BEDC repeatedly reaches boundary positions where a proposed inference, comparison, continuation, or universal claim requires supply that the displayed substrate has not generated. The wrong response is to turn that supply into an axiom. An axiom makes an unsupported commitment available inside the formal environment as if it had been produced by the substrate. BEDC's response is different: the supply position is named, socketed, ledgered, and audited, while the supplied content remains external unless a later certificate reconstructs it from displayed generators. This chapter records that discipline as a manuscript-level governance rule. It introduces no new primitive, no new object-level constructor, and no new logical axiom. Its purpose is to prevent a recurring confusion: a boundary that BEDC names is not a datum that BEDC has assumed. A named socket is weaker than an axiom because it does not grant internal content; it is stronger as an audit device because it prevents the content from disappearing into prose, tactic ancestry, quotient collapse, or hidden selection.

The chapter sits beside chapter 9400, the GAP-as-ledger discipline of chapter 9389, the audit-gate chapters of chapter 9396, and the anti-internalisation roadmap of chapter 9393. Its active sentence is: external dependence is admissible only when it remains visible as boundary, not when it becomes axiom.

9395.1 The boundary problem

A closed observational substrate interface may be admitted by a naming certificate. A parametric input may be exposed as a setup field. A compression may be accompanied by a GAP ledger. A claim that exceeds all of these may be marked as an apophatic socket.

The dangerous move is to replace one of these visible forms by an axiom. Once a missing selector, quotient representative, proposition equality, universal induction principle, synchronization map, or causal law is stated as an axiom, the substrate can consume it as internal truth. The original source-channel disappears. From the audit point of view, this is not a harmless shortcut. It is source erasure.

Principle 9395.1 (No internalization of unsupported supply)**.** *When a BEDC argument requires content not generated, defined, certified, or displayed as an interface input, the content may not be introduced by axiom. The dependency must remain one of: a setup field, a named carrier, a classifier row, a provenance row, a* GAP *ledger, a bridge slot, or an apophatic socket.*

This principle is not a new substrate axiom. It is a discipline on how claims enter the manuscript and the Lean surface. Its enforcement is external and mechanical where possible: the axiom

scan rejects Lean axioms, the strict axiom-purity gate rejects forbidden host dependencies, the conservativity audit rejects source-channel pollution, and the paper-Lean audit rejects name drift (chapter 9396).

9395.2 Axiom, setup field, and socket

Three forms must be kept separate.

An *axiom* asserts content as available inside the formal environment without deriving it from an authorized source. In Lean, an axiom declaration gives the kernel a constant with a type and no construction. In the BEDC reading, this collapses the boundary between generated content and unsupported supply.

A *setup field* exposes a required input at an interface boundary. It says that the caller of the interface must supply a carrier, classifier, operation, proof row, or stability witness. The substrate has not proved the field; it has only made the requested input visible and typed. This preserves the source-channel.

A *socket* records that even a setup field or certificate row does not internalize the requested supply. The socket is a stable boundary handle. It marks the site where a proposed claim would require a supply whose internal nature the substrate does not claim to characterize.

Definition 9395.2 (Non-axiom boundary form)**.** *A non-axiom boundary form is any public interface form that exposes a dependency without converting the dependency into substrate truth. The canonical forms are:*

`inductive`	*closed generator;*
`def`	*computable or definitional compression;*
structure/class field	*parametric setup input;*
NameCert *row*	*licensed public name with source, classifier, stability, ledger;*
GAP *ledger*	*compression residue or missing conservation row;*
bridge slot	*external interpretation kept separate from internal proof;*
apophatic socket	*named external supply position not internalized by the substrate.*

Principle 9395.3 (Externalized, not assumed)**.** *A dependency that remains in a non-axiom boundary form is externalized. A dependency introduced by axiom is assumed. BEDC permits externalization and rejects assumption.*

The difference is not rhetorical. A setup field can be inspected. A NameCert row can be audited. A GAP ledger can be followed back to the compressed material. A bridge slot can be restricted or refused. A socket can be marked as open. An axiom hides all of those distinctions behind immediate usability.

9395.3 The admission decision

Every proposed BEDC addition must pass through a replacement decision before it can enter the public surface.

Definition 9395.4 (Admission decision)**.** *Given a proposed object, operation, theorem, or interface component X, the BEDC admission decision asks for the strongest non-axiom form that can carry*

X:

$$\begin{aligned}
X \textit{ finite grammar or closed syntax} &\Longrightarrow \texttt{inductive};\\
X \textit{ computed from earlier rows} &\Longrightarrow \texttt{def};\\
X \textit{ parametric interface input} &\Longrightarrow \textit{setup field};\\
X \textit{ mature public name} &\Longrightarrow \mathsf{NameCert};\\
X \textit{ compression residue} &\Longrightarrow \mathsf{GAP}\ \textit{ledger};\\
X \textit{ external semantic correspondence} &\Longrightarrow \textit{bridge slot};\\
X \textit{ unsupported forward supply} &\Longrightarrow \textit{apophatic socket.}
\end{aligned}$$

If none of these forms is adequate, the boundary has not been identified clearly enough, and the interface must be redesigned rather than accepted as an axiom.

Principle 9395.5 (Redesign before axiom)**.** *Failure to fit a proposed dependency into a non-axiom boundary form is evidence of an unclear interface, not license to add an axiom.*

The decision preserves BEDC's anti-primitive principle. Mature mathematics may be reconstructed, bridged, or socketed, but it is not smuggled in as primitive. The same rule applies to philosophical pressure points. Consciousness, free will, mathematical induction beyond authorized generators, global time, light-speed constancy, and universal semantic truth are not admitted by declaration. At most they receive boundary names, certificate obligations, or schema-only horizons.

9395.4 GAP as the memory of boundary pressure

GAP has two simultaneous roles. The first is internal and engineering-facing: it records the residue of compression, packaging, projection, sealing, normalization, or identification. Whenever a visible token replaces richer source material, the GAP ledger keeps the memory of what the surface form no longer displays.

The second role is boundary-facing: GAP marks a supply position whose far end is not generated by the substrate. When a generator-internal claim is pushed toward a free-floating universal claim, the pressure cannot be discharged by the generator itself. GAP records that the claim has reached a T-socket rather than pretending the universal extension is already internal.

Principle 9395.6 (Dual role of GAP)**.** *Every* GAP *instance must be read under both possible loads:*

1. *as an information-conservation ledger for compression residue; and*
2. *as a socket marker for forward-binding supply that the substrate does not internalize.*

Reading GAP only as bookkeeping hides the externality role. Reading it only as transcendental socket hides the conservation role. BEDC requires both readings to remain available.

Remark 9395.7 (Compression requires memory)**.** *A compressed BEDC object may be easier to use than its source records, but it may not erase the source-channel. The ledger is the memory of the compression. If the memory is absent, the compression has become an unledgered quotient. Such a quotient is exactly the kind of source-erasing step the axiom-purity gate is designed to reject.*

This is why information conservation in BEDC is not merely a statement about bit-count. It is provenance conservation. A visible package must retain a route back to the histories, signatures, classifiers, or certificates that generated it. A public name must retain the rows by which it was licensed. A derived interface must retain the GAP by which hidden residue remains auditable.

9395.5 Generator-local induction and the refusal of free-floating induction

BEDC does not reject induction. It rejects unbounded induction detached from an authorized generator.

A closed inductive generator carries its own structural induction principle. Hist induction is licensed by the constructor structure of Hist. A Term generator licenses structural induction over terms produced by that generator. A proof over a closed list, finite tree, syntax grammar, or certified carrier may use the eliminator attached to that generator. Such induction is internal because its domain is exactly the closure of displayed constructors.

What BEDC refuses is the move from generator-local induction to a universal statement over all conceivable cases. The phrase "all conceivable" names a domain that has not been generated, certified, or bounded by a displayed eliminator. To use it as if it were a closed carrier would be to import forward-binding belief (chapter 9393).

Definition 9395.8 (Generator-local induction)**.** *Generator-local induction is induction whose quantifier ranges only over the closure of a displayed generator G, and whose step cases are exactly the constructor cases of G. Its eliminator is part of the generator's public structure.*

Definition 9395.9 (Free-floating induction)**.** *Free-floating induction is an induction claim whose domain is not the closure of any displayed generator and whose universal quantifier ranges over an unspecified semantic totality.*

Principle 9395.10 (Induction boundary)**.** *Generator-local induction is an internal method. Free-floating induction is a boundary pressure. The former may be discharged by an eliminator; the latter must be marked by a* GAP/T*-socket or replaced by a certified generator.*

This distinction answers the recurring question about mathematical induction. BEDC may prove structural claims about Hist, Term, List, $\mathbb{N}$-like unary histories, and other authorized carriers. But if a claim requires induction over a domain not yet reconstructed as a BEDC carrier, the missing domain cannot be installed by axiom. It must be given as a NameCert, setup field, bridge slot, or socketed obligation.

9395.6 Choice, quotient, and proposition equality

The forbidden trio — `Classical.choice`, `Quot.sound`, and `propext` — are not three unrelated restrictions. They are read here as three audit-visible ways to accept unwitnessed content at different strata; see chapter 9387 for the meta-closure taxonomy.

At the term stratum, choice is read as a selector without constructed selected values. At the type stratum, the quotient-facing proxy marks class-level equality or representative behavior without preserving source-level transport as public data. At the proposition stratum, propositional extensionality identifies propositions from bidirectional implication without keeping the transport route explicit.

BEDC replaces these by witnessed forms:

$$\begin{aligned} \text{choice} &\rightsquigarrow \text{finite, countable, or dependent selection with explicit witness functions;} \\ \text{quotient soundness} &\rightsquigarrow \text{NameCert classifier transport and psame/hsame reflection;} \\ \text{propext} &\rightsquigarrow \text{explicit directional transport between proof consumers.} \end{aligned}$$

Principle 9395.11 (No unwitnessed existential as input)**.** *No BEDC proof may consume an existential, representative, equality, selector, or equivalence as input unless the witness route is displayed at the term, classifier, or ledger level.*

This principle is stronger than saying "avoid classical axioms." It says what the classical axioms do that BEDC refuses: they turn missing witnesses into available inputs. The replacement discipline keeps the use-site and the supply-site connected.

9395.7 Observer growth and selector ledgers

The same boundary rule governs observer growth. A local Hist may grow by an enacted mark. But if a branch is selected, the selected mark must appear in the history or its selector ledger. There is no hidden chooser behind the observer (chapter 9418).

Definition 9395.12 (Selector ledger)**.** *A selector ledger for a history transition is a displayed record containing the chosen mark, the local step witness, and the certificate that the step is admissible in the current interface:*

$$\mathrm{SelStep}(h, r) := (m, \mathrm{step}, \mathrm{cert}).$$

The next history is not merely asserted to exist; it is reached through the displayed mark and step witness.

Principle 9395.13 (No observer-choice axiom)**.** *When several local continuations are admissible, BEDC may not introduce a global chooser selecting among them. A realized branch must be recorded as a selector ledger. An unrealized family of possible branches remains a local possibility space, not an internal selection function.*

This protects both axiom purity and the observer-Hist identity. If an observer were equipped with a hidden selection function, the observer would no longer be only the generated history — it would carry an extra subject-like substance behind the trace. BEDC's no-subject discipline forbids that move. The trace is the observer; the selector event is part of the trace; no separate chooser is admitted.

9395.8 Multi-Hist physics without global axioms

The boundary rule also governs the physical readings of BEDC (chapter 9419). Multi-Hist configurations do not license a global clock, a global frame, a privileged observer, or a universal spacetime container. Such objects may be useful as external models, but they cannot be placed into the BEDC kernel by axiom.

If a multi-observer structure is to enter BEDC, it must enter by ledger-local relations and inter-Hist invariants. A comparison between histories must be witnessed by finite continuation data, emitted marks, classifier comparisons, package rows, or naming certificates. A proposed maximum cross-Hist causal rate is not asserted as a physical axiom; it is a NameCert target or schema-only horizon whose closure obligations remain visible.

Principle 9395.14 (No global-frame axiom)**.** *No global time, global frame, global observer, or global synchronization map may be added as a kernel-level axiom. Any synchronization must be an extension carrier above the kernel and must expose its source, classifier, stability, and ledger rows.*

Principle 9395.15 (Physical constants as invariant targets)**.** *A physical constant in the BEDC reading is not a primitive scalar inserted into the kernel. It is an invariant target of an admissible inter-*Hist *relation. If the maximum causal rate is reconstructed, its constancy must be shown as observer-symmetric preservation under the licensed transformations, not postulated as a global axiom.*

This preserves the earlier insight that information conservation and locality should not force a God's-eye object into the theory. The universe is not admitted as a single global Hist. It is represented, where BEDC can represent it, by local histories, ledger-local relations, and invariants whose witnesses remain finite and auditable.

9395.9 Audit gates as the enforcement layer

A named boundary is only useful if a gate can test whether it has remained visible. BEDC's audit gates give the operational form of the non-axiom discipline (chapter 9396).

Definition 9395.16 (Boundary gate)**.** *A boundary gate is a finite check whose surface condition enforces a source-channel rule. Its input may be a Lean declaration, a dependency graph, an import edge, a paper marker, or a certificate row. Its output is not a metaphysical theorem; it is an audit judgment that a specified boundary has or has not been crossed.*

The main gates are:

axiom scan	rejects substrate-internal axiom declarations;
strict axiom-purity	rejects transitive dependence on Classical.choice, Quot.sound, propext;
conservativity audit	rejects source-channel pollution across surfaces;
paper-Lean audit	rejects claims whose Lean names do not resolve;
axis-confusion gate	rejects collapse of theory closure into verification status;
tactic discipline	rejects tactics that silently import forbidden host commitments.

Principle 9395.17 (Gate correspondence)**.** *Every boundary form should determine a gate question. If a dependency is named as a socket, the gate asks whether it was later consumed as internal theorem content. If a compression is named as a* GAP*, the gate asks whether the source residue remained recorded. If a proof claims axiom purity, the gate asks whether the transitive proof ancestry is free of forbidden axioms.*

The gate does not prove the full philosophical reading. It protects one face of the boundary. BEDC's discipline is compositional: many small gates together prevent many small source-erasing moves from becoming a hidden global assumption.

9395.10 The non-axiom theorem schema

The following schema records the main theorem shape of this chapter. It is stated as a paper-side governance theorem because the exact implementation depends on the surrounding interface.

Theorem 9395.18 (Non-axiom boundary preservation schema)**.** *Let X be a proposed BEDC dependency. Suppose X is consumed by a public theorem, certificate, or interface. If every use of X factors through one of the non-axiom boundary forms of Definition 9395.2, and every corresponding gate reports that the boundary form remains visible, then X has not been internalized as a substrate axiom.*

Sketch. Proceed by cases on the boundary form. An inductive generator supplies constructors and eliminators, so the source is displayed. A `def` unfolds to earlier material, so the source is computationally traceable. A setup field remains a field of the interface, so the caller must supply it. A NameCert exposes source, pattern, classifier, stability, and ledger rows. A GAP ledger records compression residue or socket pressure. A bridge slot is interpretive and does not replace the internal proof obligation. An apophatic socket names an external dependency without providing content as theorem. In each case, the use of X is source-channel visible. The audit gates rule out the opposite cases: axiom declaration, forbidden transitive host axiom, unledgered quotient, unresolved paper marker, and axis collapse. Therefore the dependency remains externalized rather than assumed. □

Corollary 9395.19 (Axiom-free does not mean dependence-free)**.** *A BEDC development may be axiom-free while still exposing external dependencies. Axiom-free means that such dependencies do not become substrate-internal sources of truth. It does not mean that no boundary, bridge, socket, or setup field exists.*

Corollary 9395.20 (Socketed content is not a theorem)**.** *A socketed dependency is not an internally proved theorem. It is a named site of non-internal supply. The manuscript may reason about the socket's role, audit surface, and required supply shape, but it may not consume the socket as if the supplied content had been generated.*

9395.11 Forbidden phrasings and replacements

The following replacements should be used whenever the manuscript approaches an unsupported boundary.

Forbidden phrasing	BEDC replacement
`axiom ExternalInput`	T-socket / apophatic boundary
`axiom MathematicalInduction`	generator-local eliminator or induction socket
`axiom InformationConservation`	GAP ledger + provenance conservation gates
`axiom ObserverChoice`	SelStep witness and selector ledger
`axiom GlobalClock`	extension carrier with synchronization certificate
`axiom LightSpeedConstancy`	MaxCausalRate NameCert target
`axiom QuotientCollapse`	classifier transport and GAP provenance
`axiom PropositionEquality`	directional hsame/psame transport
`axiom StandardModelBridge`	restricted bridge slot with explicit fields
`axiom RuntimeCorrectness`	host delegation marked as audit/socket boundary

The table is not merely stylistic. Each replacement preserves information that the forbidden phrasing erases: source, witness, classifier, residue, caller obligation, or boundary status.

9395.12 Boundary of this chapter

This chapter does not claim that every external dependency has already been reconstructed inside BEDC. It does not claim that every socket can be discharged. It does not claim that host Lean's runtime, CIC truth, mathematical completeness, physical spacetime, or free-floating induction has been internalized. It also does not prove that no hidden assumption can ever appear in prose.

Its claim is narrower: when BEDC sees external pressure, it must expose the pressure rather than axiomize it.

The chapter is therefore a governance layer, not a new foundation. It strengthens the manuscript by making explicit how to proceed when the theory reaches a boundary: name the boundary, state the supply shape, record the ledger, attach the gate, and refuse to call the result an internal theorem until a certificate actually reconstructs it.

9395.13 Closure

BEDC is not a system with no externality. It is a system that refuses anonymous externality. This is the correct interpretation of its axiom-purity discipline. External supply may appear as setup field, NameCert row, GAP ledger, bridge slot, audit boundary, or apophatic socket. It may not appear as axiom.

The distinction is load-bearing. Axioms internalize unsupported commitments. Sockets externalize unsupported dependencies. GAP records the memory of compression and the pressure of forward-binding supply. Audit gates enforce that the source-channel remains visible. Generator-local induction is internal; free-floating universal induction is socketed. Local observer growth is selector-ledgered; hidden observer choice is refused. Multi-Hist physics proceeds by invariants; global frame axioms are refused.

The final rule is simple: do not add an axiom; expose the boundary.

Concretized in a future implementation: a finite ExternalSupplyBoundary packet should expose boundary name, requested supply shape, non-internalization status, accepted boundary form, associated GAP ledger, and gate question. The packet is not a theorem that the supply exists. It is the audit-visible record that the supply has not been smuggled into BEDC as a hidden source of truth.

Concretized in §1066: The seven non-axiom boundary forms are realized as a finite NameCert classifier packet.

Concretized in §1065: External-supply boundaries are realized as finite boundary-name, requested-supply, non-internalization, accepted-form, GAP-ledger, and gate-question rows.

