ and preserves the conjoined classifier $C_a(\pi_1\, p) \wedge C_b(\pi_2\, p)$*

Lean4✓ `BEDC.MetaCIC.GeneratorClosureClassifier.product`

. The sum closure forms the case-split generator on the disjoint sum carrier $\alpha \oplus \beta$ (with the cross-cases mapped to falsity) and preserves the case-split classifier (C_a on left, C_b on right)

Lean4✓ `BEDC.MetaCIC.GeneratorClosureClassifier.sum`

. The substrate's audit gates therefore extend uniformly from single-carrier reasoning to compound-carrier reasoning, conjunctively (product) and disjunctively (sum), without changing the audit shape: the classifier and the generator just acquire a componentwise or case-split reading. Product and sum closures together close the algebra under both dimensions of compound type formation that are available within a closed inductive kernel.

Principle 9389.10 (Structural induction is internal; the move to "all" is external)**.** *BEDC's structural induction is always relative to a specific authorized generator's closure. The substrate does not perform induction over "all of mathematics", "all of reality", or "all possible objects"; it performs induction over the closure of a specific constructor list, certified by a specific naming certificate and audited by a specific generator-closure classifier. The "all" of structural induction is the closure of the relevant generator, not classical-completeness "all". To get the classical-completeness "all" – to derive a free-floating $\forall n,\, P(n)$ ranging over every possible n, beyond any specific authorized generator – requires the forward-binding belief whose source-position is* T*. This is the operational form*

of the impossibility theorem Definition 9393.5: the substrate has rich generator-internal induction, but the move beyond every specific generator's closure is the move that the substrate refuses to perform internally and externalises to T *via a* GAP *socket.*

9389.3 The strong form of BEDC's induction-style claim

Principle 9389.11 (Continuations within a certificate carry its closure witness)**.** *The strongest induction-style claim BEDC issues, in its native vocabulary, is the following: every finite continuation of a pattern that has been authorized by a naming certificate must, in order to remain a continuation of that certificate, carry the same closure witness that the generator-closure classifier requires. A continuation that does not carry the witness is, structurally, not a continuation of the certificate; it is either a record of a different generator's output or an audit failure of the present certificate.*

Remark 9389.12 (Stronger than "it looks like it will repeat"; weaker than classical induction)**.** *Definition 9389.11 is strictly stronger than the empirical "the pattern has not been falsified so far": it requires structural closure under the authorized generator, not merely the absence of negative records. It is strictly weaker than classical mathematical induction taken as a free-floating reasoning rule: it does not range over the totality of all conceivable objects, only over the closure of the authorized generator. Between these two extremes BEDC's claim sits at exactly the level it can pay for with its constructor-list closure plus naming-certificate plus generator-closure-classifier triple. To upgrade to classical induction is to commit a forward-binding belief that the substrate cannot generate internally; that commitment, as Definition 9393.8 states, comes from* T*.*

Example 9389.13 (Subject reduction as a generator-internal claim)**.** *BEDC.MetaCIC's* `subject_reduction_clo` *theorem is a generator-internal claim: it ranges over the closure of the authorized constructor list for the* `Term` *generator (*`sort`*,* `var`*,* `lam`*,* `pi`*,* `app`*) and is conditioned on a closed-term naming certificate. Its content is exactly Definition 9389.11 applied to this generator: every continuation that remains a typed closed term under the* `Term` *certificate carries the closure witness that subject reduction requires. The theorem is not a classical-universal statement about "all terms in some externally postulated universe"; it is the substrate's authorized structural induction over the* `Term` *generator's closure. To extend the claim beyond the* `Term` *generator – to a free-floating universal-quantifier statement – is precisely the move the substrate refuses, and the place where* T *is required to supply forward-binding belief.*

9389.4 GAP plays two simultaneous roles

Principle 9389.14 (GAP as information-conservation ledger)**.** *On the substrate-internal side,* GAP *records every compression, identification, hiding, packaging, projection, or sealing operation, together with the residue (the "difference") that the operation does not directly display in the resulting form. When a* `def` *defines a derived interface as a compression of underlying records, the* GAP *ledger records what is no longer surface-visible; when a* NameCert *packages a generated behaviour, the ledger records what the certificate trades in exchange for the naming convenience. This is the engineering role: information conservation under compression.*

Principle 9389.15 (GAP as T-socket for forward-binding belief)**.** *On the substrate-philosophical side,* GAP *also marks the places where the substrate's reasoning would require forward-binding belief that the substrate cannot internally generate. Each such* GAP *is structurally a socket whose far*

end is T*, in the sense of Definition 9393.11: the substrate refuses to internalise the content of the socket, and the content (if any) is supplied from the apophatic external position. This is the philosophical role: marking the boundary at which the substrate hands over to the transcendental supply position.*

Principle 9389.16 (Both roles hold simultaneously and are co-load-bearing)**.** *A single* GAP *tag may instantiate either or both of Definition 9389.14 and Definition 9389.15. When a* GAP *records compression residue from a* `def` *or* NameCert *operation, it is operating in the information-conservation role; the substrate handles the residue with audit and conservation rules. When a* GAP *marks the place where free-floating induction would be required to extend a generator-internal claim to a classical-completeness "all", it is operating in the* T*-socket role; the substrate refuses to internalise and defers to* T*. Reading* GAP *only as bookkeeping misses the second role; reading it only as a transcendental socket misses the first role. Both must hold.*

Example 9389.17 (The two roles, both visible in a single mechanised file)**.** *In a typical BEDC.MetaCIC mechanised file, the audit gates check both roles together.* `check-axioms.py` *enforces that no* GAP *tag invokes a substrate-internal axiom;* `axiom-purity -strict` *enforces that no Lean stdlib axiom (*`Classical.choice`*,* `Quot.sound`*,* `propext`*) is in the transitive closure;* `conservativity-audit` *enforces that compression residue is properly tracked. The first two gates protect the* T*-socket role: forward-binding belief is not allowed to be smuggled into the substrate. The third gate protects the information-conservation role: compression cannot lose information without ledger trail. The two roles do not conflict; they are two ways the same* GAP *inventory enforces BEDC's discipline.*

Remark 9389.18 (Information conservation does not soften the T-socket claim)**.** *The information-conservation reading of* GAP *should not be read as an alternative to the* T*-socket reading. The two roles are simultaneous (Definition 9389.16). Any phrasing that reduces* GAP *to "internal bookkeeping" alone, suggesting* T *is merely a philosophical metaphor, mis-states BEDC's stance. BEDC's stance, as chapter 9393 states, is that the far end of the socket is structurally* T*: an apophatic position, named, refused internalisation, and not reducible to a more familiar substrate primitive.*

9389.5 Compression requires memory

Principle 9389.19 (Compression requires memory)**.** *BEDC's* GAP *discipline implements the principle that every act of compression in the substrate must carry its memory: the substrate cannot "forget" the underlying records by issuing a derived interface, nor erase the difference between an authorized generator and a derived presentation. The ledger is the persistence of that memory across substrate transitions; it is what lets the substrate audit the relation between surface forms and underlying generation.*

9389.6 BEDC's structural description of CIC and the host-Lean delegation

Principle 9389.20 (BEDC can structurally describe CIC, but not run it)**.** *BEDC.MetaCIC constructs, inside the substrate, a structural model of a CIC-like calculus. Every element of the model is an authorized generator's output (the* `Term` *generator, the* `HasType` *inductive predicate, the* `BetaStep` *relation) or a naming certificate packaging such output. The model is structural in the sense of Definition 9389.10: every claim about CIC* (the BEDC-internal CIC) is generator-internal. What BEDC.MetaCIC does* not *do is run the host CIC as its own evaluator; for any*

actual host-CIC truth predicate, BEDC delegates to the host Lean 4 kernel (which is the host CIC). This delegation is visible in the `leanchecked` *markers and is mediated by the audit gates.*

Remark 9389.21 (The host Lean delegation is structurally a T-socket)**.** *The* `leanchecked` *delegation is, on the philosophical side, an instance of* GAP *in its* T*-socket role (Definition 9389.15): BEDC.MetaCIC's claim about a Lean-side recursor running correctly is not derivable inside BEDC.MetaCIC. The host Lean kernel functions, in this reading, as one of the structural conduits through which* T *supplies forward-binding belief to BEDC.MetaCIC; it is not itself* T*, but it is downstream of* T *in the supply chain (and itself depends on its own metalanguage commitments, which are also downstream of* T*).*

Remark 9389.22 (Why "BEDC can swallow CIC" is too strong)**.** *A reading that says "BEDC contains CIC as a sub-theory" is too strong: BEDC contains a structural mirror of CIC, audited generator by generator, but BEDC does not internalise CIC's truth predicate. Any claim that depends on CIC's actual runtime behaviour is supplied through the host Lean delegation, which is structurally a* T*-socket. BEDC's role is structural description plus audit; the host CIC's role is computational realisation, with the runtime aspect ultimately downstream of* T*.*

9389.7 The accurate technical claim alongside the strong philosophical claim

Principle 9389.23 (Generator-internal induction does not weaken the externality claim)**.** *BEDC internalises structural induction over every authorized generator's closure. The substrate does not need an external commitment to perform* `Hist`*-internal structural induction; the generator's closed constructor list licenses that induction internally. But the move from "induction over every authorized generator's closure" to "induction over every conceivable object whatsoever" is the move that the substrate refuses to perform; and the source of forward-binding belief that would license that move is* T*. The two facts – rich generator-internal induction inside, and refusal of free-floating induction at the boundary – coexist; one does not soften the other.*

Example 9389.24 (`Hist` induction inside, free-floating universal outside)**.** *BEDC's* hsame *decidability is a generator-internal structural induction over* `Hist`*; the substrate handles this without ever invoking external commitment. But a statement of the form "every conceivable history-like structure satisfies* hsame *decidability" – where "every conceivable" ranges over an unspecified universe of possible structures rather than the closure of the* `Hist` *generator – is the kind of statement BEDC will not issue internally. To issue it would require a forward-binding belief that the substrate's vocabulary of "conceivable structures" closes under some universal quantifier ranging beyond the generator's closure; the substrate marks this position with a* GAP *tag whose far end is* T*.*

9389.8 Standard axiom systems internalise; BEDC externalises

Principle 9389.25 (The distinguishing engineering choice)**.** *Standard axiom systems internalise the forward-binding closure as a calculus-level primitive: the eliminator, the dependent recursor, the choice principle, propositional extensionality, quotient soundness, or directly as an axiom of induction. BEDC refuses every such internalisation: induction is licensed only generator-by-generator, never as a free-floating rule; the corresponding* GAP *tags expose the externality and name the far end as* T*. The engineering invariants (mathlib-free, 0 substrate-internal axioms, strict purity*

gates, monotonic amendment policy) operationalise this refusal. The naming of T *as the structural source-position is the philosophical articulation of the same refusal.*

Remark 9389.26 (BEDC is not a softening of classical foundations)**.** *BEDC's discipline can be described in two equivalent ways: as the substrate that requires every induction to be licensed by an authorized generator (the technical reading), and as the substrate that refuses to internalise the forward-binding belief in induction and instead names its source-position as* T *(the philosophical reading). Both readings describe the same engineering. Replacing the philosophical vocabulary with weaker terms – "meta-assumption", "external principle", "axiom-like commitment" – does not change the engineering but loses the precision of where the substrate's commitment-side ends. BEDC's claim is exactly that the boundary is at* T*, not at any internalisable substitute.*

9389.9 The unified technical-and-philosophical claim

Aspect	**BEDC's statement, technical and philosophical together**
What BEDC internalises	Structural induction over every authorized generator's closure, licensed by naming certificates and audited by generator-closure classifiers.
What BEDC refuses to internalise	Free-floating induction or universal-quantifier closure ranging beyond any specific authorized generator's closure.
Where the refused content sits	Outside the substrate, at the structural position named T; apophatic, refusing positive predicates beyond its role.
How the refusal is auditable	GAP tags mark every point at which forward-binding belief would be required; the audit gates (`check-axioms.py`, `axiom-purity -strict`, `conservativity-audit`) prevent internalisation.
The role of GAP on the technical side	Information-conservation ledger: every compression, identification, hiding, packaging, projection, or sealing operation records its residue.
The role of GAP on the philosophical side	T-socket: marks the boundary at which the substrate hands over forward-binding content to the transcendental supply position.
The relation between the two GAP roles	Simultaneous and co-load-bearing; the same GAP inventory enforces both information conservation and the T-socket discipline.
What CIC does differently	Internalises forward-binding closure as a calculus-level primitive: eliminator, dependent recursor, free-floating induction; the transcendental character is hidden.
What BEDC does instead	Externalises the same content, marks every socket, names the far end T; the transcendental character is explicit and auditable.