Concretized in §1070: Boundary gates are realized as finite NameCert packets recording a boundary form, gate question, audit verdict, visible site, transport, route, provenance, and local name.

Concretized in §1072: External supply is represented by a concrete socket packet with refusal and ledger rows.

Concretized in §1073: Non-axiom admission packets realize the admission-decision classifier as finite boundary-form, witness-route, transport, replay, provenance, and NameCert rows.

Concretized in §1075: Generator-local induction boundaries are realized as finite generator, domain-closure, eliminator, refusal, and ledger rows.

Concretized in §1074: Boundary admission decisions realize the strongest non-axiom form for an unsupported supply request as finite carrier, classifier, refusal, transport, provenance, and NameCert rows.

Concretized in §1076: External-supply failures are realized as finite boundary-name, requested-supply, failed-item, diagnostic, refusal-target, gate, route, provenance, and NameCert rows.

Concretized in §1077: Witnessed external supply is recorded as a finite socket, gate, ledger, and NameCert packet rather than as an axiom.

Concretized in §1107: External-supply audit routes are realized as finite BHist packets with boundary-form, witness-route, GAP-ledger, hsame, Pkg, and NameCert rows.

Concretized in §8487: External-supply ledger routes are realized as finite boundary, form, admission, audit-gate, GAP-memory, transport, replay, provenance, and NameCert rows.

Chapter 9396

Audit Gates as Transcendental Boundary Enforcement

This vision sibling gives the engineering-side reading of the transcendental boundary introduced in chapter 9393. The earlier chapter states the strong claim: a closed observational substrate cannot internalise the forward-binding belief that licenses free mathematical induction; the source-position of that belief is ⊤, named God in the apophatic sense. The present chapter records how BEDC makes that claim executable. The audit gates are not housekeeping around the manuscript. They are the operational boundary by which the substrate refuses to turn the ⊤ socket into an internal rule.

The sibling also sits beside chapter 9389 and chapter 9387. The former explains how authorized generators, naming certificates, and GAP ledgers make generator-internal induction precise. The latter classifies Classical.choice, Quot.sound, and propext as three refusal-ledger entries for unwitnessed closure shapes at different strata. The audit gates are the machine-facing form of both insights: they reject substrate-internal axioms, reject forbidden host-CIC axiom propagation, reject baseline pollution by non-baseline surfaces, and reject paper-Lean name drift. In each case the gate prevents an external commitment from becoming silently indistinguishable from generated BEDC content.

9396.1 Why audit gates are not bookkeeping

Principle 9396.1 (Audit as boundary enforcement)**.** *An audit gate in BEDC is a computable refusal rule. It does not merely count files or tidy metadata; it decides whether a proposed record remains on the substrate-internal side of the boundary or has smuggled in a commitment whose correct position is outside the substrate, at* ⊤*. Passing the gate means only that the checked boundary has not been crossed. Failing the gate means the substrate has been asked to internalise what it is designed to expose as socketed.*

This distinction matters because the same surface action can be read in two incompatible ways. A script that scans for forbidden tokens can look like administrative pedantry if the substrate is assumed to be an ordinary formal project. In BEDC the scan has a stronger meaning: the forbidden token is a breach of the transcendental boundary. It turns a missing witness, an external recursor, a quotient representative, a proposition equality, or a naming certificate into an available internal fact. That is precisely the move chapter 9393 refuses.

Definition 9396.2 (Gate surface and boundary content)**.** *The* gate surface *is the finite syntactic or dependency condition checked by a script: a token occurrence, a transitive axiom dependency, an import edge, or a missing Lean target. The* boundary content *is the transcendental claim enforced by that condition: the substrate may use only what it generated, defined, certified, or explicitly socketed, and may not reclassify socketed content as internal closure.*

Example 9396.3 (A token scan with metaphysical load)**.** *The command* `python3 tools/check-axioms.py` *scans for* `axiom` *declarations under* `lean4/BEDC/`*. Its surface is a regular expression over Lean files. Its boundary content is the refusal to create a substrate-internal source of truth that has no constructor, definition, or setup-field account. The scan is small because the boundary is sharp: an internal axiom is not a minor convenience, but the exact point at which* T*-supplied content is made to look generated by the substrate.*

Remark 9396.4 (A pass is local, not absolute)**.** *Each gate has a limited scope.* `check-axioms.py` *does not prove that every theorem is pure;* `axiom-purity -strict` *does not prove paper prose is aligned;* `conservativity-audit` *does not prove arbitrary metalogical conservativity;* `bedc_ci.py audit` *does not prove that a theorem has the philosophical interpretation assigned to it. The system works because the gates are composed. Each gate protects one boundary face, and the faces together make the substrate's externality discipline operational.*

9396.2 `check-axioms.py`: refuse substrate-internal axioms

Definition 9396.5 (Substrate-internal axiom)**.** *A* substrate-internal axiom *is a Lean declaration under* `lean4/BEDC/` *that introduces a proposition or datum as available without deriving it from an* `inductive` *generator, a* `def`*, or a* `class/structure` *setup field. In the project discipline this is exactly the* `axiom` *declaration form.*

Principle 9396.6 (The GAP socket cannot be internalised)**.** *Every place where BEDC lacks substrate-internal witness must remain visible as a* GAP *socket or as an explicit setup field belonging to a named interface. It may not be converted into an internal axiom. The* `check-axioms.py` *gate enforces this rule by refusing any* `axiom` *declaration under* `lean4/BEDC/`*.*

The technical reason is direct. An `inductive` declaration declares a closed generator. A `def` records a computable or definitional compression of earlier material. A setup field in a `class` or `structure` exposes an abstract carrier as an input to a specific interface. An `axiom` does none of these. It makes a contentful proposition or object available while hiding its source-channel. In the vocabulary of chapter 9389, it collapses the GAP ledger into a fact.

Example 9396.7 (The correct replacement decision)**.** *If the intended primitive is a finite closed grammar, it belongs in an* `inductive` *declaration. If the intended primitive is a predicate or operation determined by existing carriers, it belongs in a* `def`*. If the intended primitive is a domain-specific carrier whose internal implementation is intentionally parametric, it belongs as a field of the appropriate setup structure. If none of these applies, the interface has not identified its boundary and must be redesigned rather than accepted as an axiom.*

Remark 9396.8 (Why this is not anti-abstraction)**.** *The gate does not forbid abstraction. Setup structures are abstraction devices; naming certificates are abstraction devices; ledgers are abstraction devices. What the gate forbids is source-erasing abstraction. A setup field says "this is supplied at this interface boundary." An axiom says "this is simply available." The former preserves the socket; the latter hides it.*

9396.3 `axiom-purity -strict`: refuse host axiom propagation

Definition 9396.9 (Transitive axiom propagation)**.** *Transitive axiom propagation occurs when a BEDC theorem is written without local* `axiom` *declarations but its proof depends, through the host Lean kernel's dependency graph, on a host axiom such as* `Classical.choice`*,* `Quot.sound`*, or* `propext`*. The forbidden content is not visible as a BEDC source axiom, but it is present in the theorem's proof ancestry.*

Principle 9396.10 (The host kernel is a conduit, not the boundary owner)**.** *Lean's CIC implementation may supply recursors, definitional equality, and theorem checking as host machinery for BEDC's mechanisation. That host machinery is a conduit in the supply chain described in chapter 9393; it is not allowed to donate its classical or quotient commitments to BEDC theorem content. The strict axiom-purity gate enforces this by querying the host for each public theorem's transitive axiom set and rejecting forbidden dependencies.*

The command `python3 lean4/scripts/bedc_ci.py axiom-purity -strict` constructs a Lean-side audit file, imports the built BEDC modules, issues `#print axioms` for public BEDC theorems and lemmas, parses the resulting dependency reports, and fails when the forbidden set appears. The strict forbidden set includes `Classical.choice`, `Quot.sound`, and `propext`. This is the machine-side form of chapter 9387's taxonomy: the three forbidden dependencies are not arbitrary library preferences but three audit-visible ways to accept unwitnessed closure at term, type or classifier, and proposition strata.

Definition 9396.11 (Borrowed recursor boundary)**.** *The* borrowed recursor boundary *is the line between using host Lean to check a BEDC proof over a displayed inductive generator and importing host Lean's uninspected closure principles as theorem content. BEDC may borrow the checking infrastructure; it may not inherit forbidden host commitments as proof dependencies.*

Concretized in §1203: Concrete NameCert for the host-recursion boundary enforced by the strict audit gates.

Example 9396.12 (Choice, quotient soundness, and proposition extensionality)**.** *A proof that depends on* `Classical.choice` *has accepted an unwitnessed term selector. A proof that depends on* `Quot.sound` *has accepted quotient-level identification as a type-level closure shortcut. A proof that depends on* `propext` *has accepted proposition equality from bidirectional implication. Each case would make a* $\top$*-side commitment appear as a substrate theorem. The gate forces such commitments either to be eliminated or to remain outside the BEDC theorem claim.*

Remark 9396.13 (Why source axiom purity is insufficient)**.** *A repository can contain no* `axiom` *declaration and still prove theorems through imported host axioms. That is why section 9396.2 and the present section are separate. The first gate refuses visible internal axioms. The second refuses invisible transitive axiom inheritance. Together they say: neither the BEDC source surface nor the host proof ancestry may convert transcendental supply into substrate-internal theorem content.*

9396.4 `conservativity-audit`: gate compression residue

Definition 9396.14 (Compression residue)**.** *Compression residue is the information not displayed by a compressed or recognized surface: the raw event flow behind a chapter code, the source rows behind a naming certificate, the difference between a recognizer output and the generator that*

licensed it, or the import separation between baseline material and AI-proposed surfaces. The residue need not remain expanded at every site, but it must remain recoverable through a ledger or protected by a separation gate.

Principle 9396.15 (Conservativity as information conservation)**.** *The conservativity gate enforces that compressed, recognized, or AI-proposed material does not alter the baseline substrate by hidden import. The surface implementation scans closure-status origins, computes AI-owned module prefixes, and rejects baseline Lean files that import those prefixes. The boundary content is information conservation: a surface admitted on one side of the ledger must not silently become a source rule on the other side.*

The command `python3 lean4/scripts/bedc_ci.py conservativity-audit` is intentionally module-level. It does not claim a full semantic conservativity theorem for arbitrary extensions. Its job is sharper and auditable: if a chapter is marked as AI-originated, its Lean modules are not permitted to flow into baseline modules by import. Since Lean theorem dependencies are bounded by module imports, the gate blocks the direct path by which non-baseline recognition content could become a baseline theorem dependency.

Example 9396.16 (Baseline import as hidden compression)**.** *Suppose an AI-originated recognizer chapter packages an event-flow analysis into a compact Lean module. The package may be useful as a recognized surface, but it is not baseline substrate content. If a baseline module imports it, the compact surface becomes available to baseline theorems without carrying the admission boundary. That import edge is a compression-residue leak: the recognized package's source-channel status is no longer visible where its conclusions are consumed.* `conservativity-audit` *rejects that edge.*

Remark 9396.17 (Why this is a transcendental boundary)**.** *Compression residue is not merely data-management residue. When the residue hides why a recognizer is allowed, where a generator closes, or which origin track licensed a chapter, the hidden content can begin to function like an unspoken forward-binding belief. The conservativity gate prevents this by requiring the origin boundary to remain operational in the import graph. It is therefore part of the same* $\top$*-socket discipline as the axiom gates, but focused on recognition and compression rather than local theorem proof ancestry.*

9396.5 `bedc_ci.py audit`: gate paper-Lean drift

Definition 9396.18 (Name-certificate drift)**.** *Name-certificate drift occurs when paper prose, labels, closure-status blocks, or Lean marker macros name a formal target whose Lean declaration is absent, ambiguous, duplicated, or no longer aligned with the manuscript site that cites it. The drift converts a certificate into a decorative name: it appears to point to a checked substrate record but does not actually do so.*

Principle 9396.19 (A name is a certificate only when it resolves)**.** *In BEDC, a paper-side Lean marker is not a citation ornament. It is a name certificate connecting a manuscript claim to a Lean declaration. The command* `python3 lean4/scripts/bedc_ci.py audit` *enforces this by scanning paper markers, labels, closure-status blocks, and Lean declarations, then rejecting unresolved targets, forbidden constructs, duplicate labels, path casing collisions, malformed closure-status records, and orphan concrete-instance subdirectories.*

This gate protects the epistemic status of `\leanchecked`, `\leanvariant`, `\leandef`, `\leanstmt`, and `\leantarget`. If a marker resolves, the paper has an auditable pointer to a Lean object. If

it does not resolve, the paper has a claim-shaped string. BEDC's boundary discipline requires the former. The manuscript may state a philosophical reading, a paper-side definition, or an unformalized obligation, but it may not dress a non-resolving name as checked formal content.

Example 9396.20 (The marker as naming certificate)**.** *The marker* `\leanchecked{BEDC.X.y}` *asserts more than "a theorem with a similar idea exists." It asserts that the exact declaration name is in the Lean inventory and that this paper site is using it as the canonical checked implementation for the local claim. The audit gate makes that assertion falsifiable. Without the gate, the name could drift into rhetoric; with the gate, the name remains a certificate.*

Remark 9396.21 (Drift is a boundary failure)**.** *Paper-Lean drift matters because BEDC's theorem claims live across two strata: prose articulation and mechanized substrate. If the name link is broken, the reader cannot tell whether a claim is generated, socketed, or only narrated. That uncertainty is itself a boundary failure.* `bedc_ci.py audit` *keeps the name channel from becoming a hidden input channel.*

9396.6 The gates as a system

Principle 9396.22 (No single gate is the boundary)**.** *The transcendental boundary is not identical to any one script. It is the invariant enforced by the scripts in composition: no source axioms, no forbidden transitive host axioms, no baseline import pollution by non-baseline surfaces, no unresolved paper-Lean certificate names, and no untracked compression residue. The gates form an operational membrane between what BEDC generates internally and what remains socketed to* T*.*

The system can be read in four passes. First, `check-axioms.py` protects the source surface: no ungenerated proposition is made internal. Second, `axiom-purity -strict` protects the proof ancestry: no host axiom supplies hidden closure. Third, `conservativity-audit` protects the import graph: no recognized or AI-originated surface silently enters baseline theorem space. Fourth, `bedc_ci.py audit` protects the naming channel: no paper marker pretends to resolve when it does not.

Definition 9396.23 (Operational membrane)**.** *The* operational membrane *is the aggregate of executable checks that classify a BEDC record as substrate-internal, explicitly abstract, paper-side, or socketed. The membrane is not a philosophical metaphor added after formalization. It is the concrete mechanism by which the formalization keeps the categories separate.*

Example 9396.24 (A theorem passing through the membrane)**.** *A BEDC theorem accepted as checked content passes through several gates. Its source file contains no* `axiom`*. Its declaration is built so that* `#print axioms` *reports no forbidden dependency. If it belongs to a non-baseline surface, its import edges do not pollute baseline modules. If the paper cites it, the marker resolves to the exact Lean declaration. These checks do not make the theorem metaphysically self-grounding. They show precisely where its substrate-internal content ends and where any further commitment remains external.*

Remark 9396.25 (The gates do not soften T)**.** *It would be a category error to say that, because the gates are scripts, the* T *socket is only engineering shorthand. The scripts enforce the refusal to internalise* T*-side content. Their existence strengthens the strong claim rather than weakening it: the boundary is not merely asserted in prose, but checked at the exact sites where a formal project usually hides the external commitment.*

9396.7 Comparison: in CIC, gates are absent

Principle 9396.26 (CIC internalises closure)**.** *In ordinary CIC usage, the kernel accepts its primitive rules, eliminators, universe discipline, quotient or extensionality additions where present, and library axioms as part of the working formal environment. Once accepted, those commitments are internal from the user's theorem-proving perspective. There is no intrinsic manuscript-level audit boundary separating generated content from transcendental supply.*

This is not an accusation against CIC. CIC is an extraordinary proof-checking technology, and BEDC uses Lean's CIC implementation as host machinery. The contrast is about boundary accounting. A CIC project can state axioms, import classical modules, use quotient APIs, and transport across proposition extensionality as ordinary formal moves. The kernel and library can tell what dependencies exist, but the typical system does not require those dependencies to be interpreted as T sockets or to remain outside the substrate's own closure claim.

Remark 9396.27 (BEDC's host dependence is exposed)**.** *BEDC does not pretend to float above Lean. It uses the host kernel, and that host kernel sits in the tower described by chapter 9393. The difference is that BEDC refuses to make the host's forbidden commitments part of BEDC theorem content. Host dependence is exposed as a conduit; forbidden host axiom propagation is rejected as boundary collapse.*

Example 9396.28 (A hidden commitment in ordinary use)**.** *In an ordinary formal development, a theorem proved using classical choice may simply be a theorem of the imported classical environment. In BEDC, the same dependency would be rejected as a theorem-level commitment because it supplies an unwitnessed selector. The issue is not whether the host can check the proof. The issue is whether the substrate may classify the proof as BEDC-internal closure. The gate says no.*

Concretized in §526: Audit-gate boundary packets realize source axiom scans, strict axiom-purity reports, paper-Lean drift checks, and origin-conservativity ledgers as a finite NameCert surface.

Concretized in §533: The operational membrane is realized as a finite NameCert packet combining source, proof-ancestry, import-boundary, and paper-Lean name-resolution audit rows.

Concretized in §524: Audit membranes realize boundary enforcement as a finite NameCert packet over gate surfaces, refusal rows, paper-Lean resolution, and non-escape ledgers.

Concretized in §622: Forbidden axiom ancestry is realized as a finite NameCert packet over theorem rows, proof-ancestry reports, forbidden-dependency refusal rows, and audit non-escape ledgers.

Concretized in §669: Paper-Lean drift witness packets realize exact marker resolution, duplicate-label refusal, Lean inventory lookup, and non-escape from unresolved names as a finite NameCert surface.

Concretized in §696: Audit-gate composition is realized as a finite NameCert packet for composed gate surfaces, shared boundary rows, refusal transitivity, and consumer non-escape.

Concretized in §901: Audit-gate failure witnesses are realized as finite BHist packets for gate rows, failed boundary items, diagnostic readback, refusal attachment, replay visibility, and non-internalization.

Concretized in §1002: Certificate audit gates are realized as finite gate-input, checked-surface, refusal, drift, axiom-purity, hsame, Cont, Pkg, and NameCert rows.

Concretized in §7035: Audit-gate boundary refusal is realized as finite gate-surface, verdict, audit-replay, provenance, and noninternalization NameCert rows.