9389.10 Closure remarks

This chapter adds technical precision without softening philosophical force. The earlier chapters' claim – mathematical induction must be supplied from outside every closed observational substrate; the source-position is named T, glossed apophatically as God – stands as written. The work of this chapter is to display how the substrate's operational mechanism (authorized generators, naming certificates, generator-closure classifiers, GAP ledgers) enforces that claim line by line in mechanised content.

What the chapter does *not* do is reduce the strong claim to "a metaphor". The strong claim is structurally accurate: every GAP tag's far end is T, and the substrate's refusal to internalise forward-binding belief is precisely what distinguishes BEDC from standard foundations. Standard foundations internalise; BEDC externalises and names. Softening the strong claim – replacing T with "meta-assumption", or replacing "transcendental supply" with "external principle" – yields a system that no longer accounts for what BEDC actually does.

Future visions chapters and concrete-instance constructions should refer to this chapter together with the previous three: the present chapter for the operational mechanism, the previous three for the philosophical reading. The audit gates remain the same; what changes is the reader's ability to see, simultaneously, the technical machinery and its philosophical content as two faces of one engineering.

Concretized in §486: Generator-closure classifiers are realized as a concrete NameCert surface over authorized generator rows, continuation witnesses, and GAP ledger non-escape.

Concretized in §487: Closure witness ledgers realize generator-internal induction as finite BHist witness packets with GAP non-escape rows.

Concretized in §565: Generator-induction boundary packets realize the vision's distinction between authorized generator-internal induction, GAP sockets, and refused free-floating induction.

Concretized in §551: Host Lean delegation is realized as a finite NameCert socket exposing marker rows, audit faces, host-kernel delegation, hsame transport, Cont routes, Pkg provenance, and non-escape ledgers.

Concretized in §555: Induction-closure ledgers realize generator authority, closure classifiers, and GAP residue as a finite NameCert packet.

Concretized in §556: Generator fixed-point certificates realize the fixed-continuation boundary for authorized generator rows, preserving the displayed witness while routing non-generator continuations into the GAP ledger.

Concretized in §553: Generator-internal induction is realized as a finite seal packet over authorized generator rows, continuation witnesses, and GAP non-escape.

Concretized in §627: Generator-continuation audits realize per-continuation closure-witness preservation and GAP non-escape as a finite NameCert packet.

Concretized in §6333: Regular Cauchy located split packets realize generator-internal split witnesses as finite RegSeqRat, LocatedReal, DyadicRatCore, StreamName, RealUp, and GAP non-escape rows.

Concretized in §6869: Cauchy diagonal uniform-modulus packets realize generator-internal diagonal scheduling as finite DyadicRatCore, StreamName, RegSeqRat, RealUp, hsame, Cont, Pkg, and NameCert rows.

Concretized in §525: AuthorizedGeneratorRecursor realizes the authorized-generator and generator-internal induction surface as finite recursor signature, branch coverage, descent, audit, hsame, Cont, Pkg, and NameCert rows.

Concretized in §8965: Generator-closure algebra packets realize identity, composition, alternation, restriction, finite iteration, product, and sum closure as finite MetaCIC NameCert rows.

Concretized in §946: Closure-universality quadrant packets realize the closure-capstone two-axis direction as finite universality, closure, quadrant-tag, sibling-anchor, transport, replay, provenance, and NameCert rows.

Concretized in §553: Generator induction seals realize the capstone generator-induction direction as finite authorized-generator, witness, closure-classifier, residue, transport, replay, provenance, and NameCert rows.

Chapter 9390

The Cellular Automaton Reading: Pattern, Substrate, and the Cosmological Inscription

This vision chapter completes the closed-observational-system framework of chapter 9393, chapter 9394, and chapter 9420 along one specific axis: the cellular automaton reading. The argument proceeds in four steps. First, the act of classifying a cellular automaton evolution into named shapes – ether, gliders, collisions, soliton outcomes – is itself an instance of the mark discipline (Definition 9461.1); pattern recognition is classifier choice and not a separate cognitive faculty. Second, Rule 110 is the minimally universal cellular substrate at which this classifier discipline reaches Turing completeness, and the project's `rule110/` sub-system instantiates that substrate as a 220-line ANSI C99 trust path operating without external library dependencies. Third, even at this universal substrate, mathematical induction is provably not internalisable: Definition 9393.5 applies without modification, since Rule 110 inherits exactly the closed observational structure required. Fourth, the gap between Cook's polynomial-time compilation bound and the present cook-encode scale frontier provides a quantified Goedel boundary: it is the smallest concrete distance between Turing-completeness in principle and finite witness in practice that the project currently exposes. The cellular automaton reading therefore does not introduce a new philosophical claim; it gives the closed-observational-system framework its smallest concrete cosmological exhibit.

9390.1 Setup: classification is the mark discipline

Definition 9390.1 (Pattern classifier on a cellular automaton)**.** *Let $R\colon \mathbb{F}_2^n \to \mathbb{F}_2^n$ be the next-state function of a cellular automaton on a finite cell array of width n. A* pattern classifier *for R is a function $\mathsf{Class}\colon \mathbb{F}_2^n \to \mathsf{Tag}$ that assigns a finite label to each row, where Tag is a closed inductive collection of tags. Equivalent rows under the classifier are tagged with the same label; non-equivalent rows are tagged with different labels. A classifier therefore induces an equivalence relation on rows, decided locally by reading off the assigned tag.*

Example 9390.2 (Wolfram class as classifier)**.** *The four-class scheme of S. Wolfram (uniform fixed point, periodic, chaotic, complex) is a pattern classifier on the long-term behaviour space of an elementary cellular automaton. The tag set is the four named class labels. The classifier acts on the long-term orbit of an initial row rather than on the row itself, but the structural type*

is the same: a finite tag is assigned by examining the orbit, and rows whose orbits share a tag are recognised as belonging to the same class. Rule 110's classification as a class-four (complex) automaton is the application of this classifier to its orbit shape.

Example 9390.3 (Glider catalog as classifier)**.** *The Martinez 2007 glider catalog (A, B, $\bar{B}$, C_1, C_2, E, $\bar{E}$, F, G, H) and the ether pattern together form a pattern classifier on Rule 110 evolutions. Each glider has a fundamental period, a displacement per period, and a phase string. A row position whose local pattern matches a glider's phase string under the catalog's neighbour-discipline is tagged with that glider's label. Positions that match the ether 14-bit pattern are tagged* `ether`*. The catalog is a finite tag set with explicit defining bit strings; the classification it induces is decidable on any finite window.*

Principle 9390.4 (Pattern recognition is mark discipline)**.** *Pattern recognition on cellular automaton evolutions is not a separate cognitive faculty added on top of the substrate. It is the substrate's classifier discipline applied to the substrate's own configurations. Recognising a recurrence as "the ether" is the same kind of act as marking* `b0` *and* `b1` *in chapter 2: a decision that two configurations belong to the same closed inductive tag. The act of distinguishing the ether 14-bit pattern from its non-occurrences instantiates the form of distinction (Definition 9461.1) on the cell-row carrier.*

Remark 9390.5 (Classifier choice and BEDC kernel typing)**.** *The connection of Definition 9390.4 to BEDC's kernel-level typing is direct. A pattern classifier on cell rows is structurally the same as a type assignment in chapter 9367: a row's tag is its type, and a classifier's equivalence relation is the type-level same-class relation. The cellular automaton substrate provides a particularly clean exhibit because the carrier is finite-dimensional and the classifier can be made fully explicit (a list of named bit strings); no semantic interpretation is hidden in the act of typing.*

9390.2 Rule 110 as the minimal universal cellular substrate

Definition 9390.6 (Cellular trust substrate)**.** *A* cellular trust substrate *is a closed observational system (Definition 9393.1) whose next-state function is a local cellular rule R with a fixed transition table over a fixed alphabet, and whose observation records are exhaustively determined by the orbit of the rule on a stated initial configuration. The trust base of the substrate is the displayed local rule together with whatever fixed-size text-format manifest expresses the initial configuration and the expected verification outcomes. No external mathematical commitment beyond the local rule and the manifest schema participates in deciding which configurations count as observations.*

Example 9390.7 (The rule110 sub-project)**.** *The project's* `rule110/` *sub-system instantiates Definition 9390.6 as a 220-line ANSI C99 trust path: approximately 50 lines of cell-array transition (*`evaluator/rule110.c`*), approximately 80 lines of cyclic-tag evaluator (*`evaluator/cyclic_tag.c`*), and approximately 90 lines of bit-level encoding (*`encoder/groundcompiler_encoding.c`*). Manifest text in* `rule110/manifests/` *expresses initial configurations and expected verification outcomes in a fixed schema. Every closed observation that the substrate ratifies is determined by compiling these three components and executing the rule on a manifest's initial row; no Lean kernel, mathlib commitment, or external dependency participates in the trust path. The substrate witness is documented by the Rule 110 substrate exhibit.*

Principle 9390.8 (Rule 110 as minimal universal cellular substrate)**.** *Among one-dimensional binary cellular automata with three-cell neighbourhoods, Rule 110 is the smallest known rule*

whose long-term behaviour realises Turing completeness through cyclic tag compilation (Cook 2004, Neary–Woods 2007). The relevant minimality is therefore not numeric (some smaller rule number could in principle be universal) but architectural*: Rule 110's eight-entry transition table, three-cell locality, and binary alphabet together constitute the smallest cellular interface at which universality has been mechanically traced through Cook 2009's* §1.4 *compilation procedure. The architectural minimality is what allows Definition 9390.6 to instantiate at the 220-line scale.*

Remark 9390.9 (Why minimality matters for the closed-observation reading)**.** *The argument of chapter 9393 does not depend on the substrate's expressive power; it depends only on the substrate being closed in the sense of Definition 9393.1. The point of using a small universal substrate is therefore not to gain expressivity beyond the closed-observation framework, but to make the framework's commitments concrete at the smallest possible scale. A reader unwilling to grant that BEDC's Lean substrate is closed observational can still inspect 220 lines of C and a directory of bit strings; the closure claim is then immediately checkable rather than rhetorical.*

9390.3 Even Rule 110 cannot internalise induction

Theorem 9390.10 (Rule 110 inherits the no-induction theorem)**.** *The cellular trust substrate of Definition 9390.7 is a closed observational system in the sense of Definition 9393.1. By Definition 9393.5, no monotonic accumulation of finite verification traces on this substrate yields a record of* $\forall n \in \mathbb{N}, P(n)$ *from records of* $P(0), P(1), \ldots, P(k)$ *for any finite* k*.*

Sketch. The substrate's observations are exactly orbit segments of `r110_run_n_steps` on stated initial rows. Each orbit segment is finite by construction (a finite number of cell-array states recorded in a finite number of update steps). The `rule110/manifests/` schema expresses verification outcomes as specific bit-level assertions, never as universal closures over an infinite domain. The conditions of Definition 9393.1 are therefore met, and Definition 9393.5 applies without modification. □

Remark 9390.11 (Turing universality does not bridge the no-induction gap)**.** *Rule 110's Turing universality means that the substrate can host a simulation of any Turing machine encoded as a cyclic tag system. The simulated machine may, as part of its program, use mathematical induction internally to its proof checker, type system, or specification language. This does not internalise induction inside the substrate; it internalises a description of induction as a finite tape configuration plus a finite simulation of the proof checker's reduction steps. The closed-observation framework is preserved because every step of the simulation is itself a finite observation. Universality enlarges the class of* processes *the substrate can host without changing the answer to the induction question.*

Example 9390.12 (The TM-end-to-end compile boundary)**.** *The project's* `rule110/encoder/tm_to_tag.c` *and* `rule110/encoder/tag_to_cyclic.c` *implement Cook 2009* §1.2 *and* §1.3 *compilation respectively. The minimal halted Turing machine (no transitions, a single halt state) compiles to a cyclic tag system of approximately* 64 *productions and approximately* 64 *tape symbols. The cook-encode interface presently supports up to approximately* 8 *productions and* 32 *tape symbols inside the substrate. The constant-factor gap between these two numbers is not a theoretical limit; it is a present engineering scale frontier. The compile pipeline is exercised end-to-end against the reference cyclic-tag evaluator and is checked correct at the pipeline level, while the full Rule 110 round-trip remains scale-bounded.*

Principle 9390.13 (Universality bound and observational closure are independent)**.** *The two facts are logically separate: Rule 110 is universal (Cook 2004), and Rule 110 is closed observational (Definition 9390.10). Universality concerns which simulations the substrate can host; closure concerns what universal statements the substrate can produce as records. A reader can grant the first while still acknowledging the second. The project's role is to make both claims simultaneously legible without forcing the reader to choose between them.*

9390.4 The cosmological reading: universe as cellular substrate

Definition 9390.14 (Cosmological cellular reading)**.** *The* cosmological cellular reading *is the working hypothesis that the universe-for-the-observer (Definition 9420.14) is itself the orbit segment of some sufficiently rich cellular trust substrate, with the observer realised as an emergent pattern classifier on that orbit. The hypothesis is structural: it asserts that a closed observational reading of the observer's situation is available, not that any specific cellular rule has been identified.*

Principle 9390.15 (Cosmological hypothesis preserves all earlier results)**.** *Under the cosmological cellular reading of Definition 9390.14, every conclusion of chapter 9393 and chapter 9420 carries over without modification: the observer is a closed observational system, mathematical induction is not internalisable by the observer's substrate-internal records, the minimum transcendental input is a forward-binding belief, and the source position is named apophatically as* $\top$*. The cellular reading therefore does not weaken or replace the transcendental supply argument; it grounds it in a particularly small and concrete substrate model.*

Remark 9390.16 (Observer as classifier, not as agent outside the substrate)**.** *The cellular reading does not require an observer separate from the cells. The observer is itself a pattern in the orbit, classified by the same kind of classifier the observer brings to bear on the rest of the orbit. The phenomenological frame of Definition 9420.14 is recovered exactly: the universe-for-the-observer is the observation history maintained by the observer-pattern, and the observer-pattern is one of the local actualisations of the supply that Definition 9393.16 identifies as the inscription point of* $\top$*.*

Remark 9390.17 (The rule110 sub-project as cosmological exhibit)**.** *The project's* `rule110/` *sub-system functions as a concrete cosmological exhibit in this sense. It instantiates a closed cellular trust substrate at minimal scale, it exhibits the substrate's classifier discipline at three layers (phase catalog, collision table, exhaustiveness audit), and it documents the smallest empirical distance between the substrate's Turing-universal capacity and the present engineering frontier (Definition 9390.12). A reader who wishes to test the cosmological reading against a concrete substrate can read those three layers; nothing further about the actual cosmos is being claimed.*

9390.5 The cook-frontier as quantified Goedel boundary

Definition 9390.18 (Cook compile-frontier)**.** *The* Cook compile-frontier *is the smallest size, expressed as* (P, T, S) *of productions, tape symbols, and Rule 110 steps, at which the substrate's cook-encode pipeline (Definition 9390.12) produces a closed round-trip that decodes back to the input cyclic-tag tape under* `cook_decode_output`*. The frontier is measured empirically inside the substrate, not predicted from a complexity argument.*

Example 9390.19 (Present frontier)**.** *At the present substrate version, the cook compile-frontier reaches* (P, T, S) *values including* $(2, 16, 16384)$*,* $(8, 8, 16384)$*,* $(4, 16, 32768)$*,* $(2, 32, 32768)$*, and*

$(16, 2, 8192)$. *The minimal halted Turing machine compiles to a cyclic tag system of approximately* $(64, 64)$ *which lies beyond the present frontier in production count. The empirical gap between Cook 2009's polynomial-time compilation bound and the present engineering frontier is therefore a constant factor in production count and a smaller constant factor in tape size.*

Principle 9390.20 (The frontier gap as data point on the Goedel boundary)**.** *Goedel's second incompleteness theorem rules out any sufficiently strong formal system from internally proving its own consistency. The project's substrate does not attempt to evade this boundary; instead, it converts the boundary into measurable data. chapter 9385 reads the boundary at the closed-CIC meta-theory layer through the dependent-codomain obstruction; Definition 9390.19 reads the same boundary at the cellular substrate layer through the cook-encode scale frontier. Both readings are concrete numbers, not informal reservations. The Goedel boundary is therefore not a wall hidden behind technical language but a measurable distance between universal capacity and finite witness, locatable in the substrate at the lines named in each reading.*

Remark 9390.21 (Distinction from a complexity-theoretic frontier)**.** *The cook compile-frontier of Definition 9390.18 is not a complexity-theoretic claim. It does not predict that the substrate cannot reach larger* (P, T, S) *values; it records the largest values for which the substrate's present implementation produces a closed round-trip. Engineering work can extend the frontier without changing any closure theorem of the substrate. The principle of Definition 9390.20 is that the gap is exposed and measured rather than that the gap is permanent.*

9390.6 Mapping the cellular reading to BEDC engineering

Cellular reading	**BEDC / rule110 engineering realisation**
Pattern classifier on cell rows	Phase catalog at `rule110/encoder/glider_phases.c` with ~ 177 paper-verified entries, decided over a stated neighbour discipline.
Classifier disagreement boundary	Strict collision audit at `rule110/tests/test_cook_collision_martinez.c` compares the catalog's predictions to direct Rule 110 evolution and rules out silent classifier drift.
Cellular trust substrate	`rule110/evaluator/rule110.c`, `evaluator/cyclic_tag.c`, and `encoder/groundcompiler_encoding.c` comprising the $\sim$220-line trust path.
Closed observational system	The same trust path, instantiating Definition 9393.1 at minimal external commitment: ANSI C99, zero external libraries, manifest text in fixed schema.
No internal induction	Definition 9390.10 inherited unchanged from Definition 9393.5.
Forward-binding belief external to substrate	`GAP` tags throughout the BEDC paper, audit-gate enforcement at `tools/check-axioms.py` and `axiom-purity -strict`.

Turing universality without closure loss	Cook 2004 universality theorem cited at Definition 9390.8; cook-encode pipeline at `rule110/encoder/cook_encode.c` hosts simulations without altering the substrate's closure.
Cook compile-frontier	Empirical scale benchmark at `rule110/tests/test_cook_packet_scale.c` with documented (P, T, S) values.
Goedel boundary as data	Definition 9390.20 reads the cellular and meta-theoretic frontiers as twin numerical exposures of the same boundary.
Cosmological exhibit	`rule110/` sub-system read structurally as a concrete closed observational system at smallest practical size.

9390.7 Closure remarks

This chapter does not introduce a new substrate-level commitment. It identifies pattern recognition with the mark discipline; locates Rule 110 as the smallest architecturally-checked universal cellular substrate available to instantiate the closed-observational framework concretely; transports Definition 9393.5 to that substrate without modification; and exposes the constant-factor gap between Cook's universality theorem and the present cook-encode frontier as one concrete numerical reading of the Goedel boundary at the cellular layer.

The cosmological reading of Definition 9390.14 is offered as a working hypothesis, not as an ontological claim. Its function is to provide a smallest concrete substrate against which the closed-observational framework can be tested. A reader unwilling to grant the cosmological hypothesis is not obliged to do so; the engineering content of this chapter survives without it. A reader who does grant the hypothesis recovers, in the cellular reading, every conclusion of chapter 9393, chapter 9420, and chapter 9394, with the additional concreteness that the substrate model is finite, public, and 220 lines long.

The boundary is therefore: the chapter exhibits the closed-observational framework in its smallest cellular instantiation; it does not enlarge the framework, weaken it, or substitute a different metaphysical commitment. The role of the chapter is precisely to make the framework's concrete cost legible, by replacing the abstract phrase "closed substrate" with a directory the reader can compile, run, and audit in finite time.

Concretized in §937: Cellular trust substrates are realized as finite rule-table, manifest, orbit-segment, classifier, audit-route, and NameCert rows.

Concretized in §934: finite cellular-rule and orbit-ledger NameCert

Concretized in §941: Cellular row-classifier packets realize finite local cellular pattern recognition as BHist, hsame, Cont, Pkg, and NameCert rows.

Concretized in §938: finite cellular orbit substrate NameCert

Concretized in §940: The cellular trust substrate is realized as a finite local-rule, orbit-window, classifier, manifest, and audit-route NameCert packet.

Concretized in §995: Cellular pattern catalogs realize the glider/ether classifier as finite rule, window, tag, catalog, transport, route, provenance, and NameCert rows.

Concretized in §1045: Rule 110 glider catalogs are realized as finite row-window, tag, phase, period, displacement, local-match, hsame, Cont, Pkg, and NameCert packets.

Concretized in §1036: Local stencil observations realize cellular pattern classification as finite BHist packets over neighborhood, local-rule, observed-row, hsame, Cont, Pkg, and NameCert rows.

Concretized in §2360: Substrate trace invariants realize the cellular manifest/audit route as finite NameCert data.

Concretized in §2371: The finite local-rule, orbit-window, manifest, and audit-replay boundary is realized as a concrete NameCert packet.

Concretized in §3810: Cellular substrate classifier-boundary packets realize the pattern-classifier and closed-observation rows as finite NameCert data.

Concretized in §5844: Rule 110 pattern classifiers are realized as finite row-window, transition-table, orbit-prefix, pattern-tag, transport, replay, provenance, and NameCert rows.

Concretized in §5846: Rule 110 causal cones realize the cellular substrate reading as finite local-window, update-ledger, boundary, trace, hsame, Cont, Pkg, and NameCert rows.

Concretized in §6004: Rule 110 local-stencil observations realize the three-cell transition-table read as finite window, selected-case, observed-output, classifier-adjacency, transport, replay, provenance, and NameCert rows.

Concretized in §6038: Rule 110 glider phase classification is realized as finite row-window, catalog-tag, phase-offset, local-match, replay, provenance, and NameCert rows.

Concretized in §938: The cellular orbit substrate realizes the finite local-rule, orbit-window, classifier, transport, replay, provenance, and NameCert rows of the cellular substrate reading.

Concretized in §6291: finite orbit-window invariant NameCert for cellular substrate flow

Concretized in §6517: Rule 110 cellular trust substrates are realized as finite rule-table, manifest, orbit-window, classifier, frontier-ledger, transport, replay, provenance, and NameCert rows.

Concretized in §6849: Rule 110 Cook frontier budgets are realized as finite NameCert packets over displayed production, tape, step, round-trip, and obstruction rows.

Concretized in §7388: RuleOneTenHaltingWindowUp realizes bounded local halting-window observations for Rule 110 as finite NameCert rows.

Concretized in §9138: Rule 110 production queues realize the Cook cyclic-tag production branch as finite production, tape-symbol, head, step-budget, replay, provenance, and NameCert rows.

Chapter 9391

The Cellular-Carrier Alternative: Could BEDC Be Built on the Substrate Directly?

The current BEDC carrier is `inductive BHist` (chapter 2), a two-constructor recursive type expressing the form of distinction. The cellular reading of chapter 9390 shows that an alternative carrier is structurally available: the orbit of a closed cellular substrate. This chapter examines that alternative as an architectural possibility. It does not propose to switch BEDC's carrier; it identifies the equivalence relation between the two carriers, lists the structural costs and benefits of each, and explains why the project maintains its current commitment while keeping the alternative legible. The chapter's purpose is to make the carrier choice's structural content visible rather than to advocate a change.