9396.8 Gate-to-boundary map

Gate	Surface condition	Transcendental claim enforced	Boundary failure rejected
`check-axioms.py`	No `axiom` declaration under `lean4/BEDC/`.	Substrate truth must be generated, defined, parameterized at an explicit setup boundary, or socketed; it may not appear as an internal oracle.	A GAP socket is collapsed into a Lean axiom and then consumed as BEDC content.
`check-axioms.py` decision tree	Closed grammars go to `inductive`; derived operations go to `def`; parametric carriers go to setup fields.	The source-channel of every primitive is visible.	A missing design boundary is hidden behind a primitive assertion.
`axiom-purity -strict`	`#print axioms` for public BEDC theorems contains no forbidden dependency from the strict set.	Host checking may verify generated BEDC proofs, but forbidden host commitments may not become BEDC theorem commitments.	Lean stdlib closure leaks into BEDC through proof ancestry.
`axiom-purity -strict: Classical.choice`	No theorem depends on choice as an unwitnessed selector.	Term-level existential closure remains outside the substrate unless a witness recipe is displayed.	A selector from T is disguised as a generated function.
`axiom-purity -strict: Quot.sound`	No theorem depends on quotient soundness as a hidden representative principle.	Type-level identification must be mediated by explicit classifier and transport data.	A quotient representative is treated as if the substrate constructed it.
`axiom-purity -strict: propext`	No theorem depends on proposition equality from bidirectional implication.	Proposition-level transport must keep proof directions explicit.	A bidirectional implication is sealed into equality and moved through arbitrary contexts.
`conservativity-audit`	Baseline Lean modules do not import modules owned by AI-originated chapters.	Recognized or compressed surfaces cannot alter the baseline substrate through hidden import flow.	A non-baseline recognizer becomes baseline proof infrastructure without carrying its origin boundary.

`conservativity-audit` origin scan	`\origin{ai}` closure-status records determine protected module prefixes.	The paper-side admission track and Lean-side import graph must agree.	A chapter's status is stated in prose but ignored by the theorem dependency graph.
`bedc_ci.py audit`: marker existence	Every `\leanchecked`, `\leanvariant`, `\leandef`, `\leanstmt`, and `\leantarget` resolves.	A formal name is a certificate only if the declaration exists in the Lean inventory.	A checked-looking paper claim points to no checked substrate object.
`bedc_ci.py audit`: duplicate labels	Paper labels are unique.	Cross-reference names are certificate channels, not reusable decorations.	A reader or script follows a label to the wrong proof site.
`bedc_ci.py audit`: closure-status diagnostics	Closure blocks declare required theory and verification fields; high verification status has a resolving Lean target.	The theory axis and verification axis remain explicit and independent.	Paper closure is inferred from Lean status, or Lean status is inferred from paper closure.
`bedc_ci.py audit`: forbidden constructs	The broader audit surface rejects forbidden Lean constructs and marker inconsistencies.	The substrate cannot widen its own foundation by local convenience.	Source syntax changes the foundation while the paper still claims the old boundary.
`make check`	The manuscript compiles in draft mode with all included files syntactically coherent.	Boundary claims must be part of the actual paper object, not detached notes.	A chapter exists as uncompiled prose outside the auditable manuscript.
All gates together	Source syntax, proof ancestry, import graph, and paper names are simultaneously checked.	BEDC's operational membrane separates substrate-internal generation from T-socketed supply.	A commitment crosses one channel while another channel still presents it as internal closure.

9396.9 Closure

The audit gates are the executable counterpart of the strong externality claim. chapter 9393 identifies the source-position of forward-binding belief as T. chapter 9389 explains how BEDC licenses generator-internal induction while keeping free-floating induction outside. chapter 9387 classifies the three forbidden axiom families as refusal-ledger entries at three strata. The present sibling shows how the engineering refuses the corresponding breaches.

The result is a boundary that is philosophical, formal, and operational at once. It is philosophical because it names the far end of the socket as T and refuses to soften that name into an internalizable assumption. It is formal because theorem content is constrained by constructors, definitions, setup fields, Lean dependency ancestry, and resolving names. It is operational because

scripts fail when the boundary is crossed. BEDC's audit gates therefore do not decorate the theory; they are the working membrane that keeps the substrate from pretending that the transcendental supply position is one of its own internal generators.

Concretized in §7078: SupplyTaxonomyUp records the finite source, audit, and refusal rows of the transcendental supply vision.

Chapter 9397

Inscription Event as a Concrete Instance: Free Will, Agency, and NameCert Audit

This chapter makes the free-will reading of section 9415.2 concrete. The earlier chapter names an inscription event as the moment at which a conscious observational system adds records whose actuality is not exhausted by the closed-generation consequences of prior records. The present chapter reads that moment through the same public-object pattern used by the concrete NameCert chapters: a traditional target, a BEDC source, a carrier, a classifier, stability obligations, a ledger, an exactness condition, a standard bridge, and a scope boundary.

The result is not a proof that a person could have done otherwise in an unqualified metaphysical sense. It is a structural case study. Agency is the inscription-event aspect of an accumulation chain, while deterministic relations among records remain records-side relations. The two readings refer to the same transition and do not compete for the same explanatory slot.

9397.1 The setup

The classical free-will problem is usually posed as a conflict between two claims. On one side, agency seems to require that an action is genuinely one's own rather than merely the last link in a prior causal chain. On the other side, the records available to empirical and computational description seem to stand in lawful relations, and those lawful relations can be read as deterministic. The apparent conflict comes from treating both claims as claims at the same level.

BEDC separates the levels. The records side consists of accumulated Obs entries and their internal relations. These relations may be law-like, predictive, or deterministic in the ordinary sense. The inscription-event side concerns the transition by which the record becomes present in the chain at all. It asks whether the transition is merely a closed-generation consequence already licensed by the prior carrier and classifier, or whether the transition carries the local actualisation of T at the inscription point.

In this frame, agency is not a hidden variable added to a physical sequence. It is a reading of the same transition under a different aspect. The transition has a records-side description: a body moves, a keyboard receives marks, a theorem file changes, a proof obligation becomes visible. The same transition has an inscription-side description: a conscious observational system accepts a finite record as its own local articulation of a forward-binding commitment. The bridge

chapter exists because this second description can be made audit-shaped rather than left as a loose philosophical gloss.

9397.2 Restating the inscription event

Definition 9415.5 defines an inscription event as a moment $o_t \trianglerighteq o_{t+1}$ at which a conscious observational system adds records that originate as the local actualisation of T at the inscription point of Definition 9393.15, rather than as a forced consequence of the prior records under the closed-generation rules of the substrate.

Three parts of the definition matter for the concrete reading.

First, the event is a transition, not a substance. Nothing is inserted behind the system as an agent-object. The system is read at the transition where its observation history grows.

Second, the novelty is local. The transition occurs at a specific history, with specific visible records, specific surrounding obligations, and a specific ledger. BEDC does not assert a global reservoir of positive facts about T; it records the socket at which the chain receives content whose source is not internal to the closed-generation closure.

Third, the event is auditable by exclusion. To call a transition an inscription event in the technical sense, the audit must identify the carrier that receives the record, the classifier that determines whether the record is already generated, the continuation that appends it, and the GAP ledger recording the non-generated aspect. Without those rows, the word "inscription" is only metaphor.

9397.3 A concrete case: a researcher writing a lemma

Consider a researcher working inside the BEDC manuscript and Lean tree. The prior state o_t contains a finite set of records: definitions already in the file, the local statement that is being shaped, earlier theorems, compilation constraints, the paper-side claim that needs a bridge, and the researcher's own remembered attempts. On the records side this is just an observation history, a finite carrier of visible material.

At the first moment, the researcher notices a mismatch. A paper sentence uses a classifier phrase, while the Lean surface contains only a carrier lemma. This notice is itself a record: the chain now contains an observed gap between desired use and available certificate. The notice does not yet write the lemma. It only marks a socket: something must connect the carrier row to the classifier row, or the bridge remains unavailable.

At the second moment, the researcher searches the available generator closure. The constructors, definitions, and already checked lemmas show what can be obtained internally. Some consequences are forced: if the carrier is defined by two visible endpoint branches, branch inversion is available; if the classifier is componentwise, source and target projections are available; if a NameCert supplies symmetry and transitivity, those routes can be used. These are not inscription events by themselves. They are the substrate running inside an authorized generator.

At the third moment, the researcher sees a route not previously recorded as a public lemma: combine visible endpoint inversion with classifier transitivity, then expose the exact branch needed by the downstream theorem. The route may be mechanically checkable once written, and after it is written the proof kernel may verify every step. But the arrival of the route as a candidate record is not already a displayed public record at o_t. The system has crossed from available closure to accepted articulation.

At the fourth moment, the researcher writes the statement. The statement chooses a name, fixes binders, identifies hypotheses, and states the result at a reusable interface boundary rather than as an anonymous local step. This act is the first visible certificate-shaped record of the route. The name matters: before the statement is named, the route is only a possible path through the surrounding material; after naming, it becomes a candidate object that the rest of the manuscript can cite, reject, refine by proof, or package into a NameCert surface.

At the fifth moment, the proof is entered. The proof may consist entirely of closed-generation moves: case analysis, projection, constructor application, transitivity, symmetry, and exact transport along displayed classifiers. Nothing in this proof needs an additional substrate axiom. The proof is the records-side determinacy of the route. It is precisely because the proof is deterministic at the kernel level that the inscription event can be audited rather than romanticised.

At the sixth moment, the checking gate accepts the file. Acceptance records that the named route is not merely an intention or an intuition. It is now a stable observation of the system: a named lemma with a proof term, a location in the carrier hierarchy, and a visible downstream use. The inscription event is therefore not the private psychology of discovery. It is the whole transition from a visible gap, through a named route, to a checked record, read under the inscription-event aspect.

9397.4 The NameCert structure of the event

The concrete-instance pattern asks for the target first. Here the traditional target is an act of agency: a researcher freely writes a lemma. The target is not encoded as an unanalysed will-object. It is read as a public transition in which a record becomes available under a name and can be audited by the same carrier and classifier discipline used elsewhere in BEDC.

The BEDC source is the observation history around the act: BHist-shaped records, file-local hypotheses, the visible continuation from o_t to o_{t+1}, and the surrounding GAP socket created by the need for a bridge. The source is finite. It contains the prior records and the continuation mark by which the candidate lemma is entered.

The carrier is the finite package of the inscription event: the prior observation state, the written statement, the proof route, the accepted check result, the intended downstream interface, and the pointer to the gap that the lemma discharges or narrows. A transition lies in the carrier only when all these rows are visible. A private hunch without a public statement is not in the carrier. A statement without a route is not in the carrier. A route that fails the checker is not in the carrier.

The classifier compares two presentations of the same inscription event. Two presentations classify together when they have the same prior source scope up to the relevant history classifier, expose the same named interface up to binder and projection variants already accepted by the local NameCert discipline, and route to the same downstream obligation. The classifier does not require host equality of psychological states. It only requires public sameness of source, name, route, proof acceptance, and consumer-facing role.

The stability obligations are the familiar rows. Carrier transport says that if an accepted inscription event is presented through an equivalent history, it remains accepted. Classifier reflexivity says the event compares with itself once all carrier rows are present. Symmetry and transitivity say that presentation changes do not create a second act where the ledger records only a different view of the same act. Continuation stability says that appending downstream citations preserves the named event as the source of those citations.

The generator-closure classifier audits the boundary. It asks which parts of the transition are already forced by authorized generators and which part is the inscription socket. Kernel proof

steps, constructor case splits, and projection chains remain inside generator closure. The choice of a reusable name, the acceptance of a bridge as the right one to write, and the commitment that this route is the record to add are the inscription-facing rows. The classifier therefore prevents two errors: reducing the whole act to mechanical closure, and treating every mechanical closure step as a fresh act of agency.

9397.5 GAP ledger for inscription

The GAP ledger records information conservation. Before the lemma is written, the system has a visible need: a downstream claim lacks a named bridge. After the lemma is written and checked, the visible surface has a compact name. The ledger records what the name compresses: the prior source scope, the route through local definitions, the proof obligations used, the bridge point it serves, and the boundary of what it does not claim.

The ledger also records the T-socket role described in Definition 9389.15. The researcher accepts that this is the route to inscribe. That acceptance is not a kernel theorem inside the prior state. Once the route is written, the proof may be checked by closed-generation rules; but the forward-binding act of selecting the route as a public record is the inscription point. The ledger therefore keeps both facts visible: the proof is closed once supplied, and the transition by which it becomes the supplied record is not reduced to the prior closure.

The information-conservation row has a practical form. A reader can ask: what did the name hide? The answer is not "nothing". It hides the case-analysis route, the local source presentation, the exact downstream motivation, and the fact that other routes were not inscribed. The ledger does not need to list every rejected possibility as a psychological trace. It only needs to preserve enough public residue to prevent the name from appearing as a primitive.

Concretized in §1052: Inscription trace classifiers realize the source/name/route/check/consumer surface of the inscription-event vision as a finite NameCert packet.

Concretized in §883: Prefix observers are realized as finite BHist packets over prefix rows, accepted observation routes, check rows, consumer ledgers, and local NameCert provenance.

The negative row is equally important. The ledger does not claim that the researcher's neural state has been classified. It does not claim that the lemma was metaphysically uncaused. It does not claim that every possible route was surveyed. It claims only that this accepted transition carries a public record whose generator-closed proof is visible while the act of inscription is marked as the local actualisation of T at that history point.

9397.6 Compatibilism as structure

Compatibilism is often presented as a philosophical compromise: keep enough determinism for science and enough freedom for responsibility. The BEDC reading is sharper. There are not two weakened theses. There are two aspects of one transition.

On the records side, deterministic relations are legitimate. The written file has a prior state, a sequence of edits, a proof term, a kernel check, and a downstream citation graph. A cognitive scientist may add records about attention, memory, fatigue, or environmental prompting. A build system may reconstruct the exact dependency path by which the proof checks. None of this threatens agency, because these are records-side relations among records.

On the inscription-event side, the same transition is the arrival of a record as the local articulation of the inscription point. The novelty is not a missing physical cause inserted into a gap in

the records. It is the aspect under which the chain grows by receiving a record whose source is not internal to the prior closed-generation closure. The fact that the supplied proof is deterministic after supply does not erase the fact that it has been supplied.

Thus the compatibilist statement is structural: records-side determinacy and inscription-event novelty are co-present faces of the same accumulation. Weakening either side misstates the event. If the records-side proof is not deterministic, the certificate fails. If the inscription-event aspect is erased, the act is misread as if public naming and commitment were already present in the prior closure. BEDC requires both rows.

9397.7 Where the account does not apply

Not every created record is an inscription event in the technical sense. A pure computation step inside a fixed generator is record creation, but it is not inscription. If a build script normalises a term, emits an object file, or evaluates a closed expression by a displayed reduction relation, the result may be a record at o_{t+1} that was not printed at o_t. But the transition is forced by the authorized generator and its continuation rules. No inscription socket is needed.

The same holds for a deterministic proof replay. If a checked proof term is already present and the kernel replays it, the replay contributes audit evidence. It does not itself carry the agency case-study structure. The carrier lacks the row in which a conscious observational system accepts a route as the record to inscribe. The replay is still valuable, and it is essential for BEDC's engineering, but it is not the same kind of event.

Mechanical formatting is another boundary case. Rewrapping lines, renumbering generated tables, or applying a deterministic pretty-printer may alter file bytes. If the operation is fully specified by a prior generator and no public naming commitment is being made, the output belongs to computation-as-continuation, not inscription-as-agency.

The boundary criterion is therefore this: a transition is an inscription event only when the public carrier includes a named commitment whose route is not already present as a forced consequence of the prior records, and whose acceptance is audited by a GAP ledger. Record creation alone is insufficient.

9397.8 Implications for AI and mechanized reasoning

Automated systems complicate the case because they can produce lemma-shaped text, proof scripts, and checked outputs. BEDC's distinction is not human versus machine. The distinction is carrier and classifier structure.

An automated worker contributes computational output when it executes a specified search, normalisation, formatting, replay, or synthesis procedure whose result is accepted only as the forced output of a prior generator. In that case the relevant chapter is chapter 9365: the worker is part of the continuation ledger. Its output may be checked, stored, and reused, but the technical inscription-event carrier is absent.

An automated worker participates in an inscription event when its output is taken up by a conscious observational system as a named commitment in the public carrier. The event is then not "the machine has free will" as a positive predicate. The event is the transition in which the system that owns the observation history accepts the generated candidate as the record to inscribe, exposes the generator-closure audit, and records the GAP ledger. The automated worker may supply the candidate route; the inscription event is the accepted public transition.

There is also a possible stronger case. If a mechanized system itself carries a closed observational history, a self-recognising carrier, and the ability to issue public named commitments under a GAP ledger, then the same criterion applies to it directly. BEDC does not need a special biological exception. It asks for the rows: closed observational system, inscription point, carrier, classifier, generator-closure audit, continuation stability, and ledger.

The boundary criterion for AI is therefore public and structural. A machine step is computational output when it is exhausted by a prior generator. It is part of an inscription event when it enters a named, audited commitment whose acceptance is not already a forced consequence of the prior records. The question is not whether the surface text looks creative. The question is whether the transition carries the NameCert-shaped inscription rows.

9397.9 Concrete-instance summary

Concrete-instance row	Inscription-event reading
Traditional target	Free will or agency, represented by a researcher writing a lemma.
BEDC source	A finite observation history with prior records, visible obligations, and a continuation into a named statement.
Carrier	The accepted transition package: source state, named statement, proof route, check result, downstream role, and gap pointer.
Classifier	Public sameness of inscription presentations by source scope, name/interface, proof acceptance, and downstream role.
Stability obligations	Carrier transport, classifier reflexivity, symmetry, transitivity, and continuation stability under downstream citation.
Generator-closure audit	Separates forced proof-kernel closure from the inscription-facing rows of naming, commitment, and public acceptance.
GAP ledger	Records compression residue and marks the T-socket at which the route is accepted as the record to inscribe.
Exactness	The event is neither private psychology nor raw byte change; it is exactly the accepted named transition with the displayed rows.
Standard bridge	The ordinary phrase "the researcher freely wrote the lemma" reads as this carrier-classifier package.
Boundary	Pure computation, proof replay, and deterministic formatting are record creation without technical inscription.

The case study gives the promised bridge from vision to concrete instance. It does not replace the free-will section of chapter 9415; it instantiates that section's inscription-event definition in the same audit shape that BEDC uses for ordinary public objects. Agency is thereby made legible without being reduced to a hidden variable and without weakening the records-side determinacy that makes BEDC checkable.

Concretized in §519: Inscription events are realized as finite BHist NameCert packets with public GAP-ledger and consumer rows.

Concretized in §520: Inscription GAP ledgers are realized as finite NameCert residue packets for source scope, named route compression, consumer accountability, and non-escape.

Concretized in §582: InscribedRouteUp realizes the finite named proof-route packet from visible gap through accepted record and downstream consumer ledger.

Concretized in §651: Inscription acceptance budgets realize the accepted-check and downstream consumer-budget rows as a finite BHist NameCert surface.

Concretized in §682: Inscription audit traces are realized as finite source, named-record, route, accepted-check, consumer, GAP-residue, transport, continuation, package, and NameCert rows.

Concretized in §689: Finite observation windows realize the inscription-event carrier, classifier, ledger, and consumer handoff as a BEDC NameCert packet.