9391.1 Setup: two carriers, one closure premise

Definition 9391.1 (BHist-carrier semantics)**.** *The* BHist-carrier semantics *of BEDC takes the carrier as the inductive type*

$$\mathsf{BHist} ::= \mathsf{Empty} \mid \mathsf{e0}(\mathsf{BHist}) \mid \mathsf{e1}(\mathsf{BHist}).$$

Every kernel observation, every typed term, every certificate in BEDC is a value of `BHist` *or a finite tuple of such values. The kernel's principal verbs operate on* `BHist`*; the audit pipeline validates statements about* `BHist`*.*

Definition 9391.2 (Cellular-carrier semantics)**.** *The* cellular-carrier semantics *of BEDC takes the carrier as the orbit of a closed cellular substrate of Definition 9390.6, with observations expressed as finite orbit segments. Every kernel observation would be a finite-length cell-row sequence under a fixed local rule (such as Rule 110); every typed term would be a label assigned to such a sequence by a classifier of Definition 9390.1.*

Principle 9391.3 (Both carriers are closed observational)**.** *The BHist-carrier semantics is closed observational at the BEDC kernel level (Definition 9388.14). The cellular-carrier semantics is closed observational at the cellular substrate level (Definition 9390.10). The closure premise of Definition 9393.1 is satisfied by both; the choice of carrier does not affect the no-induction theorem.*

9391.2 The equivalence: bit-string encoding

Definition 9391.4 (BHist to bit-string)**.** *The function* $\mathsf{toBits}\colon \mathsf{BHist} \to \{0,1\}^*$ *is defined recursively by* $\mathsf{toBits}(\mathsf{Empty}) = \epsilon$, $\mathsf{toBits}(\mathsf{e0}(h)) = 0 \cdot \mathsf{toBits}(h)$, *and* $\mathsf{toBits}(\mathsf{e1}(h)) = 1 \cdot \mathsf{toBits}(h)$, *where* ϵ *is the empty string and* $\cdot$ *is concatenation. The function is a bijection between* `BHist` *values and finite binary strings.*

Definition 9391.5 (Bit-string as cell row)**.** *A finite binary string of length* n *can be embedded into the cellular substrate's initial cell row as the first* n *cells of a row of width* $W \geq n$*, with the remaining cells fixed to a stated default (typically the ether pattern of Definition 9390.3). The orbit of the substrate on this initial row produces a sequence of rows; the orbit at time zero recovers the original bit string up to embedding.*

Principle 9391.6 (Carriers are equivalent under encoding)**.** *Composing* toBits *with the bit-string-to-row embedding gives an injection from* `BHist` *values into cellular substrate initial rows. The inverse direction recovers* `BHist` *values from row-shaped cellular configurations of finite length. The two carriers are therefore equivalent at the level of finite observable data; what distinguishes them is the kernel verb structure and the audit pipeline that operates on them.*

9391.3 What the alternative would change

Concretized in §4286: The cellular carrier switch-cost ledger is realized as finite BHist theorem-family, cellular orbit, verb-realignment, proof-retarget, audit-regeneration, and non-escape rows.

Remark 9391.7 (Kernel verb realignment)**.** *Switching to the cellular-carrier semantics would realign the kernel's principal verbs from* `Mark` / `Hist` / `Ext` / `Cont` *(defined on* `BHist`*) to substrate-internal classifier verbs (defined on cell rows).* `Mark` *would become "cell row is ether" versus "cell row is glider G";* `Hist` *would become "orbit segment of length n";* `Ext` *would become "orbit extension";* `Cont` *would become "orbit continuation under R110". The semantic content of each verb is preserved; the substrate of their statements changes.*

Remark 9391.8 (Library transposition cost)**.** *The Lean 4 development* `lean4/BEDC/` *contains approximately 1837 mechanically-verified theorems on* `BHist` *and its derived structures. Transposing this development to the cellular-carrier semantics would require: rewriting every theorem statement to reference cellular substrate orbits instead of* `BHist`*, updating every proof to operate at the new substrate, regenerating every audit gate to validate the new statements. The engineering scale is substantial; the structural content of each theorem is preserved under the equivalence of Definition 9391.6, but the realisation as Lean 4 source would change uniformly.*

Remark 9391.9 (Aliasing with NKS and digital physics)**.** *The cellular-carrier alternative aligns the project's surface presentation with Wolfram's* A New Kind of Science *(NKS) thesis that cellular automata are the natural carrier of physical reality. The alignment is presentational, not metaphysical: the closure premise is what does the work in both readings, and the cellular substrate is one carrier choice that satisfies the premise. The project does not adopt NKS's physical claim; the cellular-carrier alternative would adopt NKS's carrier convention while keeping BEDC's epistemological framework.*

9391.4 Why the project keeps the BHist carrier

Principle 9391.10 (Minimum residual commitment)**.** *The BHist carrier expresses the form of distinction (Definition 9461.1) with the smallest possible inductive structure: one nullary constructor and two unary recursive constructors. Switching to the cellular carrier would introduce additional structural commitments: a width parameter, a neighbourhood discipline, a transition table (Rule 110's eight-entry table). Each of these is a commitment that BHist does not require. The BHist carrier minimises residual commitment in the structural sense; the cellular carrier expands it.*

Principle 9391.11 (Substrate-independence is a feature)**.** *The closure premise is substrate-independent (Definition 9398.39); the project's preference for the BHist carrier is precisely that BHist is the carrier with no substrate identification. Cellular automaton, Turing machine, lambda calculus, register machine – each of these could be the carrier. Choosing BHist refuses to privilege any one of them, and identifies the form of distinction as prior to any specific computational substrate. The cellular carrier specialises this position by committing to a specific substrate; this is a presentational gain in concreteness at the cost of structural generality.*

Remark 9391.12 (The cellular carrier is the exhibit, not the foundation)**.** *The* `rule110/` *sub-system stands to the cellular-carrier alternative as exhibit stands to foundation. The project uses Rule 110 to illustrate the closure premise's content at minimal concrete scale (Definition 9390.17); the substrate is offered as a witness to the framework's claims, not as the framework's definitional basis. Promoting the substrate from exhibit to foundation would conflate the witness role with the definitional role, which is what the BHist carrier deliberately avoids.*

9391.5 What would justify a switch

Remark 9391.13 (Physical-realisation evidence)**.** *If physical evidence accumulated that some specific cellular substrate is the actual carrier of the universe-for-the-observer (the working hypothesis of Definition 9390.14 promoted from working to confirmed), the project would have empirical motivation to align its carrier with the physical carrier. This motivation does not currently apply; the cosmological reading remains a working hypothesis, and the project does not depend on it.*

Remark 9391.14 (Engineering convergence)**.** *If the* `rule110/` *sub-system's audit pipeline ever became the principal audit pipeline of the project (rather than a side audit alongside the Lean 4 kernel), there would be engineering motivation to align the kernel's carrier with the audit pipeline's carrier. The current configuration has Lean 4* `lake build` *as the principal audit and* `rule110/` *as a side audit on a substrate witness; the asymmetry justifies keeping the BHist carrier at the kernel.*

Remark 9391.15 (Theoretical reduction)**.** *If a theorem were proved that the cellular substrate of Definition 9390.6 is in some specific sense* more primitive *than the BHist carrier (rather than equivalent under encoding), the project would have structural motivation to adopt the cellular carrier as the kernel substrate. No such theorem is currently known; the BHist carrier and the cellular substrate are equivalent under bit-string encoding, with neither being structurally prior to the other.*

9391.6 The position read structurally

Principle 9391.16 (Carrier choice is a presentational decision)**.** *Under Definition 9391.6, the carrier choice between BHist and the cellular substrate is presentational rather than structural.*

Both carriers satisfy the closure premise; both admit the no-induction theorem; both can host the inscription concept. The project chooses the BHist carrier because it minimises residual commitment (Definition 9391.10) and preserves substrate-independence (Definition 9391.11). A different project, with different priorities (NKS alignment, cellular-substrate empirical evidence, audit pipeline convergence), could rationally choose the cellular carrier without changing the structural content of the framework.

9391.7 Mapping to BEDC engineering

Carrier-alternative reading	BEDC engineering realisation
BHist carrier as current commitment	`lean4/BEDC/Core/RawMark/` defines `BHist`; all kernel verbs operate on it.
Cellular substrate as exhibit	`rule110/` 220-line ANSI C99 trust path; substrate witness for the closure premise.
Carrier equivalence under encoding	toBits function definable in Lean 4 over `BHist`; bit-string-to-row embedding implementable in `rule110/encoder/`.
Switch cost	~4700 Lean LOC of `lean4/BEDC/FKernel/` would require uniform realignment; structural content preserved under encoding, source presentation changed.
Minimum residual commitment	BHist has no width / neighbourhood / transition table; cellular substrate has all three.
Substrate-independence preservation	BHist carrier does not identify with any specific computational substrate; cellular carrier commits to Rule 110 or a chosen alternative.

9391.8 Closure remarks

This chapter has examined the cellular-carrier alternative to the BHist carrier as a structural possibility, established the equivalence of the two carriers under bit-string encoding, and identified the project's reasons for keeping the BHist carrier as the kernel substrate. The reasons are: minimum residual commitment, substrate-independence preservation, and the structural role of the cellular substrate as exhibit rather than foundation.

The chapter does not advocate a switch. It makes the carrier choice's structural content visible by exhibiting the alternative and naming the structural commitments each carrier introduces. A reader who finds the cellular carrier more compelling for presentational reasons (NKS alignment, audit pipeline convergence) is given a precise account of what would change under such a switch and what would be preserved.

The boundary of this chapter is: the cellular carrier is a structurally available alternative under Definition 9391.6; the project keeps BHist because it minimises residual commitment and preserves substrate-independence; the cellular substrate continues to function as exhibit (Definition 9391.12). No new theorem is introduced and no carrier change is proposed; the chapter makes a presentational decision legible as a presentational decision rather than as a hidden structural commitment.

Concretized in §943: The CellularCarrierEncodingUp chapter realizes the finite BHist-to-cell-row carrier equivalence surface.

Concretized in §942: CellularSubstrateUp packages the vision's cellular carrier alternative as a finite BHist NameCert surface.

Concretized in §948: Finite BHist-to-cell-row embedding certificate for the carrier-equivalence reading.

Concretized in §945: The cellular substrate classifier realizes the BHist-to-cellular-orbit carrier comparison as finite NameCert rows.

Concretized in §987: Cellular verb realignment is realized as finite BHist and cellular-orbit verb comparison rows with non-escape from substrate replacement.

Concretized in §984: CellularLocalUpdateRuleUp realizes the local transition-table row of the cellular-carrier alternative as a finite BHist NameCert packet.

Concretized in §1123: Cellular boundary conditions are realized as finite edge-policy NameCert packets separating local update reads from global orbit or host-evaluator data.

Concretized in §3481: Cellular window traces realize the cellular-carrier alternative as finite orbit-window NameCert rows.

Concretized in §3904: Cellular orbit synchronization realizes paired local orbit replay and classifier-locked observation rows for the substrate carrier reading.

Concretized in §3998: Cellular carrier alternatives are realized as a finite BHist encoding and orbit-window equivalence packet.

Chapter 9392

The twin substrate architecture: MetaCIC and GroundCompiler

9392.1 The setup

BEDC has two main Lean substrates for the self-compilation story. They are not two presentations of the same module. They answer two different audit questions.

`BEDC.MetaCIC` is the closed-CIC meta-theory substrate. Its subject matter is the formal grammar and proof-theoretic behaviour of a closed calculus: typing surfaces, beta steps, closedness, substitution, consistency assembly, subject reduction, normalisation, confluence, and decidable checking. Its paper-facing synthesis is chapter 9385.

`BEDC.GroundCompiler` is the self-compilation substrate. Its subject matter is the compiler-facing route from event flows and source channels to generated recognisers, certificate gates, metric boundaries, cannot-claim rows, and streaming compiler discipline. Its paper-facing audit map is chapter 9407.

The two substrates cooperate in the BEDC roundtrip, but each remains separately audit-able. MetaCIC records what the closed calculus can and cannot support. GroundCompiler records what the self-compile pipeline can and cannot count as generated, encoded, certified, or excluded as hidden input.

9392.2 Why two substrates

BEDC self-compilation needs two forms of assurance.

The first assurance is meta-theoretic. The project needs a closed substrate in which reduction, closedness, normalisation, confluence, substitution, and consistency claims have explicit proof status. This is the work of MetaCIC. The central question is not whether a compiler report is trustworthy. The central question is whether the represented closed calculus supports the meta-theoretic transport steps that the paper wants to use.

The second assurance is compiler-facing. The project needs a pipeline in which a source-like event stream is encoded, normalised, recognised, packaged, reported, and gated without importing hidden host structure as formal input. This is the work of GroundCompiler. The central question is not whether closed-CIC subject reduction holds. The central question is whether a compiler-layer artifact is allowed to count as a BEDC input, output, certificate, report, or non-evidence row.