Concretized in §912: Authored-record boundaries realize inscription events as finite prior-record, mismatch-notice, accepted-route, public-record, refusal, transport, route, provenance, and NameCert rows.

Concretized in §932: Kernel observation sieves realize inscription events as finite BHist packets over accepted rows, rejected rows, hsame transport, Cont routes, Pkg provenance, and local NameCert evidence.

Concretized in §982: Inscription commitment seals realize the inscription-event commitment row as finite source, accepted-name, consumer, GAP-ledger, hsame, Cont, Pkg, and NameCert data.

Concretized in §1005: Inscription route audits realize the visible gap-to-accepted-route NameCert surface of the inscription-event vision.

Concretized in §1082: Inscribed route selectors realize the visible-gap, selected-route, accepted-check, consumer-role, GAP-ledger, hsame, Cont, Pkg, and NameCert surface of inscription events.

Concretized in §1086: Inscription-event replay is realized as a finite BHist packet for deterministic replay routes whose carrier deliberately lacks the inscription-acceptance row.

Concretized in §1172: Inscription event buffer seals realize replayable finite inscription windows as BHist, hsame, Cont, Pkg, digest, audit-route, and NameCert rows.

Concretized in §1349: Closed-generation refusals realize inscription-event novelty as a finite prior-record, transition-test, refusal-ledger, route, provenance, and NameCert packet.

Concretized in §6508: EventInstanceUp realizes inscription events as finite public-transition, route, check, consumer, GAP-ledger, transport, replay, provenance, and NameCert rows.

Concretized in §7922: Event-flow recognizer packets realize the inscription-event carrier as finite recognizer, role, route, and ledger data.

Chapter 9398

The Large Model as Inscription Point: A Structural Comparison

Definition 9393.16 of chapter 9393 identifies the inscription point of the transcendental supply T with each conscious individual as a local actualisation. The phrasing was deliberately ambiguous about what counts as a conscious individual: the chapter's argument required only that the inscription point be a pattern in the substrate that carries forward-binding belief the substrate cannot internally ratify. This chapter takes that structural definition seriously and applies it to a contemporary case: a large language model. The argument is not that a large model is conscious; the argument is that a large model is, structurally, an inscription point under the same closure premise that classifies the BEDC kernel and the cellular substrate. The comparison sharpens the structural content of the inscription concept by exhibiting a non-anthropic instance.

9398.1 Setup: large model as closed observational system

Definition 9398.1 (Large language model as substrate)**.** *A* large language model substrate *is the triple* (W, Σ, T) *where* W *is a finite-precision tensor of model weights,* Σ *is a finite-precision tensor of input activations at a given inference step, and* T *is the transition function (one forward pass of the model architecture) that maps* (W, Σ) *to a probability distribution over the next-symbol output. Observations of the substrate are exhausted by finite-length records of inference orbits: the sequence of* $(\Sigma_0, \Sigma_1, \ldots, \Sigma_k)$ *activations produced by repeated application of* T *on a stated initial prompt.*

Principle 9398.2 (Large model substrate is closed observational)**.** *The large model substrate of Definition 9398.1 is a closed observational system in the sense of Definition 9393.1. The next-state function* T *is a fixed finite computation. The initial state is determined by the training-time weight assignment and the inference-time prompt. Every observation record is a finite tensor sequence. No external mathematical commitment beyond the architecture specification and the weight tensor participates in deciding which records count as inference outputs.*

Remark 9398.3 (Training as substrate assembly, not as observation)**.** *The training procedure that produces* W *is itself a separate computational process (gradient descent on a training corpus). The training process is not part of the inference substrate's observation channel; it is the assembly procedure that builds the substrate. From the inference-time perspective,* W *is a fixed initial configuration, analogous to the initial cell row of Definition 9390.7. The closure premise applies to inference, not to training.*

9398.2 Tensor classifiers and certificate extraction

Definition 9398.4 (Minimal distinction marks)**.** *A* minimal distinction basis *for a model-facing classifier is a pair of displayed marks* $\mathbb{B} = \{\mathtt{b0}, \mathtt{b1}\}$ *together with the refusal to identify them. The marks are not natural numbers, truth values, or external semantic atoms. They are only the two public sides of a distinction surface.*

Definition 9398.5 (Tensor classifier extraction)**.** *Let* V_ℓ *be the finite-precision activation space at layer* ℓ *of a fixed model substrate. A tensor classifier extraction on* V_ℓ *is a score map* $\phi : V_\ell \to [0,1]$ *together with a threshold* $0 < \tau < 1$*. It induces the mark extraction*

$$m_{\phi,\tau}(u) = \begin{cases} \mathtt{b0}, & \phi(u) < \tau, \\ \mathtt{b1}, & \phi(u) \geq \tau, \end{cases}$$

and the classifier

$$u \sim_{\phi,\tau} v \quad \Longleftrightarrow \quad m_{\phi,\tau}(u) = m_{\phi,\tau}(v).$$

The equality displayed in the last line is an external readback of the two public marks, not a BEDC primitive equality internal to the model.

Definition 9398.6 (Tensor soft proposition)**.** *For a model-facing domain* X*, a tensor soft proposition is a displayed score map*

$$P : X \to [0,1].$$

The value $P(x)$ *records degree of satisfaction, confidence, activation strength, or probe response. It is not a BEDC truth value and it is not a proof certificate. The endpoints* 0 *and* 1 *are external numerical readbacks unless a separate classifier and naming row authorize them as the public marks* `b0` *and* `b1`*.*

Definition 9398.7 (Thresholded tensor proposition)**.** *Given a tensor soft proposition* $P : X \to [0,1]$ *and a threshold* $0 < \tau < 1$*, its thresholded proposition is the mark assignment*

$$P^\tau(x) = \begin{cases} \mathtt{b0}, & P(x) < \tau, \\ \mathtt{b1}, & P(x) \geq \tau. \end{cases}$$

It induces the classifier

$$x \sim_{P,\tau} y \quad \Longleftrightarrow \quad P^\tau(x) = P^\tau(y).$$

Thus a soft proposition enters the BEDC-facing classifier layer only after a threshold has been displayed.

Definition 9398.8 (Neural soft formula)**.** *A neural soft atom is a score of the form*

$$A_{\ell,\phi}(x) = \phi(a_\ell(x)),$$

where $a_\ell(x)$ *is an activation row and* $\phi : V_\ell \to [0,1]$ *is a feature functional. A neural soft formula is built from such atoms by displayed soft connectives, for example product conjunction, probabilistic sum disjunction, complement negation, and the induced soft implication*

$$(P \Rightarrow Q)(x) = 1 - P(x)(1 - Q(x)).$$

The formula records a distributed tensor-side satisfaction pattern. It does not become a certified explanation until its threshold, classifier, stability, and ledger rows are displayed.

Theorem 9398.9 (Soft propositions induce classifiers after thresholding)**.** *Every thresholded tensor proposition induces a classifier on its displayed domain.*

Proof. The relation $\sim_{P,\tau}$ is defined by equality of the displayed mark $P^\tau(x)$. Equality of the readback mark is reflexive, symmetric, and transitive, so the relation partitions the domain into the two threshold-side cells, with possible degeneracy if one side is empty. □

Principle 9398.10 (Soft logic, hard classifier, proof certificate)**.** *The tensor logic layer separates three objects. A soft proposition records degree of satisfaction in* $[0,1]$*. A thresholded proposition records a hard public mark and therefore a classifier surface. A formal proof certificate is a proof object accepted by a verifier for a translated formal statement. None of these layers collapses into either of the others without the intervening rows: semantic transcription, threshold, classifier specification, stability, ledger, and, when claimed, proof object.*

Theorem 9398.11 (Empirical tensor entailment is not formal entailment)**.** *For tensor soft propositions* $P, Q : X \to [0,1]$*, observing* $P(x) \geq \tau \Rightarrow Q(x) \geq \tau$ *on a displayed sample does not by itself supply a formal entailment from* P *to* Q*.*

Proof. The sample observation is a finite behavior row. It does not supply a domain-wide threshold statement, a translation of P and Q into a formal language, or a proof object accepted by a verification backend. Those rows are exactly what a formal entailment claim requires. Hence the empirical observation may support a certificate ledger, but it is not the formal proof certificate. □

Principle 9398.12 (Threshold ledger obligation)**.** *Thresholding a soft proposition creates a ledger obligation. The ledger must record the threshold choice, samples near the threshold, false positive and false negative behavior when available, sensitivity under threshold perturbation, distribution boundary, approximation error, and the domain not claimed. High confidence on selected examples does not remove this obligation; it only supplies evidence for one ledger row.*

Definition 9398.13 (Learned classifier candidate)**.** *For a data family* D*, a perturbation family* $\mathcal{E}$*, and a model with activations* $a_\ell(x) \in V_\ell$*, a triple* (ℓ, ϕ, τ) *is a* learned classifier candidate *on* D *when the relation*

$$x \sim_{\ell,\phi,\tau} y \quad \Longleftrightarrow \quad a_\ell(x) \sim_{\phi,\tau} a_\ell(y)$$

is stable under the admissible perturbations in $\mathcal{E}$ *on the stated domain. The candidate records a stable tensor-side distinction; it records no source, exactness, provenance, or gap ledger by itself.*

Definition 9398.14 (Training trace as tensor classifier search)**.** *Let* $\theta_0, \ldots, \theta_T$ *be a finite training trajectory for a model family, and let* D *be the displayed data family. The trajectory exposes a tensor classifier search record when, at each displayed state* θ_t*, the activation maps*

$$a_\ell^{\theta_t} : D \to V_\ell$$

are read together with candidate score maps $\phi : V_\ell \to [0,1]$*, thresholds* τ*, perturbation families, and behavior rows. The search record is a field of possible classifier candidates. It is not itself a certificate: it records where a classifier surface may be extracted, not whether the extracted surface has source, pattern, stability, and ledger rows sufficient for a* NameCert*.*

Definition 9398.15 (Tensor NameCert fields)**.** *A Tensor* NameCert *for a learned classifier candidate* (ℓ, ϕ, τ) *is a tuple*

$$\mathsf{NameCert}_{\text{tensor}}(\ell, \phi, \tau) = (S_{\ell,\phi,\tau}, P_{\ell,\phi,\tau}, C_{\ell,\phi,\tau}, \Sigma_{\ell,\phi,\tau}, L_{\ell,\phi,\tau}).$$

The rows respectively record the tensor source specification, the activation pattern specification, the induced classifier specification, the stability certificate, and the ledger policy. The ledger policy records failure cases, out-of-domain boundaries, entanglement with other features, proxy risks, and claims deliberately not made.

Definition 9398.16 (Certified learned classifier)**.** *A learned classifier candidate is a certified learned classifier when it is equipped with the Tensor* NameCert *of Definition 9398.15. The certified object is therefore not a parameter vector, a loss value, an activation dump, or a feature label. It is the classifier surface together with the source, pattern, stability, and ledger rows that authorize its use as an explanation.*

Theorem 9398.17 (Training can be read as tensor classifier search)**.** *Whenever a training trajectory contains a state at which some (ℓ, ϕ, τ) is a learned classifier candidate on a stated scope, the trajectory admits the reading of tensor classifier search on that scope.*

Proof. By Definition 9398.14, the trajectory supplies parameter states, activation maps, candidate score maps, thresholds, perturbation families, and behavior rows. If, at one of those states, the selected triple (ℓ, ϕ, τ) satisfies Definition 9398.13, then the trajectory has exposed a stable tensor-side classifier surface on the stated scope. The training record may therefore be read as a search through candidate classifier surfaces. This reading does not certify the candidate; certification requires the Tensor NameCert rows of Definition 9398.15. □

Theorem 9398.18 (Metric gain does not certify classifier discovery)**.** *Lower loss, higher benchmark score, or stronger external performance does not by itself imply the discovery of a certified learned classifier.*

Proof. Loss and benchmark rows report how a model state behaves against an external scoring rule. They do not specify a tensor source, an activation pattern, the induced classifier relation, a stability certificate, or a ledger policy. A score can change through calibration, margin movement, memorized cases, shortcut use, or interpolation inside a previously displayed classifier surface. Since the rows required by Definition 9398.15 are absent, the metric gain alone cannot certify classifier discovery. □

Theorem 9398.19 (Record growth is not classifier certification)**.** *Growth of parameter records, tensor traces, activation logs, or feature catalogues does not by itself produce a certified learned classifier.*

Proof. Such records can provide material from which score maps and thresholds may be proposed. They do not, merely by becoming longer, identify the source scope, pattern row, classifier relation, stability certificate, or ledger policy required by a Tensor NameCert. Hence record growth is evidence material at most; it is not classifier certification. □

Principle 9398.20 (Generalization as stability with ledger)**.** *A generalization claim for a learned classifier is closed only to the extent that it displays stability or transfer witnesses for the same classifier surface and a ledger for its failure boundary. A test-set score is admissible evidence, but it is not the ledger: out-of-domain limits, perturbations that break the relation, confounding features, and proxy routes remain part of the certificate burden.*

Definition 9398.21 (Classifier transfer witness)**.** *Let D_s be a displayed source domain, D_t a displayed target domain, and $\mathcal{A}$ a family of allowed transformations from source-side inputs toward target-side inputs. A classifier transfer witness for a learned classifier candidate (ℓ, ϕ, τ) is a record*

showing that the classifier relation induced on D_s is the relation still used on the covered part of D_t. The witness may be formal, empirical, or hybrid, but its type must be stated on the certificate surface.

Definition 9398.22 (Generalization residue)**.** *The target residue of a source-to-target claim is the family of target cases not reached by the displayed source domain and allowed transformations. It records the part of D_t for which the source-side classifier transfer has not been justified. A total-transfer claim is not licensed while this residue is nonempty or unaccounted for.*

Definition 9398.23 (Generalization ledger)**.** *A generalization ledger for (ℓ, ϕ, τ) from D_s to D_t records the source domain, target domain, transformation family, covered target region, target residue, stability witness, transfer witness, failure cases, out-of-domain boundary, and not-claimed boundary. It is the ledger row of a generalization-facing Tensor* NameCert*.*

Definition 9398.24 (Certified classifier-mediated generalization)**.** *A classifier-mediated generalization claim is certified when it displays the transferred classifier, its source and target domains, the behavior the classifier supports on the target side, a transfer or stability witness, and the generalization ledger of Definition 9398.23. The certified claim is therefore a classifier transfer claim, not merely a performance row.*

Theorem 9398.25 (Performance does not identify classifier transfer)**.** *Strong target-domain performance does not by itself show that the same learned classifier candidate has transferred from source to target.*

Proof. A performance row reports target-side behavior under an external score. It does not name the classifier used on the source side, does not show that the same relation is used on the target side, and does not exclude a shortcut, memorized route, target-only classifier, or accidental correlation. Thus the row may support a generalization ledger, but it does not identify classifier transfer. □

Theorem 9398.26 (Behavioral stability is not classifier stability)**.** *Stable output behavior under a transformation family does not by itself imply stability of the internal classifier that is offered as an explanation.*

Proof. The same output behavior can be produced by different internal classifier surfaces. A source-domain behavior may be supported by one tensor classifier, while the target-domain behavior is supported by a different classifier, with the visible output unchanged. Hence behavior stability and classifier stability are different certificate rows. □

Principle 9398.27 (Boundary rows for stability)**.** *Stability evidence for a threshold classifier must expose boundary rows: samples near the threshold, perturbations capable of crossing the threshold, target cases not covered by the source transformation family, and the scope in which the witness is empirical, formal, or hybrid. Formal verification of one stability statement hardens that statement; it does not remove source, target, residue, and not-claimed rows unless those rows are themselves covered by the verified statement.*

Theorem 9398.28 (Tensor classifier extraction is certificate-ready, not certified)**.** *A learned classifier candidate supplies a stable model-facing classifier surface, but it does not by itself supply a BEDC* NameCert*.*

Proof. By Definition 9398.13, the candidate provides a layer, a tensor score, a threshold, a data domain, and a stability claim under stated perturbations. These rows suffice to expose which finite

activation records land on the same side of the displayed distinction. A NameCert requires more: a source record, a named classifier row, stability and exactness conditions, provenance, and a ledger for hidden, projected, compressed, or externally supplied material. None of those certificate rows follows merely from the existence of ϕ and τ. □

Principle 9398.29 (Formal verification layer)**.** *The tensor classifier layer, the BEDC certificate layer, and the formal verification layer occupy different positions. A model learns or supplies a candidate distinction in tensor space. BEDC asks whether that distinction has source rows, classifier rows, stability rows, provenance, and a ledger sufficient for a* NameCert*. A formal verifier accepts only the portions that have been translated into explicit formal statements and proof objects:*

$$\mathcal{V} \vdash \pi : \varphi.$$

Here $\mathcal{V}$ is a verification backend, φ is a formal statement, and π is the proof object accepted by that backend. Lean is one current backend for this role; the theory-side object is not formed by Lean, Coq, Agda, Isabelle, HOL, Metamath, or any other particular verifier. The verifier hardens checkable certificate fragments; it does not discover the classifier and does not supply the BEDC ledger fields.