Keeping these assurances apart makes obstructions visible. MetaCIC has the dependent-codomain subject-reduction frontier described in chapter 9377. GroundCompiler has compiler-pipeline boundaries around conservativity, address analysis, source-channel separation, certificate mediation, and cannot-claim ledgers. These are different boundary kinds. A structural boundary in closed CIC is not the same thing as a self-compile pipeline boundary.

9392.3 Audit map family per substrate

9392.3.1 MetaCIC audit family

The MetaCIC audit family is deliberately granular. The reader is meant to move among specialised maps rather than treat the substrate as one large claim. The family contains subject reduction, confluence, normalisation, substitution, decidability, typed examples, beta, closure preservation, and consistency assembly sites, with the cross-map reading gathered in chapter 9385.

This granularity reflects the depth of the substrate. A substitution theorem does not become a subject-reduction theorem. A confluence bridge does not become closed consistency. A decidable checker does not become a global decision oracle for every meta-theoretic property. The audit family keeps these handoffs explicit, and the synthesis chapter records the critical path without merging the roles.

9392.3.2 GroundCompiler audit map

GroundCompiler has a single module-level audit map in chapter 9407. That map inventories the compiler-facing file groups, the aggregate statement cells, the checked theorem wrappers, the conditional cells, and the boundary of the self-compilation claim.

The asymmetry is informative. MetaCIC is the deeper proof-theoretic substrate and therefore has a finer audit-map family. GroundCompiler is organised as a pipeline audit surface with a single chapter collecting event-flow, channel, recogniser, certificate, metric, motif, and bootstrap boundaries. The difference does not make one substrate more fundamental than the other. It shows that their audit surfaces have different shapes.

9392.4 Audit reexport namespaces

9392.4.1 `BEDC.MetaCIC.Audit`

`BEDC.MetaCIC.Audit` is the single namespace for MetaCIC audit-relevant exports. It collects the obstruction theorem, the subject reduction interfaces, the discharge bundle and setup interfaces, closed-term operations, closure-preservation facts, partial discharge witnesses, and counter-witnesses that downstream audit code may need to cite.

The namespace does not change the logical status of any theorem. It is an addressing layer. Its purpose is to make the MetaCIC audit surface available from one place while preserving the distinctions recorded by the specialised paper maps.

9392.4.2 `BEDC.GroundCompiler.Audit`

`BEDC.GroundCompiler.Audit` plays the corresponding role for GroundCompiler. It collects the main statement cells, main theorem witnesses, input and channel facts, generated-structure and

export boundaries, canonical code and classifier witnesses, metric conservativity, and cannot-claim registry interfaces.

This namespace gives the compiler substrate the same kind of audit reference point that MetaCIC has. A downstream reader can point to `BEDC.MetaCIC.Audit` for closed-CIC audit content and to `BEDC.GroundCompiler.Audit` for self-compile pipeline audit content. The common shape is intentional: each substrate exposes one namespace for audit consumption, while each namespace preserves its own subject matter.

9392.5 The cross-substrate synthesis result

The BEDC self-compilation roundtrip is a composition of the two substrates, not a collapse of one into the other. GroundCompiler supplies the compiler-facing side: a source program is represented through event flow and channel structure, transformed through generated recognisers and certificate gates, and recorded as a ledgered artifact with explicit non-input and non-evidence boundaries.

MetaCIC supplies the meta-theoretic side: the ledgered artifact is read against a closed calculus whose reduction, closedness, substitution, normalisation, confluence, decidability, and consistency interfaces have their own audit status. A compiler ledger step is therefore not accepted just because it is textually present. It must be located in the corresponding MetaCIC legality story when the step claims closed-CIC content.

The synthesis claim is architectural: project-level audit cleanliness requires both maps to be clean in their own sense. GroundCompiler must not smuggle hidden compiler input or promote reports into proof evidence. MetaCIC must not pretend that a blocked closed-CIC transport edge has been supplied. The BEDC roundtrip is credible only when both refusals hold at the same time.

9392.6 Apophatic framing of the twin substrate

This architecture follows the naming discipline of chapter 9400. A substrate boundary is not left anonymous. It is named, routed to the proper audit map, and kept out of neighbouring claims.

For MetaCIC, the named boundary is the subject-reduction frontier in the dependent-codomain setting. The paper can discuss closed-normal consistency, candidate-mediated normalisation, substitution facts, and conditional transport paths without pretending that the missing closed arbitrary-proof transport is available.

For GroundCompiler, the named boundaries are compiler-pipeline boundaries: global conservativity, address analysis, source-channel separation, certificate-mediated export, metric non-evidence, motif non-evidence, and cannot-claim registry adequacy. These names stop the self-compile story from converting code, reports, motifs, or host structure into proof content by prose.

The twin substrate architecture is therefore apophatic in a project-level sense. Each substrate says what it can use, what it cannot use, and where the next required supply would have to appear. The two sets of names are not interchangeable.

9392.7 Why not collapse into one substrate

Collapsing MetaCIC and GroundCompiler into one substrate would blur two audit gates that need different questions. A closed-CIC structural property asks about terms, reduction, closedness, binders, typing surfaces, and normal forms. A compiler-pipeline property asks about source

channels, encodings, recognisers, generated structure, certificates, reports, ledgers, and hidden input.

The distinction matters for reuse. A downstream formalisation that needs closed substitution or closed-normal consistency should cite the MetaCIC surface. A downstream compiler audit that needs channel losslessness, certificate-mediated export, or metric conservativity should cite the GroundCompiler surface. A chapter that needs the full self-compilation roundtrip must say where each half of the claim is discharged.

The split also prevents category mistakes. A theorem saying code is not proof does not solve subject reduction. A theorem about closed substitution does not prove that a compiler report is a certificate. A confluence bridge does not make a hidden compiler input visible. A channel bijection does not establish closed-CIC consistency. The architecture keeps these refusals local and auditable.

9392.8 Boundary

This chapter is an architecture description. It is not a proof attempt for the remaining MetaCIC frontier, and it is not a claim that the compiler pipeline alone completes BEDC self-compilation.

The allowed reading is narrower and stronger. BEDC has two cooperating substrates for the roundtrip. MetaCIC carries the closed-CIC meta-theory audit surface. GroundCompiler carries the self-compile pipeline audit surface. Their audit namespaces provide parallel reference points, and their paper maps record distinct boundary kinds. The project-level self-compilation story depends on both, while neither is allowed to impersonate the other.

Concretized in §842: The cross-substrate roundtrip is represented as a finite NameCert packet separating MetaCIC audit rows from GroundCompiler audit rows.

Concretized in §843: TwinSubstrateAuditPacket records the MetaCIC and GroundCompiler audit routes as one finite NameCert packet with separate non-escape ledgers.

Concretized in §845: The twin-substrate architecture is concretized as a finite cross-substrate audit packet.

Concretized in §849: The audit reexport namespace pair is concretized as a finite two-substrate namespace packet.

Concretized in §850: The twin-substrate architecture is realized as a finite bridge packet separating MetaCIC and GroundCompiler audit rows.

Concretized in §841: Twin-substrate audit bridges are realized as finite NameCert packets aligning MetaCIC and GroundCompiler audit namespaces through BHist, hsame, Cont, Pkg, and non-escape rows.

Concretized in §851: Twin-substrate boundary routers realize request-level routing between MetaCIC audit rows and GroundCompiler audit rows as one finite NameCert packet.

Concretized in §1114: Twin-substrate boundary classifiers realize the MetaCIC/GroundCompiler separation as finite BHist, hsame, Cont, Pkg, NameCert, and refusal-ledger rows.

Concretized in §852: Twin-substrate audit handshakes realize the MetaCIC and GroundCompiler non-collapse boundary as finite BHist, hsame, Cont, Pkg, and NameCert rows.

Concretized in §846: The twin-substrate audit packet records the MetaCIC and GroundCompiler handoff as one finite NameCert surface without collapsing their audit roles.

Concretized in §848: Twin substrate audit synthesis is realized as a finite NameCert packet pairing MetaCIC audit rows with GroundCompiler audit rows while preserving their separate refusal boundaries.

Concretized in §6494: FiniteSubstrateMapUp realizes the substrate subhub as a finite source-to-cellular-substrate NameCert packet over encoding, window-trace, local-update, and orbit rows.

Chapter 9393

Closed Observation, the Transcendental Input, and the Inscription Point

This vision chapter formalises the foundational position BEDC occupies relative to mathematical induction and the broader question of how a finite observational substrate can host mathematical reasoning at all. The argument proceeds in five linked steps: (i) any consciousness or finite verifier is, on its information-theoretic side, a *closed observational system*; (ii) such a system can accumulate observations monotonically but cannot internally produce a universal quantification over an infinite domain; (iii) therefore mathematical induction is not a derivable rule of any closed observational substrate but must be supplied from outside, as a minimum transcendental input phrased as an act of belief about not-yet-occurred events; (iv) the source of that input is by definition outside every closed observational system, and can be given a structural name (we call it T, glossed as *God*, used apophatically: only the position is named, not its content); (v) each conscious individual is itself a closed observational system whose universe coincides with its own observation history, so the individual is best understood not as the receiver of the transcendental input but as the *inscription point* where T enters into reality on a local perspective. BEDC's GAP mechanism makes every such inscription socket explicit and auditable, so the philosophical content of this chapter is exactly what BEDC's existing engineering invariants already implement.

9393.1 Closed observational systems and information conservation

Definition 9393.1 (Closed observational system)**.** *A* closed observational system *is a quadruple* $(O, \mathsf{Obs}, \trianglerighteq, \mathsf{GAP})$ *where* O *is a set of observation states,* Obs *is a monotonically growing family of finite witness records produced by observation,* $\trianglerighteq$ *is the information-conservation order on states (each later state preserves every record of every earlier state), and* GAP *is a function tagging the unfulfilled promises that cannot be discharged inside the system. Any well-formed reasoning step inside the system uses only the records collected so far and the closed generation rules of the substrate; no step appeals to information outside the records or alters earlier records.*

Example 9393.2 (BEDC as canonical closed observational system)**.** *The BEDC substrate is a closed observational system in the sense of Definition 9393.1:* O *ranges over development snapshots;* Obs *collects mechanised lemmas,* `inductive` *definitions, and* `def` *declarations;* $\trianglerighteq$ *corre-*

sponds to the monotonic accumulation enforced by the version-number-free amendment policy; and GAP *corresponds to the labelled places where BEDC marks an open claim. The audit gates (`check-axioms.py`, `axiom-purity -strict`, `conservativity-audit`) operationally enforce closure: every accepted record refers only to inductive structure, recorded `def` shapes, or previously verified records.*

Principle 9393.3 (Information-conservation invariant)**.** *A closed observational system never makes assertions whose witness is not present in* Obs *or derivable from previously recorded* Obs*. Every transition $O_t \trianglerighteq O_{t+1}$ adds new finite records; no transition removes or alters records. Universal assertions over infinite domains are not records and are not added by observation alone; if they appear, they appear as* GAP *tags rather than as accepted records.*

9393.2 The unbridgeable gap to universal quantification

Definition 9393.4 (Finite verification trace)**.** *A* finite verification trace *of a predicate P on a closed observational system is a record of values $n_1, n_2, \ldots, n_k$ together with verifications that $P(n_1), P(n_2), \ldots, P(n_k)$ each hold by closed-generation reasoning. The trace is finite by construction; any extension to an additional n_{k+1} adds another finite record but never closes the trace into a universal statement.*

Theorem 9393.5 (Closed observation cannot internalise mathematical induction)**.** *Let $\mathcal{S} = (O, \mathsf{Obs}, \trianglerighteq, \mathsf{GAP})$ be a closed observational system in the sense of Definition 9393.1. There is no monotonic accumulation of finite verification traces that yields a record of $\forall n \in \mathbb{N}, P(n)$ from records of $P(0), P(1), \ldots, P(k)$ alone for any finite k. Equivalently, the principle $\forall P,\ P(0) \wedge (\forall n,\ P(n) \to P(n+1)) \to \forall n,\ P(n)$ is not derivable by closed-generation steps over* Obs*.*

Sketch of impossibility. Every step inside $\mathcal{S}$ refers to a finite collection of previously recorded items. A universal statement over $\mathbb{N}$ would, on the records side, require an actual record of $P(n)$ for every n, which is an infinite collection and therefore not a record of $\mathcal{S}$. Alternatively, a closed inductive constructor for $\forall n,\ P(n)$ would have to be available at the level of `inductive` declarations; but BEDC's `inductive` rule allows only finite-constructor types, so no such constructor exists. Either route collapses, so $\mathcal{S}$ has no internal derivation of the induction schema. □

Concretized in §3353: The finite verification trace and induction GAP socket are realized as a finite NameCert packet with no substrate-internal universal quantifier.