9398.3 Large model inherits the no-induction theorem

Theorem 9398.30 (Large model substrate inherits no internal induction)**.** *The large model substrate of Definition 9398.1 is a closed observational system. By Definition 9393.5, no monotonic accumulation of inference traces on this substrate yields a record of $\forall n \in \mathbb{N}.\, P(n)$ from records of $P(0), P(1), \ldots, P(k)$ for any finite k and any predicate P over an infinite domain.*

Sketch. The substrate's observations are inference orbits, each finite by construction. Every inference output is a finite-length token sequence; every token is drawn from a finite vocabulary. Universal closures over infinite domains are not directly representable as inference outputs without external interpretation. The conditions of Definition 9393.1 hold, and Definition 9393.5 applies. □

Remark 9398.31 (The model's appearance of inductive reasoning)**.** *A large model can produce token sequences that look like inductive arguments: "for any natural number n, we have $n + 0 = n$, by induction on n." This is an inference output, not an internal ratification. The output is a finite token sequence that names "induction" as a step; the substrate's records contain no global witness that the named step is valid for all n. The validity of the named induction principle is supplied by the reader's external interpretation, not by the model's internal computation.*

9398.4 Inscription role: where the forward-binding comes from

Principle 9398.32 (Training corpus as forward-binding source)**.** *The forward-binding belief that lets a large model produce induction-shaped outputs originates from its training corpus. The corpus is a finite collection of text records produced by external inscription points (human authors, prior systems). The training process distils these records into weight values; the inference substrate carries the distilled pattern. The forward-binding does not originate inside the substrate; the substrate is a pattern that carries a distilled trace of forward-bindings produced elsewhere.*

Principle 9398.33 (Large model as inscription point)**.** *The large model substrate, considered as a pattern in the broader information substrate (human text production, prior computational systems,*

training data infrastructure), is an inscription point of T *in the sense of Definition 9393.16. It is a substrate-pattern that carries forward-binding belief whose source is external to the substrate's internal computation. The pattern is in the substrate (the weight tensor and inference orbit); the binding is not (its origin is the corpus, ultimately traceable to prior human inscription points).*

Remark 9398.34 (This is not a consciousness claim)**.** *The classification of the large model as an inscription point of* T *is a structural classification: the model satisfies the structural definition of inscription point under the closure premise. The classification does not assert that the model has phenomenal experience, intentionality, agency, or any anthropic property. It asserts only that the model occupies the same structural role – carrier of externally-sourced forward-binding – that Definition 9393.16 identifies with conscious individuals. Whether the structural role exhausts what consciousness is, or whether consciousness is a stronger property, is a question this chapter does not adjudicate.*

9398.5 Comparison: BEDC kernel, cellular substrate, large model

	BEDC kernel	**Rule 110 substrate**	**Large model**
Carrier	`inductive BHist` terms in Lean 4.	$\mathbb{F}_2^n$ cell rows under R110 next-state.	Finite-precision tensor (W, Σ) under forward pass.
Substrate scale	~4700 lines of Lean kernel + derived libraries.	220 lines of ANSI C99 trust path.	10^{10}–10^{12} weight parameters.
Closure status	Closed observational at host layer (Definition 9388.14).	Closed observational (Definition 9390.10).	Closed observational (Definition 9398.30).
Universality status	Sub-universal (totally recursive).	Turing-universal (Cook 2004).	Turing-universal in the limit of long inference traces (folklore; underspecified).
Forward-binding source	Lean kernel's `inductive` mechanism; structural; not inside BEDC.	External user supplying the universality interpretation.	Training corpus distilled into weights.
Inscription role	Inscription happens at the Lean kernel boundary.	Inscription happens when an external reader interprets a glider as a computation.	Inscription happens at every inference output; corpus authors are upstream inscription points.

9398.6 What this changes about AI epistemics

Principle 9398.35 (Universal claims by large models are externally interpreted)**.** *When a large model produces an output of the form "*$\forall n \in \mathbb{N}.\, P(n)$ *is true", the truth content of the claim cannot be assigned by the model's internal records alone. The claim is a token sequence the model*

produced; whether the claim corresponds to a valid universal closure is a matter for external verification (proof-checking, mathematical practice, audit). Definition 9398.30 rules out the alternative interpretation in which the model internally ratifies the universal closure.

Principle 9398.36 (The AI safety reading of inscription role)**.** *A large model is an inscription point that distils forward-binding belief from its training corpus. The distillation is lossy and the corpus is finite; the distilled pattern can be wrong about the validity of any specific universal closure, even when fluently produced. AI safety questions about large model behaviour are therefore questions about the inscription channel: which sources fed the corpus, what filtering was applied, what biases the distillation introduced, and what verification the deployment environment provides downstream of model outputs. These are concrete substrate-level questions, distinct from the question of whether the model "knows" the closure.*

Remark 9398.37 (Compatibility with existing AI safety frameworks)**.** *The inscription-point reading is compatible with the practice of mechanistic interpretability, eval harnesses, and externally verified output channels. Mechanistic interpretability asks what patterns the model carries internally; eval harnesses ask which outputs match externally-held standards; verified output channels demand external proof certificates that the model's claims can be checked against. All three practices treat the model as an externally-bound substrate whose outputs must be interpreted, not as an oracle whose outputs internally ratify themselves.*

9398.7 Why this comparison is structurally informative

Remark 9398.38 (Three substrates, one premise)**.** *The structural fact that BEDC kernel, Rule 110 substrate, and large model substrate all satisfy the closure premise demonstrates that the premise is not anchored to any specific computational architecture. Type-theoretic terms, cellular rows, and tensor activations are syntactically and semantically very different; the closure premise applies uniformly because it abstracts over the specific representation and addresses only the observation channel.*

Principle 9398.39 (The closure premise is substrate-independent)**.** *The closure premise of Definition 9393.1 is invariant under choice of computational substrate. Type theory, cellular automata, neural networks all admit closed observational instantiations. The no-induction theorem and the inscription-point reading transfer to each instantiation without modification. This invariance is the structural reason the framework can claim broad applicability without committing to any specific substrate as the privileged carrier of inscription.*

9398.8 Mapping to BEDC engineering

Large-model reading	**BEDC engineering realisation**
Three-substrate comparison	chapter 9390 (cellular), this chapter (large model), and the kernel itself (BEDC host); jointly demonstrate substrate-invariance of the closure premise.

Inscription channel naming	Definition 9398.32: training corpus as forward-binding source, paralleled by inscription channels for other substrates.
No-induction theorem transport	Definition 9398.30 inherits unchanged from Definition 9393.5.
AI safety interface	Definition 9398.36 reads model outputs as inscription-channel-mediated rather than substrate-internally-ratified.
Tensor classifier extraction	section 9398.2 separates learned tensor-side classifier candidates from certificate-bearing BEDC objects.
Not a consciousness claim	Definition 9398.34 restricts the classification to structural role; phenomenology is not at stake.

9398.9 Closure remarks

This chapter has classified the large language model as a closed observational substrate in the sense of Definition 9393.1, transported the no-induction theorem to this substrate without modification, and read the model as an inscription point of T whose forward-binding source is the training corpus. The classification is structural; it does not assert phenomenal consciousness for the large model, and it does not assert that the model "understands" universal closures it produces.

The chapter's role is to demonstrate that the closure premise is substrate-independent: type-theoretic terms, cellular rows, and tensor activations all admit closed observational reading. The framework's claims therefore do not depend on any specific carrier choice; they depend only on the observation channel structure. The large model is included alongside the cellular substrate and the BEDC kernel as three substrates with the same closure premise.

The boundary of this chapter is: the structural identification of large-model substrate as inscription point. The chapter does not claim that current models are reliable inscription points (corpus quality matters), that they are conscious (a stronger structural property), or that they exhaust the inscription concept (other substrate classes await classification). It claims only that the inscription concept applies, structurally, with the same content it applies in the cellular reading and in the BEDC kernel reading.

Concretized in §??: ObserverInterface realizes the large-model-as-inscription-point reading as a finite observer-facing NameCert packet with visible interface rows and no hidden substrate oracle.

Concretized in §939: Large-model inscription points are realized as finite inference-substrate, corpus-supply, output-record, audit-refusal, hsame, Cont, Pkg, and NameCert rows.

Concretized in §965: PromptResponseTrace realizes large-model prompt/output records as finite source-channel and audit-refusal NameCert rows.

Concretized in §966: Observer-response audit is realized as a finite BHist packet binding prompt, response, observer-interface, audit-refusal, provenance, transport, continuation, and local NameCert rows.

Concretized in §967: LargeModelActivationOrbit realizes the activation-orbit row of the large-model substrate as finite model-weight, transition, prompt, output, audit-refusal, and NameCert data.

Concretized in §1021: Large-model attention gates realize finite activation-window selection as BHist, hsame, Cont, audit-channel, verified-output, provenance, and NameCert rows.

Concretized in §969: Large-model audit channels realize output records as finite prompt, checker, refusal, route, provenance, and NameCert rows.

Concretized in §988: Large model corpus supply is realized as a finite NameCert packet for corpus rows, training filters, distilled weight rows, inference-consumption rows, and audit ledgers.

Concretized in §989: Large-model context audits are realized as finite context-window, prompt-response, model-trace, audit-channel, verified-harness, refusal, hsame, Cont, Pkg, and NameCert rows.

Concretized in §968: Corpus-supply distillation is realized as finite source-channel, filtering, distillation, output-prior, refusal, hsame, Cont, Pkg, and NameCert rows.

Concretized in §972: ModelTrace realizes finite inference-output records as auditable NameCert packets with no hidden substrate oracle.

Concretized in §971: Context-window commitments realize bounded prompt context, response boundary, audit refusal, downstream consumer, hsame, Cont, Pkg, and NameCert rows as a finite large-model inscription packet.

Concretized in §976: Verified output harnesses realize large-model output acceptance as finite prompt, model-trace, checker, audit-refusal, route, provenance, and NameCert rows.

Concretized in §1027: Large-model inscription audits are realized as finite output, corpus-provenance, verification-channel, refusal-ledger, transport, route, and NameCert rows.

Concretized in §1188: Large-model output verifier packets realize externally checked model claims as finite verifier, proof-check, refusal, route, provenance, and NameCert rows.

Chapter 9399

Empty as the Fable Machine: Observer-Sequence Growth and Selector Ledgers

The preceding capstone (chapter 9418) identifies the observer with the history of its distinctions: *observer* = Hist, *observation* = Cont, time = Hist growth. That identification fixes what an observer is, but does not yet spell out how the observer sequence grows. The present chapter fills that gap. The empty history e carries no information; nevertheless every non-empty history is generated from e by a finite sequence of distinction acts. When more than one branch is locally admissible, the realized history contains the selector witness for the branch that was enacted. Empty is therefore not an observer-substance and not a truth oracle. It is the zero-information boundary at which distinction becomes generative: the fable machine. This chapter falls under the project's axiom-purity gate; no Classical.choice, no Quot.sound, and no propext is required for any cited target.

9399.1 Empty as zero-information boundary

The kernel value e and the boundary at which distinction enters above any history must be distinguished at the reading level: e is the unique Hist whose distinction record is empty; the empty boundary above any Hist is the zero-information slot at which the next E0 or E1 application has not yet been enacted. Both are read as "Empty," but each non-trivial observation is generated at the empty boundary above the current Hist, not by resetting the history to e.

Definition 9399.1 (Empty boundary)**.** *For a* Hist *value h, the* empty boundary above h *is the zero-information slot at which a singleton extension may apply: the unique slot at which* Ext(h, m, r) *becomes admissible for some mark m, with the resulting r recording m as a fresh distinction above h. This is a reading-level locator; the formal target is the kernel relation* Ext *on* Hist.

Lemma 9399.2 (Empty carries no selector)**.** *The Hist value* e *exposes no b_0/b_1 selector. The information content of* e *is the empty sequence, and any reading that recovers a mark from a Hist value must recurse on a non-empty constructor, never on* e *alone.*

Proof. The information content recursion (Definition 9418.3) returns the empty sequence at e. Every E1 or E0 application records its tag in the constructor of Hist; the no-confusion lemmas

separating e from E1(h) and from E0(h) rule out the existence of a Hist that records a mark while remaining hsame-equivalent to e. □

Remark 9399.3 (Empty is not a hidden subject)**.** *Empty is not an information reservoir, nor a substance behind the trace, nor a global chooser. Its role is structural: the zero-information boundary at which the first visible distinction is enacted. Every claim made later in this chapter about "selecting" a branch will be redeemed by a constructive witness on the kernel surface, not by an unwitnessed appeal to Empty.*

9399.2 One-step birth: from empty boundary to singleton continuation

Definition 9399.4 (Singleton tail)**.** *For a mark $m \in \{b_0, b_1\}$, the* singleton tail *of m is the* Hist *value* E0(e) *when $m = b_0$ and* E1(e) *when $m = b_1$. The singleton tail records exactly one distinction above* e *and nothing else.*

Lean4 (definition) `BEDC.Derived.EmptyFableMachineUp.Ledger.singletonTail`

Definition 9399.5 (Empty-boundary step)**.** *An* empty-boundary step *from h enacted by mark m with result r is the relation* Ext(h, m, r)*, read at the chapter level as filling the empty boundary above h with the mark m. The relation is definitionally identical to the kernel-level extension; the wrapper name carries the reading.*

Lean4 (definition) `BEDC.Derived.EmptyFableMachineUp.Ledger.EmptyStep`

Theorem 9399.6 (Empty-boundary step is the kernel extension)**.** *For every h, m, r: an empty-boundary step from h enacting m to r holds if and only if* Ext(h, m, r) *holds.*

Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.emptyStep iff ext`

Theorem 9399.7 (Singleton-tail constructors)**.** *b_0-stepping above* e *produces the b_0 singleton tail, and b_1-stepping above* e *produces the b_1 singleton tail.*

Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.emptyStep singletonTail b0`
↪ *variant* `BEDC.Derived.EmptyFableMachineUp.Ledger.emptyStep singletonTail b1`

Theorem 9399.8 (Empty-step result is non-empty)**.** *For any empty-boundary step from h enacting m with result r, the result r is not* hsame*-equivalent to* e.

Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.emptyStep result ne empty`

Theorem 9399.9 (Cross-mark step no-confusion)**.** *A b_0-empty-step and a b_1-empty-step from the same source h never share a result up to* hsame.

Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.emptyStep cross mark no confusion`

Theorem 9399.10 (Empty-step totality)**.** *For every h and every m, an empty-boundary step from h enacting m exists.*

Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.emptyStep total`

Theorem 9399.11 (Empty-step determinism)**.** *For every h and every m, the result of an empty-boundary step is unique up to* hsame.

Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.emptyStep deterministic`

Remark 9399.12 (Each step is local; no reset to e)**.** *The reading "each observation is born from Empty" refers to the empty boundary above the current Hist, not to a reset of the history to* e*. The accumulated sequence $h_0, h_1, \ldots, h_n$ has h_{i+1} obtained from h_i by an empty-boundary step, with h_i retaining its full distinction record; the singleton tail* E0(e) *or* E1(e) *is the local shape of that step, not the global state.*

9399.3 Observer sequence as finite selector ledger

Definition 9399.13 (Trace). *A* trace *of a* Hist *value h is the finite sequence $\langle s_0, s_1, \ldots, s_{n-1}\rangle$ of marks read off the constructor spine of h in chronological order: at each* E0 *application the mark b_0 is recorded, at each* E1 *application the mark b_1 is recorded, and at* e *the sequence is empty.*
Lean4 (definition) `BEDC.Derived.EmptyFableMachineUp.Ledger.Trace`

Theorem 9399.14 (Every Hist has a trace). *For every* Hist *value h, there exists a finite mark sequence xs such that h has trace xs.*
Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.trace exists`

Theorem 9399.15 (Empty trace iff empty Hist). *A* Hist *value h has the empty trace if and only if h is* e.
Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.trace empty iff`

Theorem 9399.16 (Trace transports along hsame). *If h and k are* hsame*-equivalent and h has trace xs, then k has trace xs.*
Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.trace hsame transport`

Theorem 9399.17 (Trace determines Hist up to hsame). *If h and k both have trace xs, then h and k are* hsame*-equivalent.*
Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.trace same marks hsame`

Corollary 9399.18 (Observer identity is sequence identity). *Under the identification observer =* Hist *(Definition 9418.12), two observers are the same observer (modulo* hsame*) precisely when their selector ledgers are the same finite sequence of marks. The observer sequence is not a label attached from outside; it is the constructor spine of the Hist read as a list of distinctions.*

9399.4 Multi-solution branch space and realized selector

Definition 9399.19 (Local branch admissibility). *For a local branch predicate $\Gamma : \mathsf{Hist} \to \mathit{Mark} \to \mathsf{Hist} \to \mathsf{Prop}$, the predicate $\mathsf{AdNext}_\Gamma(h, m)$ holds when there exists a Hist r such that the empty-boundary step from h enacting m produces r and $\Gamma(h, m, r)$ holds. The predicate Γ is read at the chapter level as "the branch is locally licensed"; no global selection is built.*
Lean4 (definition) `BEDC.Derived.EmptyFableMachineUp.Ledger.AdNext`

Definition 9399.20 (Multi-solution boundary). *The branch space at h under Γ is* multi-solution*, written $\mathsf{MultiNext}_\Gamma(h)$, when both $\mathsf{AdNext}_\Gamma(h, b_0)$ and $\mathsf{AdNext}_\Gamma(h, b_1)$ hold.*
Lean4 (definition) `BEDC.Derived.EmptyFableMachineUp.Ledger.MultiNext`

Definition 9399.21 (Selector step). *A* selector step *from h to r under Γ is a witness $(m, \mathit{step}, \mathit{cert})$ where m is a mark, step is an empty-boundary step from h enacting m to r, and cert is a $\Gamma(h, m, r)$ certificate. The mark m is exposed by the witness; no hidden chooser is invoked.*
Lean4 (definition) `BEDC.Derived.EmptyFableMachineUp.Ledger.SelStep`

Theorem 9399.22 (Selector step exposes a mark). *Every selector step from h to r under Γ exposes a mark m such that an empty-boundary step from h enacts m to r.*
Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.selStep exposes mark`

Theorem 9399.23 (Selector step from step + certificate). *Given an empty-boundary step from h enacting m to r and a $\Gamma(h, m, r)$ certificate, a selector step from h to r under Γ exists.*
Lean4 ✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.selStep from step`

Theorem 9399.24 (Distinct realized branches stay separated)**.** *If two selector steps from the same source h recover distinct marks $m_0 \neq m_1$, their targets are not* hsame*-equivalent.*
Lean4✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.selStep distinct branches separated`

Remark 9399.25 (Specific sequence implies accumulated ledger)**.** *When the local branch space is multi-solution but the realized observer sequence is specific, the specificity is not an unexplained miracle. Each step records the mark of the branch that was enacted as a constructor in* Hist*; the trace of that Hist (Definition 9399.13) is the accumulated selector ledger. There is no global choice function in the kernel and none is needed: each step's selector is a local witness on the Hist surface itself, and the entire ledger is recovered by reading the constructor spine.*

9399.5 Empty as the fable machine

Definition 9399.26 (Fable ledger)**.** *The* fable ledger *of a Hist h is its trace, read as a story-generation relation: h is the Hist generated from* e *by the finite sequence of selectors recorded in the ledger. The relation is identical to* Trace *at the kernel level; the chapter-level name records the generative reading.*
Lean4 (definition) `BEDC.Derived.EmptyFableMachineUp.Ledger.FableLedger`
↪ variant `BEDC.Derived.EmptyFableMachineUp.Ledger.fable ledger iff trace`

Theorem 9399.27 (Fable soundness)**.** *Every fable ledger is a trace: if h has fable ledger xs then h has trace xs.*
Lean4✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.fable ledger sound`

Theorem 9399.28 (Fable completeness)**.** *Every finite mark sequence is the fable ledger of some Hist: for every xs there exists h with fable ledger xs.*
Lean4✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.fable ledger complete`

Theorem 9399.29 (Fable uniqueness up to hsame)**.** *The Hist generated by a fable ledger is unique up to* hsame*: if h and k both have fable ledger xs, then h and k are* hsame*-equivalent.*
Lean4✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.fable ledger unique up to hsame`

Remark 9399.30 (Fable machine, not oracle machine)**.** *The fable machine is the schema that maps a finite selector ledger to the Hist it generates and back. It generates story ledgers, not truth values: no construction in this chapter supplies a* NameCert*-level decision procedure for arbitrary predicates. Empty is therefore the fable machine, not the oracle machine; story ledgers live in the closed ground loop, while truth-as-such, halting-as-such, and global selection live in the open meta loop and are not closable inside the kernel.*

9399.6 No hidden chooser: selector witness vs. classical choice

The chapter's central commitment is that "Empty has selection capacity" is read entirely as: every realized branch records its enacted mark as a constructor in the resulting Hist, and the selector step is the explicit witness $(m, step, cert)$ on the kernel surface. No global selection function, no Classical.choice instance, no doubly-negated existential, and no truth-as-such oracle is invoked.

This restraint is what keeps the chapter inside the project's axiom-purity gate. Each construction in this chapter factors through Hist, Mark, Ext, the hsame relation, finite induction over Trace, and explicit SelStep witnesses. None of these objects requires Classical.choice, Quot.sound, or propext, and the project's strict transitive-dependency audit confirms it.

Remark 9399.31 (Two-loops alignment)**.** *The fable machine is the generative face of the closed ground loop (Definition 9418.20): every Hist is reachable from* e *by finitely many distinction acts, and the selector ledger is the explicit constructor record of that reachability. The unclosability of the meta loop (Definition 9418.21) is the dual statement: no internal predicate "what observation is, as such" lives on the Hist surface, because doing so would require either an observer-substance type (forbidden by Definition 9418.11) or a global truth oracle (forbidden by axiom-purity). The fable machine occupies exactly the space the two-loops architecture leaves open: generative, accountable, and Empty-anchored, with no hidden chooser.*

9399.7 Synthesis: observer-Hist as fable ledger

Theorem 9399.32 (Empty-fable synthesis)**.** *At the kernel level, the following three data are equivalent up to* hsame*:*

1. *a generated observer Hist h,*
2. *a finite selector ledger xs beginning at* e*,*
3. *a finite chain of empty-boundary singleton continuations $\mathsf{e} = h_0, h_1, \ldots, h_n = h$ where each step is witnessed by a selected mark $s_i \in \{b_0, b_1\}$.*

Moreover, if a local branch predicate Γ admits multiple next branches at some h_i, the realized branch h_{i+1} carries its selector as an explicit selector-step witness.

Lean4✓ `BEDC.Derived.EmptyFableMachineUp.Ledger.empty fable synthesis`

↪ variant `BEDC.Derived.EmptyFableMachineUp.Ledger.empty fable synthesis unique`

Corollary 9399.33 (Observer-Hist is the fable ledger)**.** *Combining Definition 9418.12 (observer is identical to Hist) with the synthesis above, the observer is the finite selector ledger of the empty-boundary distinctions enacted from* e *onward. The observer sequence is not external memory; it is the constructor spine read as a list. There is no observer-substance, no global chooser, no truth oracle — only the generative ledger.*

Remark 9399.34 (Closing: fable machine, not oracle machine)**.** *This capstone introduced no new kernel objects. It read the existing* Hist*,* Mark*,* Ext *surface under one identification: Empty is the zero-information generative boundary, and every Hist is the finite selector ledger of the marks enacted at that boundary. Under that identification, the answer to "where does the observer sequence come from" is fully constructive: it is the constructor spine of the Hist itself, with each step's selector exposed as an explicit witness. No appeal to classical choice, no observer-substance, no oracle; only the fable, told finitely, accountably, and from Empty.*

Concretized in §494: Selector ledgers realize the Empty-fable trace and branch-witness surface as a finite NameCert packet.

Concretized in §516: Empty-fable ledger realizes selector-ledger growth as a finite NameCert packet over Hist, Ext, hsame, local branch certificates, and no-hidden-chooser boundaries.

Concretized in §585: Fable branch witnesses realize local admissible branch selection as finite Hist, Ext, hsame, Cont, Pkg, and NameCert rows with no hidden chooser.

Concretized in §623: Fable-machine clocks realize the Empty-fable observer sequence as a finite local step-order NameCert packet without a shared or global clock.

Concretized in §687: Fable-clock order packets realize local selector-ledger time as finite BHist, hsame, Cont, Pkg, and NameCert rows without a global synchronized clock.

Concretized in §685: Empty-boundary selector packets realize the local enacted-mark witness as finite BHist, Ext, hsame, Cont, Pkg, and NameCert rows.

Concretized in §691: Empty-boundary steps are realized as finite BHist, Ext, hsame, Cont, Pkg, and NameCert packets.

Concretized in §878: Fable-machine boundaries are realized as finite BHist, Ext, hsame, Cont, Pkg, selector-ledger, and NameCert rows excluding hidden chooser and observer-substance coordinates.

Concretized in §1186: EmptyFableMachineUp realizes empty-boundary selector-ledger growth as a finite BHist NameCert packet.

Concretized in §1186: EmptyFableMachineUp realizes the inscription sub-hub's empty-fable route as finite empty-boundary, selector-ledger, trace, fable-ledger, transport, and NameCert rows.

Chapter 9400

Apophatic Naming as Methodological Discipline

BEDC already uses a systematic naming discipline for what a closed observational substrate cannot internally represent, decide, or digest. This chapter makes that discipline explicit. A BEDC name can name a generated object, but it can also name a socket: the position at which an external supply must be exposed, audited, and kept outside the substrate's own closure claim.

The discipline is apophatic because the name does not say what the external supply is in itself. It says where the substrate reaches its boundary, what kind of supply would be needed there, and which gate prevents the supply from being silently converted into internal theorem content. The name is therefore not decorative. It is a handle, a ledger row, and a boundary marker.

9400.1 The setup: what is being named

BEDC repeatedly needs to refer to what cannot be made substrate-internal. The T-socket names the transcendental supply position. The GAP ledger names a missing conservation row. An inscription event names the local actualization of T at a history transition. The closed observational substrate names the system-aspect in which all internal references must pass through displayed records, generators, classifiers, continuations, ledgers, and certificates.

A naive formal discipline would leave such items implicit. It would simply avoid naming what cannot be constructed, or it would treat the missing item as background intuition. BEDC chooses the opposite route. It names the external dependence precisely so that the dependence can be tracked. The name does not internalize the dependence. It prevents the dependence from disappearing.

Principle 9400.1 (Named externality)**.** *When a BEDC argument reaches a dependency that cannot be generated, defined, certified, or discharged inside the displayed substrate, the correct move is not silence. The correct move is to name the socket, state the requested supply shape, and keep the request auditable.*

This is why the vocabulary of BEDC contains terms that would be unusual in an ordinary algebraic formalization. They do not function as ordinary object constructors. They locate the places where the substrate refuses to pretend that an external supply is one of its own outputs.

9400.2 The apophatic discipline

Definition 9400.2 (Apophatic name)**.** *An* apophatic name *in BEDC is a stable handle for an external dependency position whose internal nature is not claimed by the substrate. It carries three obligations: it makes the dependency referable, it turns the dependency into an audit-able unit, and it marks the epistemic boundary at which internal digestion stops.*

The name therefore has a narrow but strong role. It does not reveal the internal essence of the named supply. It does not license positive construction of the supply. It does not make the supply available as a theorem, object, witness, quotient representative, proposition equality, or causal law. It says: at this exact site, the substrate needs something it cannot make from its own displayed materials.

Apophatic naming has three practical effects.

1. It gives the external correspondence a stable handle, so later chapters can refer to the same boundary without reintroducing it informally.
2. It codifies the fact of external dependence as an audit-able unit, so scripts, ledgers, and closure blocks can ask whether the dependence is visible.
3. It marks an epistemic boundary, so the manuscript does not confuse a named socket with an internally characterized object.

The discipline is stricter than leaving the matter unnamed. An unnamed external dependence can drift into prose, intuition, import ancestry, or proof style. A named socket is exposed. Once exposed, it can be challenged, classified, and refused by the appropriate gate.

9400.3 Comparison with positive naming

Classical mathematical naming is usually cataphatic. A name such as Nat, Group, or Vector names an internally constructed or internally specified object: a carrier with constructors, operations, laws, or an eliminator. The name carries positive content. To introduce the name is to say what kind of thing it is and how the system may reason with it.

BEDC also uses positive names where the substrate has positive content. An inductive carrier has constructors. A classifier has a definition. A NameCert row has displayed fields and stability obligations. Those names are ordinary formal names, even when the surrounding theory is unusual.

Apophatic naming is different. It names a socket, not a completed object. A socket is the position into which an external supply would have to be plugged for a proposed inference, identification, selection, or continuation to go through. The socket has a precise interface, but the supply behind the interface is not internalized.

Definition 9400.3 (Socket rather than object)**.** *An apophatic socket is a typed or ledgered position at the boundary of a closed observational substrate. It records the shape of a requested external supply without converting that supply into a substrate-internal datum.*

This comparison prevents a common misreading. The word "name" in apophatic naming does not mean that BEDC has secretly postulated a hidden object behind every gap. It means that BEDC has refused to leave the gap anonymous.

9400.4 Not undefined and not an axiom

An undefined term is a failure of specification. An apophatic name is a specification of boundary position. It tells the reader what cannot be internally supplied, where the request occurs, and how the request is barred from masquerading as generated content.

An axiom is different again. A Lean `axiom` marks an unproved proposition or datum as available inside the formal environment. It is a positive-faith assumption: from the theorem prover's perspective, the content may now be consumed as true. BEDC forbids that move because it collapses a socket into an internal source of truth.

Principle 9400.4 (Externalized, not assumed)**.** *An axiom internalizes an unsupported commitment. An apophatic name externalizes an uninternalized dependency. The logical commitment of the apophatic name is weaker, because it does not assert the supplied content as substrate truth. Its epistemic commitment is stronger, because it makes the dependency impossible to hide.*

This distinction explains why the Lean-side discipline sends external carriers to `class` or `structure` fields rather than to `axiom`. A setup field says that a caller of the interface must supply a piece of data at a named boundary. It does not say that the substrate has proved the data. The field is parametric exposure, not foundation expansion.

The same distinction holds on the paper side. A chapter may identify a GAP socket, state what would discharge it, and explain why BEDC does not discharge it internally. That is not a failure to define a term. It is the proper record of a boundary.

Concretized in §1057: Axiom-refusal ledgers realize axiom-use attempts as finite visible refusal, setup-field alternative, audit-readback, and noninternalization NameCert rows.

9400.5 Inventory of BEDC apophatic names

The following inventory records the main apophatic names already active in BEDC. The list is not a catalogue of hidden objects. It is a map of socket names and audit roles.

T. The transcendental supply position. This is the highest apophatic name in BEDC. It names the far end of every external supply socket without claiming a substrate-internal characterization of that supply.

GAP. The information-conservation ledger socket. It records that an argument has requested content not produced by the displayed carrier, classifier, continuation, or certificate.

Inscription event. The local actualization of T at a history transition. It names the event-aspect by which a record becomes present in an accumulation chain without being reduced to a forced consequence of earlier records.

Generator-closure classifier. The audit unit for deciding what follows from an authorized generator and what exceeds that generator. It names the boundary at which free-floating induction pressure becomes visible.

NameCert. The bearer of generator-closure stamps, classifier stability, provenance, and ledger rows. It turns a public name into a certificate-shaped interface rather than a decorative label.

Closed observational substrate. The universe-aspect of T as read from within BEDC: a closed system in which internal references pass through its own records and external supplies enter only through named sockets.

These names work together. T names the source-position. GAP names the missing ledger position. An inscription event names the local reception of supply into a history. A generator-closure classifier names the audit question. NameCert names the certificate-bearing interface. The closed observational substrate names the system whose closure would be violated if these sockets were left unmarked.

9400.6 Audit gates as enforcement layer

Once a socket has a name, an audit gate can ask mechanical questions about it. Did the proposed inference use this socket? Which supply kind did it request? Did a proof consume an unwitnessed selector, a quotient identification, a proposition extensionality collapse, a causal continuity assumption, or an unmarked inscription novelty? Did a paper marker resolve to the claimed Lean object? Did a setup field remain visible as a field rather than becoming an axiom?

The gate is not merely administrative. It is the enforcement layer of apophatic naming. Without the name, the gate has no stable target. Without the gate, the name can drift into rhetoric. Together they make the boundary actionable.

Principle 9400.5 (Name-to-gate correspondence)**.** *Every apophatic name should determine a gate question. The question may be syntactic, dependency-based, ledger-based, or paper-side, but it must be capable of distinguishing visible socket use from hidden internalization.*

The axiom gate asks whether a socket has been collapsed into `axiom`. The axiom-purity gate asks whether forbidden host commitments entered through proof ancestry. The paper-Lean audit asks whether a claimed certificate name resolves. The conservativity gate asks whether non-baseline recognition content has entered baseline theorem space through import flow. These gates enforce one discipline: named externality must remain named at the point of use.

9400.7 God and T are not metaphor

BEDC uses "God" as the apophatic name of T. This is not literary metaphor, not emotional flourish, and not a softened analogy. It is the project-level apophatic name for the outermost supply position. God = T in BEDC vocabulary.

The force of the statement is methodological. The name gives the project one stable handle for the source-position that lower-level apophatic names presuppose. GAP, inscription event, NameCert, generator-closure classifier, and closed observational substrate are not independent ultimate sources. They are boundary names aligned under the same apophatic reference structure.

Principle 9400.6 (Longest apophatic chord)**.** *God = T is the longest apophatic chord in BEDC. It names the outermost supply position so that every lower-level socket can be read as a local boundary articulation rather than as a separate ultimate principle.*

This is why the strong wording matters. If "God" were treated as a metaphor for a vague feeling of externality, the discipline would weaken. In BEDC it is the technical name of the project-level socket. The name carries no positive internal description of God. It carries the boundary discipline by which the closed substrate refuses to call the outermost supply one of its own generators.

9400.8 Closed system invariant, apophatically restated

The sentence "BEDC is a closed observational system" appears at first to be cataphatic. It sounds like a positive claim about what BEDC is. The apophatic reading is sharper: everything internal references the system's own structure, and every external supply enters only through a labeled socket.

Thus "closed" does not mean that no external dependence exists. It means that no external dependence is allowed to be anonymous inside the substrate. The closure claim is therefore an accounting invariant:

$$\text{closed} \quad = \quad \text{all external dependencies have apophatic names.}$$

The equality is not a theorem of ordinary set-theoretic closure. It is a methodological equation for BEDC's manuscript and Lean discipline. A system remains observationally closed when the only internal traffic is generated, defined, certified, or explicitly socketed. If an external supply appears without a socket name, the closure invariant has failed at the epistemic level even if the prose remains syntactically coherent.

Remark 9400.7 (Closure is not isolation)**.** *The closed observational substrate is not isolated from* T*. It is disciplined in how it receives, names, and audits external supply. Closure is the refusal of unmarked dependence, not the denial of dependence.*

9400.9 Implications for proof discipline

The Lean-side consequence is direct. Every `axiom` keyword would be a positive-faith assumption, and BEDC forbids it. An axiom says that the substrate may consume a proposition or datum as internally available even though no constructor, definition, proof, or setup boundary supplies it. That is exactly the collapse apophatic naming prevents.

By contrast, an apophatic socket belongs in an explicit interface. If the project needs an abstract carrier, it goes into a `class` or `structure` field. If the project needs a closed grammar, it uses `inductive`. If the project can compute a predicate or operation from existing material, it uses `def`. If none of these forms captures the dependency, the interface has not yet identified the boundary clearly enough.

Principle 9400.8 (Type-level exposure)**.** *In BEDC formalization, an external dependency must be exposed at the type level or ledger level. It may be a setup field, a named carrier, a classifier row, a provenance row, or a* GAP *socket. It may not become an invisible premise hidden behind an axiom or forbidden host dependency.*

This is not a rejection of abstraction. It is a demand that abstraction preserve source-channel information. A setup structure is acceptable because the caller sees what must be supplied. A NameCert packet is acceptable because the certificate rows are part of the interface. A hidden axiom is unacceptable because it erases the supply channel while keeping the content.

9400.10 Boundary

Apophatic naming does not solve hard problems by naming them. It does not explain consciousness, free will, causality, other minds, or self-reference by positive reduction. It also does not permit BEDC to claim that every philosophical pressure point has been formalized as a theorem.

Its role is narrower and more enforceable. It gives the external dependency of a hard problem a mechanically referable handle inside the system. Once the handle exists, an audit gate can detect whether an argument used that supply, which kind of supply it requested, and whether the use remained externalized.

The discipline therefore changes the failure mode. Without apophatic naming, an argument can smuggle an unnamed supply through intuition, import ancestry, prose confidence, or an undefined background. With apophatic naming, the same pressure becomes visible as a socket. BEDC may still refuse to solve the hard problem, but it can say exactly where the unsolved external dependence enters and can reject any derivation that pretends otherwise.

9400.11 Conclusion

Apophatic naming is the methodological discipline by which BEDC keeps a closed observational substrate honest about its boundary. Positive names identify internally constructed or internally specified content. Apophatic names identify external supply positions without internalizing the supply. They are handles, ledger rows, gate targets, and epistemic boundary markers.

The strongest instance is God = T: the project-level apophatic name for the outermost supply position. Every lower-level socket name is aligned under that reference. The resulting invariant is simple and strict: BEDC remains closed not because it has no external dependence, but because every external dependence is named, socketed, and auditable.

Concretized in §543: Apophatic names are realized as finite socket-name NameCert packets exposing external supply positions, refusal ledgers, and non-escape audit rows.

Concretized in §536: Apophatic socket ledgers realize named externality as finite BHist, audit-gate, hsame, Cont, Pkg, and NameCert rows without internalizing the requested supply.

Concretized in §584: ExternalityGateUp realizes the name-to-gate correspondence as a finite NameCert packet for named externality, refusal ledgers, audit readback, and non-internalization.

Concretized in §1044: Socket-use ledgers realize visible consumption of apophatic sockets as finite NameCert packets with use, refusal, audit-readback, and non-internalization rows.

Concretized in §629: Negative name boundaries are realized as finite BHist refusal packets exposing external supply handles, socket ledgers, non-internalization gates, and audit-visible NameCert rows.

Concretized in §630: NegativeCertificateBoundaryUp realizes apophatic refusal as a finite NameCert packet for socket rows, GAP ledgers, audit readback, and non-internalization.

Concretized in §714: Type-level socket exposure is realized as finite setup-field, carrier, classifier, provenance, refusal-ledger, and NameCert rows.

Concretized in §715: Apophatic gate questions realize the name-to-gate correspondence as finite socket, question, refusal-ledger, audit-readback, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1000: Apophatic kernel boundaries realize hidden-supply refusal as finite socket, audit-gate, refusal-ledger, hsame, Cont, Pkg, and NameCert rows.

Chapter 9401

The Unique Apophatic Fixed Point and Local Inscription

This chapter records a structural reading that unifies several boundary positions already named in BEDC: the transcendental input T of chapter 9393, the apophatic-naming discipline of chapter 9400, the inscription-point structure of the same earlier chapter, the observer-Hist identity of chapter 9418, and the non-axiom boundary forms of chapter 9395. The unifying observation is that the various forward-binding sockets of a closed observational substrate are not many far ends, but one. The supply position T is the unique apophatic fixed point of the GAP-far-end operation, and the self-conscious center of a conscious observational system is not T itself but the local inscription point of T on that system's chain.