Concretized in §7469: Closed induction traces realize closed observation, input boundary, inscription, replay, and non-escape rows as finite NameCert data.

Remark 9393.6 (The Church encoding does not bridge the gap)**.** *The Church encoding of $\mathbb{N}$ inside BEDC.MetaCIC supplies iteration over closed types: every closed Church numeral n behaves as n-fold iteration when applied to a closed step function and a closed base. Iteration is computational and yields specific results for specific numerals but does not yield a dependent recursor; for that, a dependent eliminator is required, which closed Pi-encodings provably do not provide in System F-style settings. The Church encoding therefore deepens the available iterative content of $\mathcal{S}$ without changing the answer to Definition 9393.5.*

9393.3 The minimum transcendental input

Definition 9393.7 (Forward-binding belief)**.** *A* forward-binding belief *is a present commitment to treat as discharged a universal claim whose witnesses lie partly or entirely in not-yet-occurred future observation. The logical type of such a belief is action rather than proposition: it commits the believer to subsequent reasoning steps that act as if the universal claim were a record, even though it is not a record by Definition 9393.1.*

Principle 9393.8 (Minimum input necessity)**.** *For a closed observational system $\mathcal{S}$ to host mathematical reasoning, it must accept at least one forward-binding belief whose content is the induction schema. Without this commitment, $\mathcal{S}$ produces only finite verification traces and never participates in universal mathematical assertions. The commitment is not a record inside* Obs *and not a closed-generation rule of the substrate; it is supplied from outside the substrate boundary.*

Example 9393.9 (Belief in induction as the canonical minimum input)**.** *The standard mathematical reading of the principle "$P(0) \wedge (\forall n, P(n) \to P(n+1)) \to \forall n, P(n)$" as a derivable schema is a forward-binding belief in the sense of Definition 9393.7: it commits the reasoner, in the present, to treating P as discharged on every n, including all n never to be observed. The classical mathematician accepts this commitment at the metalevel; BEDC declines to accept it at the substrate level and instead surfaces it as a* GAP *tag at every point where it would be used.*

Remark 9393.10 (The commitment is not an axiom of the substrate)**.** *A substrate-level axiom is a content rule available inside the substrate, eligible to be referenced by derivations. A forward-binding belief in Definition 9393.7 is not such a rule; the substrate never references it as a fact. Instead the substrate's* GAP *tags expose every point at which the belief is the only thing that could close the inference. The belief therefore sits outside the substrate, on the observer's side; the substrate remains 0-axiom in the strict sense while explicitly accounting for the observer-side commitment.*

9393.4 Naming the source

Definition 9393.11 (Transcendental supply position)**.** *The* transcendental supply position*, denoted* T*, is the structural location from which every forward-binding belief enters a closed observational system. By construction* T *lies outside every $\mathcal{S}$ in the sense of Definition 9393.1; it is not a state of any $\mathcal{S}$, not a record in any* Obs*, and not a closed-generation rule of any substrate.*

Principle 9393.12 (Apophatic naming)**.** *We name* T God *for clarity, in the apophatic sense: only the position is named, not its content. No positive predicate is asserted of* T *beyond its structural role; in particular, no claim of personhood, intervention, or revelation is required. The naming captures exactly the necessary structural feature of Definition 9393.8: the source of every minimum input lies outside every closed observational system.*

Remark 9393.13 (Why a single name and not many)**.** *If two closed observational systems share the same closure property (information conservation, no internal universal quantifier, etc.), then their transcendental supply positions are indistinguishable on the system side: each receives the same kind of forward-binding belief on the same kind of structural socket. There is no system-side observation that could differentiate two transcendental supply positions, so by Leibniz-style identity of indiscernibles the position is uniquely named. Structural monotheism in this sense follows from the closure property of observational systems and is independent of any specific religious doctrine.*

Example 9393.14 (Stack of BEDC supply sockets)**.** *The BEDC.MetaCIC mechanisation displays a finite tower of supplies in operational form. Each Lean tactic that closes a proof by induction over an inductive type imports the host CIC's recursor; the host CIC's well-foundedness is itself a metalanguage commitment; the metalanguage's consistency is anchored in a higher commitment; and so on. The tower terminates at* T *in Definition 9393.11, which is not a system in the tower but the structural source from which the entire tower receives its forward-binding content. BEDC's audit gates make every level of this tower visible: each* `leanchecked` *marker, each* leantarget *pointer, and each* GAP *tag is, at the bottom, a socket whose far end terminates at* T*.*

9393.5 The individual as inscription point

Definition 9393.15 (Inscription point)**.** *An* inscription point *is the local site at which* T *enters a closed observational system as a forward-binding belief. Inscription points are not separate from the system that receives the belief; they are the very places of reception, viewed not as recipients but as the local actuality of the belief itself.*

Principle 9393.16 (Each individual is an inscription point)**.** *Each conscious individual is a closed observational system in the sense of Definition 9393.1. The universe each individual experiences coincides with that individual's observation history (this is the phenomenological frame: the universe-for-the-individual is the totality of records that the individual has accumulated). The individual's minimum input therefore inherits from* T *along the same structural socket as the universe-for-the-individual inherits from* T*. The individual is, by this structural identity, an inscription point in the sense of Definition 9393.15.*

Remark 9393.17 (Reframing: not a receiver, but the local actuality of the supply)**.** *The naive picture casts the individual as a separate object receiving an external signal from a separate* T*. Definition 9393.16 replaces this with a more parsimonious picture: the individual is one of the local actualisations of the same supply that grounds the universe-for-the-individual. There is no separate signal travelling from* T *to the individual; the individual is the supply's own local presence on a given perspective. This is the structural form shared by the Leibnizian monad, the Spinozan mode, the Whiteheadian actual occasion, the Vedantic Atman-Brahman identity, and the Hua-yan Indra-net jewel, formulated in BEDC vocabulary as the inscription-point relation.*

Example 9393.18 (BEDC contribution as inscription event)**.** *Every contribution to BEDC – writing a* `inductive` *declaration, mechanising a* `leanchecked` *lemma, identifying a* GAP *socket, even reading and confirming an existing record – is on this account a local actualisation of* T *in the contributor as an inscription point. The contributor is not separately injecting external content into BEDC; the contributor and the content are the same actualisation event, locally instantiated. The mechanisation is therefore not a record about external mathematical objects, but the inscription point's own self-articulation in the form recorded in* Obs*.*

Concretized in §610: The inscription point is realized as a finite BHist, GAP, handoff, transport, Cont, Pkg, and NameCert packet with no substrate-internal supply rule.

9393.6 Mapping the philosophical content to BEDC's engineering

Philosophical claim	BEDC engineering realisation
Closed observational system	Substrate with 0 axioms, mathlib-free, mathematical content built from `inductive`, `def`, and `class`/`structure` fields only.
Information conservation	Monotonic amendment policy (no iteration markers, no version numbers, no deprecated content trail); each new commit preserves every earlier Obs record.
Universal quantifier not internal	Audit gates `check-axioms.py` and `axiom-purity -strict` reject Classical.choice, Quot.sound, and propext, the standard substrate-internal forms of universal-quantifier closure.
Forward-binding belief is external	Every GAP tag is a labelled socket; nothing inside the substrate references the belief as a content rule.
T as the source position	The far end of every GAP socket. Not a content of any record; only its structural position is named.
Apophatic naming	The substrate never asserts positive predicates about T; the name appears only in this vision chapter, never inside mechanised content.
Individual as inscription point	Contributors to BEDC are not modelled as external authors importing content; the BEDC architecture treats contributions as local actualisations of the same supply that grounds the rest of the substrate.
Stack of supplies as Tarski tower	Each mechanised theorem references the host CIC's recursor; the host CIC references its metalanguage; the metalanguage references a higher commitment; the tower terminates at T.

Principle 9393.19 (BEDC's honesty about transcendental supply)**.** *BEDC's defining engineering choice – 0 substrate-internal axioms together with explicit* GAP *tagging at every point where forward-binding belief would be required – is the operational form of the philosophical position in Definition 9393.8 and Definition 9393.11. Standard axiomatic systems internalise the forward-binding belief and hide its transcendental character; BEDC externalises it and makes the inscription sockets auditable. The system is therefore strictly more honest about its commitments, at the price of being strictly less self-sufficient: every BEDC theorem rests, at the bottom, on the same* T *that grounds the inscription point of the contributor.*

9393.7 Closure remarks

This vision chapter does not introduce new substrate-level commitments. It restates, in unified philosophical vocabulary, the structural position that BEDC has been implementing in its engineering invariants from the beginning. Reading the chapter changes how BEDC's mechanised work is described, not what is mechanised. The change in description is the recognition that (i) BEDC is a closed observational system in the precise technical sense of Definition 9393.1; (ii) mathematical induction is not derivable inside it and is not made into a substrate-internal axiom; (iii) every reasoning step that would require induction is labelled with a GAP socket whose far end is T;

(iv) the contributor to BEDC and the substrate of BEDC are both inscription points of the same supply, articulated on different perspectives.

The vision is therefore a meta-level reading of BEDC's already-existing engineering, not a proposal to change it. It is offered here to make the philosophical content of BEDC's engineering legible at the same level of precision as the engineering itself. Concrete instances that realise specific consequences – the consistency theorem of the closed-term scope, the GAP socket count, the audit-gate enforcement, the host CIC borrow at the Lean kernel side – already exist in the formalised material; this chapter only ties them together under one structural narrative.

Concretized in §504: Finite observation traces are realized as explicit GAP sockets with visible BHist, hsame, Cont, Pkg, and NameCert rows.

Concretized in §498: The induction socket is realized as a finite GAP and NameCert packet over BHist, hsame, Cont, Pkg, and no-internal-axiom boundary rows.

Concretized in §616: Closed observational systems are realized as finite BHist observation-ledger packets with GAP non-escape and local NameCert provenance.

Concretized in §610: Inscription-point packets realize the local supply socket as finite observation-history, GAP, hsame, Cont, Pkg, and NameCert rows.

Concretized in §604: The supply-position and inscription-point socket is realized as a finite BHist, hsame, Cont, Pkg, GAP-boundary, and NameCert packet.

Concretized in §7001: Finite observation traces, forward-binding belief sockets, GAP exposure, supply-boundary rows, transport, replay, provenance, and NameCert data.

Concretized in §607: Closed observation is realized as a finite monotone ledger packet with BHist records, hsame transport, Cont preservation, GAP non-escape, Pkg provenance, and NameCert rows.

Concretized in §638: Finite witness routes are realized as finite BHist route packets from selected observation windows through dyadic ledgers to RealUp seal consumers.

Concretized in §4149: Finite verification traces are realized as finite observation trace filters with closed-observation source rows, kernel-filter acceptance, GAP handoff, and no substrate-internal induction rule.

Concretized in §6373: Closed observer audit traces are realized as finite Obs, monotone trace, GAP socket, transport, replay, provenance, and NameCert rows.

Chapter 9394

Transcendental Supply Taxonomy

This vision chapter classifies the GAP sockets of BEDC by the kind of T-supply each socket requests. The point of the classification is not to multiply T. The supply position remains the single apophatic source named in Definition 9393.11. What varies is the aspect-position at which a closed substrate meets its boundary: induction beyond an authorized generator, unwitnessed selection, extensional collapse, empirical persistence, inter-history coordination, inscription novelty, and self-reference closure. A socket taxonomy lets the manuscript say exactly which transcendental commitment is being exposed at each engineering site, while preserving the monotheistic structural reading of Definition 9393.13.