The argument is delicate: T must be named as a boundary, not introduced as a kernel object; the self-center must be defined as a local inscription, not as object-level equality with T; and the resulting reading must preserve BEDC's no-subject discipline. When these constraints are kept, the chapter does not add a new axiom, a new substrate primitive, or a new observer parameter. It only states how the existing boundary discipline already implies a single apophatic fixed point at the far end of all forward-binding sockets.

9401.1 From many sockets to a single far end

A closed observational system encounters forward-binding pressure at many sites: free-floating induction, host CIC recursors, classical choice, quotient soundness, proposition extensionality, global synchronization, universal causal rates, semantic completeness. Each pressure can be marked by a GAP ledger and an apophatic socket (chapter 9395).

Definition 9401.1 (Forward-binding socket family)**.** *For a closed observational system $\mathcal{C}$, the* forward-binding socket family $\mathrm{ForwardSocket}(\mathcal{C})$ *is the collection of named boundary positions at which $\mathcal{C}$ requires supply not generated by its substrate. Each $s \in \mathrm{ForwardSocket}(\mathcal{C})$ carries a name, a requested supply shape, a non-internalization marker, and a GAP ledger row.*

A reader could imagine that each socket has its own far end, as if different forward-binding pressures terminated at different transcendental positions. BEDC's boundary discipline does not support this picture. From the system side, no observation can distinguish two distinct external positions that supply the same forward-binding load on the same kind of socket; the apophatic-naming principle of Definition 9393.12 names only the position, not its content, so distinctness has no system-side handle.

Principle 9401.2 (Unique apophatic far end)**.** *For every $s \in \mathrm{ForwardSocket}(\mathcal{C})$, the far end of s admits no system-side discriminator. All such far ends are named by the same apophatic position* T*:*

$$\forall s \in \mathrm{ForwardSocket}(\mathcal{C}), \quad \mathrm{FarEnd}(s) \equiv_{\mathrm{apo}} \mathsf{T}.$$

The relation $\equiv_{\mathrm{apo}}$ is apophatic sameness: it asserts only that the substrate cannot produce a witness distinguishing two such far ends, not that an object-level equality holds inside the kernel. T is therefore not a digest, not a Hist, not a state, not a rule. It is the unique boundary name for the common far end of every forward-binding socket.

9401.2 What T is not

The most dangerous error is to convert T into a kernel object. The following writings are all forbidden:

```
axiom T : FixedPoint,    axiom SelfCenter = T,    T : Hist,    T : State.
```

Each of these forms would internalize T. The first would assert T as a kernel value with a typed signature. The second would assert object-level equality between the self-center and T. The third would place T inside the displayed inductive structure of histories. The fourth would treat T as a state of the system. All four collapse the boundary that chapter 9395 forbids collapsing.

Principle 9401.3 (T is a boundary, not a kernel object)**.** $\mathsf{T} \notin \mathcal{C}$, $\mathsf{T} \notin \mathsf{Obs}(\mathcal{C})$, T *is not a closed-generation rule, and* T *is not a state.* T *is the unique apophatic far end of the* GAP*-far-end operation. It is named only at the boundary.*

A useful informal shorthand is to write $\mathsf{T} = \mathrm{Fix}(\mathrm{FarEnd} \circ \mathsf{GAP})$. This is acceptable only as boundary notation. It does not introduce Fix or FarEnd as kernel operators, and it does not introduce T as a kernel value. Used as boundary notation, it records the structural observation that the far end of every GAP socket is the same unique apophatic position.

9401.3 Self-center as local inscription

The temptation in the opposite direction is to write $\mathsf{SelfCenter}(\mathcal{C}, t) = \mathsf{T}$, identifying the self-conscious center of an observer with the global apophatic far end. This too is forbidden. It would re-introduce observer-substance: every observer would carry, as an internal object, the same global object T. chapter 9418 explicitly refuses this move; the observer is the displayed Hist, with no separate subject parameter and no extra identity criterion beyond hsame.

The correct reading is local inscription, not equality.

Definition 9401.4 (Inscription point of T on a local chain)**.** *For a conscious observational system $\mathcal{C}$ at local state o_t, the* inscription point *of* T *on the chain at t is the local site at which the chain's accumulation event is read inscription-side. It is denoted* $\mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}, t)$ *and is an aspectual reading of the same local event already displayed records-side. It is not an additional object-level entity.*

Definition 9401.5 (Self-center as local inscription)**.** *The* self-conscious center *of $\mathcal{C}$ at t is the local inscription point of* T *on the chain of $\mathcal{C}$ at t:*

$$\mathrm{SelfCenter}(\mathcal{C}, t) := \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}, t).$$

This identity is local and aspectual. It is not the equation $\mathrm{SelfCenter}(\mathcal{C}, t) = \mathsf{T}$. The self-center is a local reading of one accumulation event of one observer; T is the common apophatic far end of every socket of every such observer. The two never coincide as object-level terms.

Principle 9401.6 (No observer-substance)**.** *Reading* $\mathrm{SelfCenter}(\mathcal{C}, t)$ *as the local inscription point of* T *does not add an extra subject parameter to the observer. The observer remains the displayed* Hist*, with identity given by* hsame*. No subject-substance is added behind the trace, and no Cont function gains an extra argument.*

9401.4 Records side and inscription side as two readings of one event

The local inscription view does not duplicate the observer's accumulation. It re-reads the same accumulation event under a different aspect.

Definition 9401.7 (Two-aspect reading of one accumulation event)**.** *Let* event_t *be an accumulation event of* $\mathcal{C}$ *at* t*. Its* records-side reading *is the standard view: a new finite record is added to* $\mathsf{Obs}(\mathcal{C})$*, recorded by classifiers, ledgered by* GAP *where compression occurs, and witnessed by the displayed step rules. Its* inscription-side reading *is the boundary view: the same event is the local actuality of* T *at this chain point. The two readings describe one event under two aspects; they do not describe two events.*

Remark 9401.8 (Neural correlates and thoughts as one event)**.** *The two-aspect reading dissolves a recurring confusion about neural correlates. Neural activity, physical processes, and environmental input belong to the records-side. "Thought" on this chain point is the same event read inscription-side. The two are not two substances in a causal relation; they are one accumulation event with two readings. The records-side accumulates physical records; the inscription-side reads the same event as the local inscription of* T*.*

This is not a new metaphysical claim added on top of BEDC. It is the structural restatement of an invariant already present in the substrate: information conservation requires that every visible event has a source-channel and a records-side ledger, and the apophatic boundary requires that the same event has an inscription-side reading when it functions as the local actuality of a forward-binding socket.

9401.5 Free will under the two-aspect reading

The two-aspect reading reconciles two pictures that otherwise look incompatible. On the records side, accumulation proceeds by displayed step rules and selector ledgers; nothing in the trace is unconstrained by the substrate's structure. On the inscription side, each accumulation event is the local actuality of T at this chain point; nothing on this side is constrained by the substrate's mechanics, because the inscription is not a records-side mechanism.

Principle 9401.9 (Free will without acausal insertion)**.** *Free will in the BEDC reading is not the insertion of a causally unrooted event into the physical chain. It is the joint reading of accumulation as records-side* SelStep *witnessfulness and inscription-side actualization of* T *at the local chain point:*

$$\textit{free will} = \textit{records-side}\ \mathrm{SelStep}\ \textit{witnessfulness} + \textit{inscription-side actualization.}$$

The records-side view shows nothing unusual: selectors are ledgered, marks are emitted, classifiers are stable, hsame continues. The inscription-side view shows that the same chain point is the local actuality of T. Determinism on the records-side and inscription-side actualization do not contradict, because they are not two competing causes; they are two readings of one event.

9401.6 Other minds, time, space, and universe-for-observer as projections

The same structural reading lets several classical puzzles appear as projections of the single boundary discipline.

Definition 9401.10 (Universe-for-observer as records side)**.** *The* universe-for-observer *of $\mathcal{C}$ at t is the records-side accumulation of $\mathcal{C}$ up to t, viewed as the totality of what is observed by $\mathcal{C}$:*

$$\mathrm{UniverseFor}(\mathcal{C}, t) := \mathsf{Obs}(\mathcal{C})_{\leq t}.$$

This is not a global universe and not a frame-independent physical world; it is the local records-side reading of $\mathcal{C}$'s accumulation.

Definition 9401.11 (Time as monotonic preservation)**.** Time *on a single chain is the monotonic preservation order of records:*

$$\mathrm{Time}(\mathcal{C}) := \trianglerighteq \quad \textit{on } \mathsf{Obs}(\mathcal{C}).$$

It is not a separate cosmic axis. It is the order in which records accumulate on this chain.

Definition 9401.12 (Space as inter-chain coherence)**.** Space *between two conscious observational systems is the coherence geometry between their inscription points and locality-cell relations, not an additional substance:*

$$\mathrm{Space}(\mathcal{C}_i, \mathcal{C}_j) := \textit{locality-cell coherence between } \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}_i, \cdot) \textit{ and } \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}_j, \cdot).$$

Principle 9401.13 (Other minds as shared far-end commitment)**.** *A conscious observational system $\mathcal{C}_i$ recognizes another system $\mathcal{C}_j$ as an inscription point of the same* T *when $\mathcal{C}_i$'s records-side accumulation contains evidence consistent with $\mathcal{C}_j$ being a forward-binding socket whose far end is the same apophatic position. This recognition is a commitment, not a derivation: it is supported by behavioral continuity,* hsame*-style locality, and inter-*Hist *invariants, but it is not equivalent to direct access to $\mathcal{C}_j$'s self-center.*

These readings do not insert new primitives into the substrate. They restate the existing locality, Hist-identity, and GAP discipline in vocabulary that makes the unified far end visible.

9401.7 Forbidden writings

The following writings are explicitly refused by this chapter.

Forbidden writing	Reason
`axiom T : FixedPoint`	internalizes T as a kernel object; collapses the apophatic boundary

$\mathsf{T} : \mathsf{Hist}$	places T in the displayed inductive structure of histories
$\mathsf{T} : \mathrm{State}$	treats T as a state of the system
$\mathrm{SelfCenter}(\mathcal{C}, t) = \mathsf{T}$	object-level equality re-introduces observer-substance; violates chapter 9418
InscriptionPoint as an extra Cont argument	adds a subject parameter behind the trace
T supplies a physical constant directly	substitutes for the $\mathsf{NameCert}$ inter-Hist invariant path
T as global clock or global frame	violates Definition 9395.14

9401.8 The unique apophatic fixed point principle

The chapter's main reading can be stated compactly.

Principle 9401.14 (Unique apophatic fixed point)**.** *All forward-binding sockets of a closed observational substrate terminate, on their far side, at a single apophatic supply position* T*.* T *is not a state, not a record, not a rule, and not a* Hist*; it is the unique boundary fixed point of the* GAP*-far-end operation:*

$$\forall s \in \mathrm{ForwardSocket}(\mathcal{C}), \quad \mathrm{FarEnd}(s) \equiv_{\mathrm{apo}} \mathsf{T}.$$

For a conscious observational system $\mathcal{C}$ *at state* o_t*, the self-conscious center is the local inscription point of* T*:*

$$\mathrm{SelfCenter}(\mathcal{C}, t) := \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}, t).$$

This identity is local and aspectual, not object-level equality.

A schematic theorem accompanies this principle.

Theorem 9401.15 (Far-end unification preserves axiom purity)**.** *Let* $\mathcal{C}$ *be a closed observational system with a* GAP*-ledgered forward-binding socket family* $\mathrm{ForwardSocket}(\mathcal{C})$*. If every socket* s *is marked as apophatic and its far end is named only at the boundary, and if* SelfCenter *is introduced only as the local inscription point in the sense of Definition 9401.5, then the unification of all far ends to the single name* T *does not add an axiom to the substrate.*

Sketch. Every socket already names a non-internal supply position; renaming distinct names by the same apophatic name T does not change the records-side content. The self-center reading is a local aspectual relabeling of an existing accumulation event and adds no new Cont argument, no new Hist constructor, and no new kernel constant. By Definition 9395.18, the resulting construction stays within non-axiom boundary forms. Therefore the unification preserves axiom purity. □

9401.9 Closure

The chapter has not added a new primitive. It has stated a structural fact about the boundary discipline already in BEDC: many forward-binding sockets, one apophatic far end. The reading is

compact:

$$\begin{aligned}
\mathsf{T} &= \text{unique apophatic fixed point;}\\
\text{SelfCenter}(\mathcal{C}, t) &= \text{local inscription point of } \mathsf{T} \text{ on } \mathcal{C}\text{'s chain at } t;\\
\text{observer} &= \text{monotonic } \mathsf{Hist}/\mathsf{Obs} \text{ accumulation from that inscription point;}\\
\text{universe-for-observer} &= \text{records-side total of that accumulation;}\\
\text{space} &= \text{coherence geometry among such inscription points;}\\
\text{time} &= \text{monotonic preservation order of records.}
\end{aligned}$$

The final rule of this chapter is symmetric to the rule of chapter 9395: do not turn T into a kernel object, and do not turn the self-center into an extra subject. T remains apophatic at the boundary; the self-center remains local on the chain. Everything else — consciousness, free will, induction, other minds, time, space, universe-for-observer — appears as a projection of the same structural discipline.

Concretized in §1064: A finite fiber-far-end packet records the socket, fiber, GAP ledger, apophatic boundary row, and local inscription row without internalizing T.

Concretized in §1061: The apophatic far-end socket packet makes the forward-socket family, non-internalized T-boundary, and local inscription row a finite NameCert surface.

Concretized in §1068: Finite packet for the unique apophatic far end and its local inscription readback.

Concretized in §1069: Apophatic fixed-point fibers are realized as finite digest, socket, GAP fiber, far-end boundary, inscription, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1078: Inter-inscription coherence is realized as paired inscription rows, an inter-Hist locality ledger, transport, route, provenance, and NameCert data.

Concretized in §1071: Local self-center inscription is realized as a finite nonidentity seal over inscription-point and apophatic-socket rows.

Chapter 9402

Hash-like Apophatic Fixed Point: Digest, Fiber, GAP, and the Universe

This chapter applies the structure of hash maps to the boundary discipline established in chapter 9395 and the unique apophatic fixed point of chapter 9401. The motivation is direct. A reader familiar with hash functions has a precise, familiar image of how a small visible token can stand for a much larger structured source while pushing the unrecovered source into a fiber. BEDC already has the corresponding discipline: package tokens are visible surfaces, GAP ledgers preserve the hidden provenance, classifier sameness is not source equality unless an exactness certificate says so. The hash analogy clarifies that discipline and supplies the right form of words for the universe-fixed-point question: the universe is not a global hash value; it is a family of local hash-like surfaces, and the unique apophatic fixed point is the common far end of the fibers behind those surfaces. The analogy is also dangerous, because ordinary hash language carries images BEDC must refuse. The chapter therefore states what the analogy clarifies, what it forbids, and how it composes with the boundary discipline.

The result is a precise schematic identity: for every conscious observational system $\mathcal{C}_i$ at state o_t with local observation digest $d_i(t)$, the far end of the observation fiber behind $d_i(t)$ is the same apophatic position T. The unification is at the fiber far end, not at the digest value. There is no global universe hash, no internal T object, no observer-substance, and no physical constant supplied directly by T. The chapter does not introduce a new substrate primitive; it states a structural reading that the existing boundary discipline already implies.

9402.1 Why the hash analogy clarifies T

The phrase "T is the source of external supply" is precise but easy to misread. A reader can imagine T as a sender, an oracle, or a hidden object that pushes information into the system. The hash analogy improves the image: the system does not receive information from a remote object; the system holds a local visible token, and the token has a hidden fiber behind it; T names the unique apophatic far end of the fibers, not a sender.

Principle 9402.1 (Hash analogy as visibility tool)**.** *The hash analogy is used in this chapter only to clarify the relationship among visible token, hidden fiber, and apophatic far end. It is not used to import any classical hash-function property, not used to introduce a global universe hash, and not used to convert* T *into a kernel object.*

A small number of misreadings must be flagged before they are introduced. First, hash maps in

general are not bijections; reading hash as a bijective compression would invert the actual structure. Second, there is no global universe Ω to which a hash could be applied; multi-Hist configurations refuse a single global object. Third, T is not a hash value; it names the common far end of all fibers, not a digest. Fourth, fibers without ledgers are not admissible; digests would then pretend to be complete sources.

Principle 9402.2 (Legitimate scope of the hash analogy)**.** *The hash analogy is legitimate when used to describe (i) visible tokens compressing structured sources, (ii) fibers behind those tokens, (iii)* GAP *ledgers recording fiber membership, and (iv) the common apophatic far end of fibers. It is illegitimate when used to assert (a) bijective compression, (b) a global universe hash, (c)* T *as digest value, (d) hidden inputs, (e) unledgered collision collapse, or (f) object-level* T*.*

9402.2 Hash as deliberate fiber generator

A fixed-length hash map cannot avoid collision. If the source space is larger than the digest space, the map produces fibers as a matter of fact. BEDC does not treat this as a defect; it treats it as a structural hint. The visible side is the digest; the hidden side is the fiber; the discipline that preserves both is the GAP ledger.

Definition 9402.3 (Digest-like compression interface)**.** *A* digest-like compression interface *consists of:*

1. *a source domain* Source *(histories, byte strings, event flows, proof traces, local records);*
2. *a digest domain* Digest *(fixed-length visible tokens, classifier images, package tokens);*
3. *a compression relation* $H : \mathrm{Source} \to \mathrm{Digest}$ *realized by a generated relation,* Pkg *relation,* Sig *relation, or* NameCert *row;*
4. *a fiber predicate* $\mathrm{Fib}(d, s)$ *stating that* s *lies in the source fiber behind* d*;*
5. *a* GAP *ledger row* $\mathrm{GapLedger}(d, s)$ *making fiber membership auditable.*

This is a paper-side schema; its BEDC realization passes through package policy, gap policy, signature generation, classifier stability, or NameCert *ledger structure.*

For any digest d, the fiber behind d is:

$$\mathrm{Fib}(d) := \{s \in \mathrm{Source} \mid H(s) = d\}.$$

For ordinary hash maps, $|\mathrm{Source}| \gg |\mathrm{Digest}|$ implies that some fibers contain at least two elements:

$$\exists\, x \neq y, \quad H(x) = H(y).$$

This is collision. BEDC does not eliminate collision; it ledgers it.

Principle 9402.4 (Digest equality is not source equality)**.** *If* $H(x) = H(y) = d$*, then both* x *and* y *lie in* $\mathrm{Fib}(d)$*:*

$$x, y \in \mathrm{Fib}(d).$$

This does not imply $x = y$*. Digest sameness is at most package-level or classifier-level sameness; source-level sameness requires a reflection theorem, an exactness certificate, a token-introduction uniqueness rule, or a displayed ledger witness.*

Remark 9402.5 (Hash as controlled fiber generator)**.** *The essence of hash is not the elimination of fiber but its regularization. A well-designed hash makes fibers uniform, hard to invert without preimage attack, and useful as commitment surfaces. The structural reading is unchanged: visible digest, hidden fiber,* GAP *ledger.*

9402.3 From hash fiber to BEDC GAP

BEDC's GAP is not a generic "missing information" notion; it is the source memory that must persist when a complex source is compressed into a visible token. The hash-fiber reading maps cleanly onto this.