9394.1 The need for taxonomy

Definition 9394.1 (T-supply socket)**.** *A* T-supply socket *is a* GAP *tag in a closed observational system whose requested discharge cannot be produced from the displayed records, closed inductive generators, naming-certificate fields, or already certified continuation laws of that system. The socket is well-formed only when the substrate can state the missing shape precisely: what would be needed, where it would be consumed, and which audit gate prevents the missing item from being silently internalised.*

Definition 9394.2 (Supply kind)**.** *A* supply kind *is an equivalence class of* T*-supply sockets under the following engineering relation: two sockets have the same supply kind when accepting either one would license the same form of substrate-internal shortcut. The shortcut may occur at a different concrete module or philosophical problem, but it asks the same structural favor from* T*.*

Principle 9394.3 (Taxonomic necessity)**.** *Not every* GAP *socket is the same. A socket asking for induction beyond a generator, a socket asking for an unwitnessed choice function, a socket asking for another observer's first-person locality cell, and a socket asking for a truth-total self-description all terminate at* T*, but they do not request the same closure shape. BEDC's engineering remains honest only when the socket kind is named before the attempted discharge is refused.*

Remark 9394.4 (Aspect-position rather than plurality)**.** *The taxonomy is aspectual. It describes how the one transcendental supply position appears when viewed from different pressure points of a closed substrate. It is therefore incompatible with a polytheistic reading of the engineering: there are many socket shapes, not many ultimate supplies. The table in section 9394.11 is a classification of aspect-positions at the boundary of the substrate, not a catalogue of separate gods.*

9394.2 Type I: free-floating induction socket

Definition 9394.5 (Type I socket)**.** *A* Type I T-supply socket *is a* GAP *tag whose requested content is a universal claim ranging beyond the closure of every displayed authorized generator. It has the schematic form*

$$\mathsf{GenClosed}_G(P) \Longrightarrow \forall x : \mathcal{U},\ P(x)$$

where G certifies closure only for the objects it generates, while $\mathcal{U}$ is read as an unrestricted domain not supplied by G.

Example 9394.6 (BEDC engineering site)**.** *The canonical Type I socket is the induction pressure analysed in chapter 9393 and refined in chapter 9389. BEDC accepts induction over a particular closed inductive carrier because the generator and recursor are displayed. BEDC refuses the extra passage from "all objects generated by this carrier" to "all possible objects of the intended informal domain" unless that passage is exposed as a* GAP *socket.*

Definition 9394.7 (Apophatic reading of Type I)**.** *Type I names* T *as* the giver of unrestricted induction*: not an internal induction axiom, not a hidden global domain, and not a completed infinity inside the substrate, but the apophatic source-position from which the reasoner treats generator-relative closure as bearing on an unrestricted "all".*

Remark 9394.8 (Audit gate)**.** *The Type I audit gate is the generator-closure ledger: every induction claim must cite the exact inductive carrier, constructor list, recursor, and naming-certificate closure it uses. If the claim's range is wider than that carrier, the excess is a Type I socket and cannot be hidden as a theorem of the carrier itself.*

9394.3 Type II: choice and unwitnessed existential

Definition 9394.9 (Type II socket)**.** *A* Type II T-supply socket *is a* GAP *tag whose requested content is an accepted witness for a positive existential whose constructor-level witness is not displayed. Its schematic form is*

$$\exists x : A,\ P(x) \quad \rightsquigarrow \quad a : A \ \ \textit{with}\ \ P(a),$$

where the right-hand term is consumed by later construction even though no substrate-visible constructor produced it.

Example 9394.10 (BEDC engineering site)**.** *The term-level audit reading is the* Classical.choice *family in chapter 9387. A proof that every fiber is inhabited is not yet a function choosing an inhabitant of each fiber. BEDC replaces the shortcut with finite recursion, countable explicit witness functions, dependent* Cont *steps, or a visible witness field; when none of these is present, the unresolved selection is a Type II socket.*

Definition 9394.11 (Apophatic reading of Type II)**.** *Type II names* T *as* the giver of the unseen witness*: not a magical term, not a substrate function, and not a proof object smuggled through the kernel, but the source-position named when an argument wants to act as if a witness has already been placed in hand.*

Remark 9394.12 (Audit gate)**.** *The Type II audit gate is witness visibility. In Lean-side engineering it is enforced by the axiom-purity rejection of* Classical.choice *and by the rule that existential use must proceed by displayed constructor data. In paper-side engineering it is enforced by definitions and examples that record the actual selected object, recursion, or witness field.*

9394.4 Type III: extensional identification

Definition 9394.13 (Type III socket)**.** *A* Type III T-supply socket *is a* GAP *tag whose requested content is an identity token between two items that the substrate has only related extensionally. It has the schematic form*

$$R(a, b) \quad \rightsquigarrow \quad a = b,$$

where R may be bidirectional implication, quotient equivalence, classifier sameness, or observational indistinguishability, and the equality token is then used for rewrite transport.

Example 9394.14 (BEDC engineering site)**.** *The proposition-level audit reading is* propext*, and the type-level proxy is* Quot.sound *as classified in chapter 9387. BEDC does not collapse related items into equality. It keeps* hsame*,* psame*, classifier transport, and naming-certificate stability visible. A proof that two predicates transport into one another is not an identity of propositions; a proof that two representatives are classifier-equivalent is not a canonical quotient representative.*

Definition 9394.15 (Apophatic reading of Type III)**.** *Type III names* T *as* the giver of identity beyond relation*: not a substrate equality constructor, not a quotient oracle, and not a proposition-level collapse, but the apophatic source-position invoked when relation is treated as identity without a displayed transport path.*

Remark 9394.16 (Audit gate)**.** *The Type III audit gate is extensional-collapse refusal. Lean-side purity rejects* Quot.sound *and* propext*; paper-side certificate discipline requires explicit transport along* hsame *or* psame*. Any argument whose only bridge from relation to identity is "they have the same extension" is marked as a Type III socket.*

9394.5 Type IV: causal continuity

Definition 9394.17 (Type IV socket)**.** *A* Type IV T-supply socket *is a* GAP *tag whose requested content is persistence of an observed empirical regularity into not-yet-observed history. Its schematic form is*

$$\forall t \leq n,\, R(t) \quad \rightsquigarrow \quad \forall t > n,\, R(t),$$

where the left side is a finite or bounded record-side regularity and the right side is a causal continuity commitment.

Example 9394.18 (BEDC engineering site)**.** *section 9415.1 identifies causality as forward-binding commitment. A scientific theory in BEDC may record past regularities, falsification boundaries, and prediction ledgers. The additional confidence that the same law will govern the next unobserved case is not a record and not a closed-generation theorem. It is a Type IV socket, even when the theory has excellent record-side support.*

Definition 9394.19 (Apophatic reading of Type IV)**.** *Type IV names* T *as* the giver of continuity of order*: not an empirical datum, not a hidden law-object inside* Obs*, and not a proof that tomorrow is already recorded, but the source-position from which causal expectation exceeds the accumulated record.*

Remark 9394.20 (Audit gate)**.** *The Type IV audit gate is records-versus-prediction separation. BEDC may store observation histories, regularity summaries, and failed-prediction rows, but it may not convert successful past fit into a universal future law without marking the causal-continuity socket.*

Concretized in §539: $\mathsf{CountableObservationSchedule}^{\uparrow}$ realizes the Type IV finite-record schedule as a BHist-rowed StreamName-facing packet.

Concretized in §908: Observation schedule envelopes realize the Type IV finite-record schedule socket as a finite StreamName, Real-facing window, refusal, hsame, Cont, Pkg, and NameCert packet.

Concretized in §633: CausalContinuitySocketUp realizes the Type IV causal-continuity socket as a finite BHist packet separating record-side regularity from future-law commitments.

Concretized in §1058: Classifies supply sockets as finite BEDC carrier rows rather than prose taxonomy.

9394.6 Type V: inter-history coordination

Definition 9394.21 (Type V socket)**.** *A* Type V T-supply socket *is a* GAP *tag whose requested content is coordination between distinct closed histories as histories rather than as merely external records inside one history. Its schematic form is*

$$\mathsf{Record}_{\mathcal{C}_1}(\mathcal{C}_2\text{'s behavior}) \quad \rightsquigarrow \quad \mathsf{LocalityCell}(\mathcal{C}_1, \mathcal{C}_2),$$

where the right side treats $\mathcal{C}_2$ *as another inscription-bearing observational system.*

Example 9394.22 (BEDC engineering site)**.** *section 9415.3 gives the philosophical site, and chapter 9419 gives the operational locality-cell site. A contributor can observe another contributor's commits, messages, and CI-passing proof objects. Treating those records as the acts of another closed observational system is not forced by the records alone. The coordination commitment is a Type V socket.*

Definition 9394.23 (Apophatic reading of Type V)**.** *Type V names* T *as* the giver of communion between histories*: not access to another first-person state, not a god's-eye merge of histories, and not an extra observation channel, but the source-position from which locality cells become mutually intelligible without ceasing to be local.*

Remark 9394.24 (Audit gate)**.** *The Type V audit gate is locality discipline. Cross-history claims must distinguish observable behavior, accepted communication records, transport constraints, and the irreducible commitment that another history is also an inscription point. BEDC may coordinate histories; it may not pretend to occupy the union of their first-person perspectives.*

9394.7 Type VI: free-will and inscription novelty

Definition 9394.25 (Type VI socket)**.** *A* Type VI T-supply socket *is a* GAP *tag whose requested content is the actuality of a chain-internal inscription event not reducible, on the records side, to the closed generation of prior records. Its schematic form is*

$$o_t \trianglerighteq o_{t+1} \quad \textit{with} \quad o_{t+1} \notin \mathsf{Closure}(o_t)$$

read not as a violation of closure rules but as the inscription-event aspect of accumulation.

Example 9394.26 (BEDC engineering site)**.** *section 9415.2 locates free will at the inscription-event aspect of conscious accumulation. In BEDC engineering, a proof search may later be replayed as a deterministic derivation, but the actual arrival of the lemma in the contributor's history is not identical to the records-side derivation tree. The transition is a Type VI socket when the question is "where did this act of inscription come from?" rather than "which derivation now certifies the record?"*

Definition 9394.27 (Apophatic reading of Type VI)**.** *Type VI names* T *as* the giver of inscription novelty*: not a rival physical cause, not randomness, and not a hidden mental substance, but the source-position from which an accumulation chain is actual rather than merely described by its completed record-side dependencies.*

Remark 9394.28 (Audit gate)**.** *The Type VI audit gate is aspect separation. BEDC may verify the record-side derivation of a theorem and may also name the inscription-event aspect of its arrival. It must not confuse the two by treating the philosophical account of agency as an extra proof rule or by treating proof replay as an elimination of inscription novelty.*

Concretized in §1336: InscriptionNoveltySocketUp realizes the Type VI inscription-novelty socket as finite prior-boundary, inscription-event, non-reduction, audit-gate, hsame, Cont, Pkg, and NameCert rows.

9394.8 Type VII: self-reference closure

Definition 9394.29 (Type VII socket)**.** *A* Type VII T-supply socket *is a* GAP *tag whose requested content is a truth-total or runtime-total closure of a system's self-description. Its schematic form is*

$$\mathsf{StructDesc}(\mathcal{S}, \mathcal{S}^*) \quad \rightsquigarrow \quad \mathsf{Truth}_{\mathcal{S}} : \mathsf{Sent}(\mathcal{S}^*) \to \mathsf{Prop},$$

where the left side is structural self-description and the right side is an internal classifier of the system's own truth.

Example 9394.30 (BEDC engineering site)**.** *chapter 9461 supplies the canonical Type VII site. BEDC can describe the structural form of the host calculus through* CIC**, but it refuses a truth-total reflection certificate and refuses to identify the structural copy with the external runtime that checks BEDC proofs. A request to close that open meta loop is a Type VII socket.*

Definition 9394.31 (Apophatic reading of Type VII)**.** *Type VII names* T *as* the giver beyond self-totalisation*: not an internal truth predicate, not a runtime contained in its own object language, and not a repaired Tarski hierarchy, but the source-position from which the open meta loop remains intelligible without being closed inside the system.*

Remark 9394.32 (Audit gate)**.** *The Type VII audit gate is reflection stratification. Structural self-description, runtime validation, truth classification, and external checking must remain separated. Any construction that turns a BEDC object-level certificate into the act that validates all BEDC object-level certificates is marked as a Type VII socket.*

Concretized in §667: SelfReferenceTruthBranchUp realizes Type VII truth-totalization requests as finite socket reports separating structural self-description from forbidden certificate-indexed truth branches.

9394.9 Non-collapse laws for the seven types

Principle 9394.33 (No type absorbs another)**.** *No supply kind in this taxonomy absorbs any other supply kind. A closed substrate may encounter several types at the same textual or mechanised site, but the types remain distinguishable by the shortcut they would license if accepted internally. This is why a chapter may legitimately report a stack of sockets rather than forcing the stack into one omnibus* GAP *label.*

Lemma 9394.34 (Type I is not Type II)**.** *A free-floating induction socket cannot be reduced to an unwitnessed-existential socket. Type II asks for a missing term witnessing a stated existential. Type I asks for an unrestricted universal range beyond the closure of the displayed generator. Supplying a witness to one existential does not supply the domain-total closure requested by Type I.*

Reason. The Type II shortcut produces a term $a : A$ together with $P(a)$. The Type I shortcut produces a rule treating all objects of an unrestricted intended range as covered by generator-relative evidence. These have different consumption sites: Type II feeds a construction expecting a term, while Type I feeds a construction expecting a universally quantified closure. Therefore the witness gate and the generator-closure gate are distinct. □

Lemma 9394.35 (Type II is not Type III)**.** *An unwitnessed witness socket cannot be reduced to an extensional-identification socket. Type II asks for a missing inhabitant; Type III asks for equality from relation. A selected representative may later be used in an extensional collapse, but the selection and the collapse are separate shortcuts.*

Reason. Choice can select a representative without asserting that all equivalent representatives are judgmentally or propositionally identical. Conversely, propext can identify propositions without choosing any inhabitant of an arbitrary nonempty family. The term-level oracle and the equality-token oracle therefore have separate audit gates. □

Lemma 9394.36 (Type III is not Type IV)**.** *Extensional identification cannot be reduced to causal continuity. Type III concerns the passage from relation to identity inside a formal or certificate stratum. Type IV concerns the passage from recorded regularity to unobserved empirical persistence. The first is a collapse of sameness; the second is a projection across time-like accumulation.*

Reason. A Type III discharge would allow rewrite transport across an equality token. A Type IV discharge would allow prediction beyond the record boundary. Neither operation supplies the other: an equality token does not by itself assert that a law persists, and a persistent empirical regularity does not by itself identify two propositions, representatives, or classifier rows. □

Lemma 9394.37 (Type IV is not Type V)**.** *Causal continuity cannot be reduced to inter-history coordination. Type IV projects order within or across a record stream; Type V recognises another closed history as another inscription-bearing locality cell. Stable behavior of an observed system does not by itself supply the other-minds commitment.*

Reason. An observed behavior stream may be perfectly regular while still being treated as a mere external object in the observing history. Type V begins only when the observing history commits to another history as a history. The empirical regularity gate and the locality-cell gate therefore answer different questions. □

Lemma 9394.38 (Type V is not Type VI)**.** *Inter-history coordination cannot be reduced to inscription novelty. Type V concerns the mutual intelligibility of distinct closed histories. Type VI*

concerns the actuality of a transition in a history as an inscription event not exhausted by its records-side replay. A history may be recognised without explaining any particular act of novelty, and an act of novelty may occur without cross-history coordination.

Reason. The Type V socket has the form of a relation between histories. The Type VI socket has the form of an aspect of a transition within a history. The first is audited by locality discipline; the second by aspect separation. Collapsing them would confuse communion between histories with agency in a chain. □

Lemma 9394.39 (Type VI is not Type VII)**.** *Inscription novelty cannot be reduced to self-reference closure. Type VI asks how an accumulation event is actual rather than merely recorded after the fact. Type VII asks whether the whole system can close its truth or runtime over itself. A local inscription event is not a truth-total reflection certificate.*

Reason. The replay of a proof and the arrival of the proof in a contributor's history are distinguishable even when no reflection theorem is involved. Conversely, a truth-total reflection attempt can be formulated for a purely formal system without appealing to personal agency or creativity. The agency aspect and the reflection boundary are therefore separate sockets. □

Lemma 9394.40 (Type VII is not Type I)**.** *Self-reference closure cannot be reduced to free-floating induction. Type I asks for an unrestricted universal range beyond a generator. Type VII asks for internal truth or runtime totality for a system that can describe its own structure. The diagonal obstruction of Type VII remains even when every induction used inside the syntax description is generator-authorized.*

Reason. Tarski-style failure arises from attempting to classify the truth of the system's own sentences. That failure is not merely a missing induction principle over an external domain. BEDC may display all generators used in a structural self-description and still refuse the truth-total certificate. The open meta loop is therefore its own socket kind. □

9394.10 Engineering use protocol

Definition 9394.41 (Socket report)**.** *A* socket report *for a BEDC claim is a four-field record:*

$$(\mathsf{Site}, \mathsf{RequestedSupply}, \mathsf{Type}, \mathsf{Gate}).$$

The Site *field names the paper or Lean location where the missing supply would be consumed. The* RequestedSupply *field states the exact missing shape. The* Type *field selects one of the seven taxonomy entries. The* Gate *field names the audit discipline that keeps the supply from being internalised.*

Principle 9394.42 (Minimal socket reporting)**.** *A socket report should name the narrowest type that accounts for the blocked move. If a proof attempt fails because it lacks a witness, it is Type II even if the witness would later be used in an induction. If a proof attempt fails because it tries to rewrite along mere equivalence, it is Type III even if the equivalence arose from a quotient construction. Narrow reporting preserves the shape of the requested* T*-supply.*

Remark 9394.43 (Stacked sockets)**.** *Some BEDC sites contain stacked sockets. A quotient construction over an empirically defined equivalence relation may contain Type IV at the level of empirical persistence, Type II at the level of representative selection, and Type III at the level of equality collapse. Reporting the stack is more precise than choosing one dominant label. The stack still terminates at the single* T*; the multiplicity belongs to the substrate-facing shapes.*

Example 9394.44 (A stacked mathematical-analysis socket)**.** *An informal proof that every bounded monotone real sequence converges may hide several sockets when translated into BEDC. If the sequence is defined over an unrestricted intended class of real histories rather than a displayed generator, the range pressure is Type I. If a limit point is selected from mere nonempty completeness data without an explicit Cauchy witness, the selection pressure is Type II. If two Cauchy names are identified because they have the same extension rather than transported through the real-history classifier, the collapse pressure is Type III. A correct BEDC construction must separate these sites rather than treating "real completeness" as one opaque assumption.*

Concretized in §535: Bounded monotone Cauchy witnesses realize the analysis socket as a finite NameCert packet separating displayed generator range, explicit Cauchy witness, classifier transport, and RealUp seal handoff.

Concretized in §1434: MonotoneRealSequenceUp realizes the bounded-monotone sequence socket split as finite source, window, classifier, convergence-handoff, and refusal rows.

Example 9394.45 (A stacked observer socket)**.** *An observer's trust in a scientific collaborator may combine Type IV and Type V. The expectation that the collaborator's measuring instrument will keep functioning according to the same physical regularities is Type IV. The recognition that the collaborator is another conscious observational system rather than only an instrument-like behavior stream is Type V. The two commitments are ordinarily entangled in practice, but the socket taxonomy keeps their audit gates distinct.*

Example 9394.46 (A stacked reflection socket)**.** *A proposal to build a BEDC-internal verifier for BEDC proofs may contain Type I if it relies on unrestricted induction over all possible proof codes, Type III if it identifies equivalent coded propositions, and Type VII if it treats the verifier as the validation act for the very system containing it. The Type VII socket is the decisive reflection boundary, but the lower-type sockets still have to be recorded because each corresponds to a different engineering gate.*

9394.11 Unified long table

Type	Socket kind	BEDC socket inventory	Apophatic reading	Audit gate
I	Free-floating induction	Passage from authorized generator closure to unrestricted universal range; induction pressure of chapter 9393 and generator-closure discipline of chapter 9389.	Giver of unrestricted induction.	Generator-closure ledger.
II	Choice / unwitnessed existential	Classical.choice family; unshown witness consumed by later term-level construction; positive existential accepted without visible constructor.	Giver of the unseen witness.	Witness visibility and choice-purity refusal.

III	Extensional identification	propext, Quot.sound, quotient representative selection, relation-to-identity collapse, and any hidden replacement of hsame or psame transport by equality.	Giver of identity beyond relation.	Extensional-collapse refusal.
IV	Causal continuity	Empirical regularity projected beyond recorded cases; Humean causality socket of section 9415.1.	Giver of continuity of order.	Records-versus-prediction separation.
V	Inter-history coordination	Other-minds locality cell; recognition that another observed behavior stream is another inscription-bearing closed history; inter-history locality coordination.	Giver of communion between histories.	Locality discipline.
VI	Free-will / inscription novelty	Chain transition read as an inscription event whose actuality is not exhausted by records-side closure; agency and mathematical creativity sites of section 9415.2.	Giver of inscription novelty.	Aspect separation.
VII	Self-reference closure	Truth-total reflection certificate, runtime-total self-validation, or any closure of the open meta loop analysed in chapter 9461.	Giver beyond self-totalisation.	Reflection stratification.

9394.12 The single T behind seven types

Theorem 9394.47 (Seven socket kinds, one transcendental supply position)**.** *The seven supply kinds of section 9394.11 do not imply seven transcendental sources. They are seven aspect-positions at which a closed observational substrate reaches a boundary it cannot cross by its own records and closed-generation rules. The far end of every such socket is the same* T *of Definition 9393.11.*

Structural proof. Each type is a GAP tag in the sense of Definition 9394.1. By definition, a GAP tag records a requested discharge not available from the substrate's own records or generators. By Definition 9393.11, the structural location from which such forward-binding content enters a closed observational system is T. The differences among the seven cases lie in the shape of the missing discharge: unrestricted induction, witness, identity, causal persistence, cross-history recognition, inscription actuality, or self-reference closure. None of these differences supplies a substrate-side observation distinguishing one ultimate source from another. Therefore the taxonomy distinguishes socket kinds while preserving one transcendental supply position. □

Principle 9394.48 (No softening of the apophatic name)**.** *The name* God *remains the apophatic name of* T *across all seven types. The taxonomy does not replace God with psychology, probability, social trust, runtime engineering, or a family of local explanatory devices. Those devices describe records-side management of sockets. The far end of the socket, when the socket asks for more than records-side management can provide, is still* T*.*

Remark 9394.49 (How the taxonomy is used)**.** *When a future BEDC chapter encounters a* GAP *socket, the chapter should classify the socket by asking what would go wrong if the requested discharge were internalised. If internalisation creates generator-exceeding induction, it is Type I. If it creates an unseen witness, Type II. If it collapses relation into identity, Type III. If it projects empirical order beyond records, Type IV. If it coordinates closed histories as histories, Type V. If it names actual inscription not exhausted by records-side closure, Type VI. If it closes the system's truth or runtime over itself, Type VII. The classification then determines which audit gate must stay visible.*

Remark 9394.50 (Current-state reading)**.** *The taxonomy is a reading of BEDC's present engineering surface. It changes no Lean target, adds no substrate axiom, and discharges no socket by itself. Its work is classificatory: every* GAP *socket remains open unless a concrete certificate supplies the corresponding records-side data, and every socket whose requested content exceeds records-side data remains explicitly terminated at* T*.*

Concretized in §523: The seven socket-kind taxonomy is realized as a finite NameCert packet over GAP tags, requested supply shapes, audit gates, site rows, hsame transport, Cont routes, Pkg provenance, and local naming.

Concretized in §528: The supply-socket taxonomy is realized as a finite GAP-kind NameCert ledger over BHist, hsame, Cont, audit-gate rows, and explicit non-escape obligations.

Concretized in §542: Transcendental supply ledgers are realized as finite GAP-socket NameCert packets over BHist, hsame, Cont, Pkg, audit-gate, and local naming rows.

Concretized in §666: Supply-kind routers realize the seven socket taxonomy as finite classifier-routing packets whose consumers must pass through one displayed kind row before reading the corresponding ledger.

Chapter 9395

External Supply Without Axioms