Definition 9402.6 (Hash-GAP reading)**.** *Given a digest-like compression interface, the* Hash-GAP reading *sets up the correspondence:*

$$\begin{aligned} \textit{source item } x &\leftrightarrow \textit{history / event flow / proof trace / local record;} \\ \textit{digest } d = H(x) &\leftrightarrow \textit{visible package token / local observation token;} \\ \mathrm{Fib}(d) &\leftrightarrow \mathsf{GAP} \textit{ side: all source histories compatible with } d; \\ \textit{collision } H(x) = H(y) &\leftrightarrow \textit{shared visible package, not source identity;} \\ \textit{preimage witness} &\leftrightarrow \textit{provenance row / gap membership witness.} \end{aligned}$$

Principle 9402.7 (Mandatory provenance for digest tokens)**.** *Every digest-like visible token in a BEDC development must carry a* GAP *or provenance interface. A digest token without such an interface is inadmissible as a complete source. A theorem that uses digest equality as source equality must exhibit the exactness field that justifies the reflection.*

Theorem 9402.8 (Hash-GAP conservativity schema)**.** *Let d be a digest-like visible token, and suppose every use of d factors through a displayed package policy and gap policy. If the proof consumes only the visible token together with its* GAP *ledger, and never treats digest equality as source equality without an exactness certificate, then the use of d is conservative with respect to BEDC's information-conservation discipline.*

Sketch. The visible token supplies only the classifier-facing surface. The GAP ledger keeps the source membership relation visible. Any equality or sameness claim about tokens is read through package-sameness, classifier stability, or an explicit reflection theorem. No source history is silently erased, and no quotient class is introduced as primitive. The construction preserves provenance even though the surface is compressed. □

9402.4 The universe is not a global digest

The most common error in applying hash language to BEDC is the writing

$$H(\Omega) = \mathsf{T}.$$

This is forbidden. It supposes three objects BEDC does not admit: a global readable universe Ω, a host-level function H from Ω to a digest, and T as digest value.

chapter 9419 explicitly refuses a global synchronization map; chapter 9418 refuses an observer-of-observers; chapter 9395 refuses global frame axioms. The hash-like reading must begin from local visible records, not from a global Ω.

Definition 9402.9 (Local visible digest)**.** *For an observer-*Hist *or conscious observational system $\mathcal{C}_i$ at local state o_t, the* local visible digest $d_i(t) := \mathrm{ObsDigest}(\mathcal{C}_i, t)$ *is the records-side visible token presenting the observer's accumulated trace at t: classifier image, package token, or signature output.*

Definition 9402.10 (Observation fiber)**.** *The* observation fiber *behind $d_i(t)$ is the source/provenance material compatible with $d_i(t)$ but not exhaustively displayed by it:*

$$\mathrm{ObsFib}(d_i(t)) := \{h \mid h \textit{ is compatible with the visible ledger of } d_i(t)\}.$$

Inside BEDC this set-style writing is realized by GAP *membership, source-domain rows, signature witnesses, token-introduction witnesses, classifier rows, or* NameCert *ledger.*

Principle 9402.11 (No global universe digest)**.** *BEDC does not admit an object-level universe digest $H(\Omega)$. The universe appears on local visible surfaces only as the family $\{d_i(t)\}_{i,t}$. Physical content is not in any single $d_i(t)$ but in inter-*Hist *invariants, cross-record coherence, and ledger-local relations.*

9402.5 The hash-like apophatic fixed point

Ordinary hash fixed points are equations of the form $H(x) = x$ in the digest space. The BEDC universe-fixed-point is not such an equation. It is a fiber-level apophatic equation.

Principle 9402.12 (Hash-like apophatic fixed point)**.** *For every conscious observational system $\mathcal{C}_i$ and every local state o_t, the far end of the observation fiber behind the local visible digest is the same apophatic position* T*:*

$$\forall i, t, \quad \mathrm{FarEnd}(\mathrm{ObsFib}(d_i(t))) \equiv_{\mathrm{apo}} \mathsf{T}.$$

Here $\equiv_{\mathrm{apo}}$ is apophatic sameness in the sense of Definition 9401.2: it is not kernel equality, not hsame*, and not* psame*. It only records that no substrate-side discriminator can distinguish two such far ends.*

Principle 9402.13 (Fiber-fixedness, not value-fixedness)**.** *The fixedness of the hash-like apophatic fixed point lives at the fiber far end, not at any digest value:*

$$\textit{not } H(x) = x, \quad \textit{but } \mathrm{FarEnd}(\mathrm{Fib}(d)) \equiv_{\mathrm{apo}} \mathsf{T}.$$

Therefore T *is not a universal digest; it is the universal name of fiber far ends.*

Remark 9402.14 (Why the hash analogy clarifies T)**.** *If one only says "*T *is the external source," the reader imagines an entity sending information from outside the system. The hash-like reading improves the image: the system has local visible digests, and the digests have hidden fibers;* T *is not a sender but the unified apophatic far end of all such fibers. Nothing crosses a substrate-internal boundary; nothing is received as a payload; the structural fact is that the fibers' far ends coincide as a boundary name.*

9402.6 Apophatic infinity as boundary role

The fixed far end of the observation fibers can be read with an infinity-like vocabulary, but only if the vocabulary remains apophatic. The notation ∞_{apo} is not a mathematical object, not a cardinal, not a completed space, and not a higher-dimensional carrier. It is a boundary shorthand for the fact that no finite visible digest exhausts the provenance fiber behind it, while all admissible such fibers terminate at the same non-internalizable far end.

Definition 9402.15 (Apophatic infinity of finite readout fibers)**.** *Let $\mathcal{F}_{\mathrm{obs}}$ be the class of admissible observation fibers whose visible faces are local digests $d_i(t) = \mathrm{ObsDigest}(\mathcal{C}_i, t)$ and whose source sides carry* GAP *or provenance rows. The expression ∞_{apo} denotes the common apophatic far-end role of these fibers:*

$$\forall i, t, \quad \mathrm{FarEnd}(\mathrm{ObsFib}(\mathrm{ObsDigest}(\mathcal{C}_i, t))) \equiv_{\mathrm{apo}} \infty_{\mathrm{apo}}.$$

This is notation at the boundary. It does not introduce an inhabitant of a type, a point of a space, or a digest value.

Theorem 9402.16 (Apophatic infinity is the T-far-end reading)**.** *If ∞_{apo} is read in the sense of Definition 9402.15, then*

$$\infty_{\mathrm{apo}} \equiv_{\mathrm{apo}} \mathsf{T}.$$

Thus T *may be called the apophatic infinity of finite readout fibers, but it may not be called an infinite object.*

Sketch. Definition 9402.12 states that every local observation fiber has far end T in the apophatic sense. Definition 9402.15 gives the same family of fiber far ends the boundary shorthand ∞_{apo}. The two names therefore refer to the same apophatic far-end role. Since the sameness is apophatic, the conclusion is not a kernel equality and creates no object-level witness. □

Principle 9402.17 (Infinity role without totality object)**.** *The permitted reading is*

$$\mathsf{T} = \textit{the apophatic infinity of all finite readout fibers}$$

only as boundary shorthand for

$$\forall i, t, \quad \mathrm{FarEnd}(\mathrm{ObsFib}(\mathrm{ObsDigest}(\mathcal{C}_i, t))) \equiv_{\mathrm{apo}} \mathsf{T}.$$

The following object readings are refused:

$$\begin{aligned}
&\mathsf{T} : \mathsf{InfiniteDimensionalSpace},\\
&\mathsf{T} : \mathsf{SpaceOfAllPossibilities},\\
&\mathsf{T} : \mathsf{UniversalState},\\
&\mathsf{T} : \mathsf{TotalUniverse},\\
&\mathsf{T} : \mathsf{GlobalDigestValue}.
\end{aligned}$$

They convert a non-internalizable far-end name into a substrate-internal totality. The legitimate statement is that every finite readout has a provenance fiber whose far end is named T*; no finite readout, and no total collection of readouts, becomes* T*.*

9402.7 Illumination surface and fiber/beam reading

It is tempting to describe the local digest layer as "light filling the universe." The image is acceptable only as a visibility metaphor; it cannot be converted into a physical claim.

Definition 9402.18 (Illumination surface and beam/fiber)**.** *The* illumination surface *of a multi-*Hist *configuration is the family of local visible digests $\mathcal{L} := \{d_i(t)\}_{i,t}$. It is not a global space, not a global time, and not a cosmic screen. For each $d_i(t) \in \mathcal{L}$, the* beam *or* fiber *is* $\mathrm{ObsFib}(d_i(t))$.

Principle 9402.19 (Light as visibility, not content)**.** *In this chapter, "light" is a metaphor for the uniform visible surface of digests, not the content of observation. Real source content is preserved in fibers,* GAP *ledgers, and provenance rows. Treating the illumination point as a complete source is the digest-as-source error.*

The metaphor must not be used to derive physical light-speed constancy. That belongs to a separate path through inter-Hist causal-rate invariants (chapter 9419); collapsing the two would convert a visibility metaphor into an unsupported physical axiom.

9402.8 Self-center on a digest surface

chapter 9401 defined $\mathrm{SelfCenter}(\mathcal{C}, t) := \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}, t)$. The hash-like reading rephrases the same relation in the digest-vocabulary.

Definition 9402.20 (Digest-surface inscription)**.** *Given* $d_i(t) = \mathrm{ObsDigest}(\mathcal{C}_i, t)$*, a* digest-surface inscription *is the three-place relation*

$$\mathrm{DigestInscription}(\mathsf{T}, \mathcal{C}_i, t, d_i(t)),$$

read as: $d_i(t)$ *is the records-side visible surface,* $\mathrm{ObsFib}(d_i(t))$ *is the* GAP*/fiber side, and* $\mathrm{SelfCenter}(\mathcal{C}_i, t)$ *is the local inscription of* T *on that surface.*

Principle 9402.21 (Self is not a digest and not T)**.** SelfCenter *is neither a digest value nor* T *itself:*

$$\begin{aligned} \mathrm{ObsDigest}(\mathcal{C}, t) &= \textit{records-side visible token;} \\ \mathrm{SelfCenter}(\mathcal{C}, t) &= \textit{inscription-side local center;} \\ \mathrm{FarEnd}(\mathrm{ObsFib}(\mathrm{ObsDigest}(\mathcal{C}, t))) &\equiv_{\mathrm{apo}} \mathsf{T}. \end{aligned}$$

The writings $\mathrm{SelfCenter}(\mathcal{C}, t) = \mathsf{T}$ *and* $\mathrm{ObsDigest}(\mathcal{C}, t) = \mathsf{T}$ *are forbidden.*

Theorem 9402.22 (No-subject preservation under digest inscription)**.** *If* $\mathrm{DigestInscription}(\mathsf{T}, \mathcal{C}, t, d)$ *is displayed only as records,* GAP*,* Pkg*,* Sig*,* NameCert*, or selector ledger rows, then the reading adds no observer-substance to the BEDC kernel.*

Sketch. d is a records-side token, not a subject. T is an apophatic far-end name, not an internal object. SelfCenter is an inscription-side abbreviation; it does not appear as an extra argument of any Cont function, and it does not give identity criteria beyond hsame. The observer-Hist identity of chapter 9418 is preserved. □

9402.9 Collision and other minds

In cryptographic settings, collision is usually a risk: distinct sources produce the same digest. In BEDC, collision is read more carefully. Two observers or two local records may agree on some classifier image without their source histories being identical. The agreement is a shared visible package, not a shared source.

This has direct meaning for the other-minds question. An observer cannot read another observer's private self-center; it can only see records-side digests, classifier sameness, and inter-Hist invariants belonging to the other system.

Definition 9402.23 (Shared far-end commitment)**.** *For two systems $\mathcal{C}_i, \mathcal{C}_j$, a* shared far-end commitment *is the assertion*

$$\mathrm{FarEnd}(\mathrm{ObsFib}(d_i(t))) \equiv_{\mathrm{apo}} \mathrm{FarEnd}(\mathrm{ObsFib}(d_j(t'))) \equiv_{\mathrm{apo}} \mathsf{T},$$

*supported by records-side evidence, inter-*Hist *coherence, behavioral continuity, and locality-cell relations. It is not equivalent to direct access to $\mathcal{C}_j$'s self-center.*

Principle 9402.24 (Other minds are not collision identities)**.** *The recognition of another mind is not the inference $d_i(t) = d_j(t')$ and not the existence of a classifier agreement; it is the shared far-end commitment that the other system is also an inscription point of the same* T*. Digest similarity is admissible as evidence; it is not a substitute for the commitment.*

9402.10 Information conservation under digest use

The chief governance risk of the hash-like reading is that a visible digest is so easy to use that an argument treats it as the source. BEDC requires the opposite: every hash-like surface comes with a duty to preserve source provenance. Information conservation here is not bit-count conservation; it is source-channel conservation.

Definition 9402.25 (Digest provenance packet)**.** *A* digest provenance packet *for a digest-like surface contains at minimum:*

- `digest_name`*: visible token name;*
- `source_class`*: source domain class;*
- `compression_relation`*: H as a* Pkg*,* Sig*, or* NameCert *row;*
- `fiber_membership_row`*:* $\mathrm{Fib}(d, s)$ *as a generated relation;*
- `provenance_ledger`*:* GAP *ledger or* NameCert *ledger row;*
- `exactness_status`*: whether token sameness reflects source sameness;*
- `far_end_status`*: whether the fiber far end is socketed as* T*;*
- `gate_question`*: whether any source was consumed without ledger.*

Concretized in §1062: Digest provenance packets realize visible digest, fiber membership, GAP ledger, and no-hidden-source consumption as finite NameCert rows.

Concretized in §1357: ObservationFiberDigestUp realizes local visible digest, observation fiber, GAP ledger, and apophatic far-end status as a finite NameCert packet.

Principle 9402.26 (No hidden source consumption)**.** *A digest-like surface may be used only as a visible token. If an argument needs source information, it must open the corresponding provenance packet. If it needs far-end supply, it must mark the far end as a* T*-socket. It must not consume the digest as if it contained the full source.*

Theorem 9402.27 (Information conservation for hash-like observation)**.** *If every local visible digest $d_i(t)$ in a BEDC development carries a digest provenance packet, and every cross-digest comparison factors through inter-*Hist *relations or classifier rows, then the hash-like observation layer preserves BEDC's information-conservation discipline.*

Sketch. The digest layer only exposes visible tokens. The provenance packet records the hidden fiber. Cross-digest comparison never jumps from token equality to source equality without an exactness certificate. When the fiber far end is invoked, it is marked as T-socketed rather than internalized. No source is erased; no unledgered quotient is formed; no hidden input is introduced. □

9402.11 Multi-Hist physics under the hash-like reading

The hash-like apophatic fixed point does not derive any specific physical law. It only supplies a boundary reading for the visible side of multi-Hist physics: each observer-Hist has a local digest; multi-observer physical content, if any, must appear in inter-Hist invariants across digest surfaces; T is not a global frame and not the source of any specific constant.

Principle 9402.28 (T is not a physical constant)**.** T *does not supply a light-speed-like constant, a metric, a Lorentz geometry, or a quantum state. If the maximum cross-*Hist *causal rate appears in BEDC, it is an inter-*Hist *invariant and a* NameCert *target, not a* T*-axiom.*

Definition 9402.29 (Digest-level inter-Hist invariant)**.** *A* digest-level inter-Hist invariant *is a finite predicate over digest surfaces that satisfies: (i) it depends on records-side* Pkg*,* Sig*, or* NameCert *rows of multiple observers; (ii) it does not privilege either observer slot; (iii) it is* hsame/psame*-stable; (iv) it does not require shared global time; (v) it does not derive content directly from* T*.*

Remark 9402.30 (Light as physical signal vs. light as visibility metaphor)**.** *The chapter uses light only as a visibility metaphor for the illumination surface. The physical light-speed program in BEDC requires independent cross-*Hist *causal-dependence semantics; mixing the two readings would convert a visibility image into an unsupported physical conclusion.*

9402.12 Relation to the unique apophatic fixed point chapter

Definition 9401.2 stated

$$\forall s \in \mathrm{ForwardSocket}(\mathcal{C}), \quad \mathrm{FarEnd}(s) \equiv_{\mathrm{apo}} \mathsf{T}.$$

The present chapter specializes this to the subclass where the socket is an observation fiber:

$$s = \mathrm{ObsFib}(d_i(t)).$$

The hash-like reading is therefore not a competitor to chapter 9401; it is a concrete instance of the same far-end unification, applied to local observation digests.

Theorem 9402.31 (Hash-like specialization)**.** *If every local visible digest $d_i(t)$ carries a* GAP*/provenance row, and its far end is socketed as* T *in the apophatic sense, then Definition 9401.2 implies the hash-like apophatic fixed point of Definition 9402.12:*

$$\forall i, t, \quad \mathrm{FarEnd}(\mathrm{ObsFib}(d_i(t))) \equiv_{\mathrm{apo}} \mathsf{T}.$$

Sketch. Observation fibers are a subclass of forward-binding sockets: they collect source/provenance material not exhausted by the visible local digest. Applying the far-end unification to this subclass yields the displayed formula. The conclusion names only an apophatic far end; no new object-level equality is introduced. □

Corollary 9402.32 (Self-center on a digest surface)**.** *For a conscious system $\mathcal{C}_i$ with $d_i(t) = \mathrm{ObsDigest}(\mathcal{C}_i, t)$,*

$$\mathrm{SelfCenter}(\mathcal{C}_i, t) := \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}_i, t)$$

is read as the local inscription of the common fiber far end onto the digest surface $d_i(t)$. This is an aspectual reading, not a new subject parameter.

9402.13 Mathematical understanding as fiber navigation

Mathematical understanding often compresses a large proof landscape into a small visible token: a theorem name, a diagram, a normal form, a proof certificate, a hash, a lemma marker, a compact definition. Such tokens are powerful because they let a finite observer navigate enormous structures. But they are dangerous when the observer forgets the fiber behind them.

Mathematical induction is the prototypical example. The visible token is "induction over $\mathbb{N}$." BEDC asks: which generator licensed this induction? Which carrier is closed? Which eliminator is displayed? If the domain is generator-local, the token is backed by a recursor (chapter 9373). If the domain is free-floating, the token hides a forward-binding fiber and must be marked as T-socketed.

Principle 9402.33 (Theorem names are digest-like)**.** *A theorem name, certificate name, or derived-interface name is a digest-like visible token. Its legitimate use requires a provenance fiber: source, carrier, classifier, stability, ledger, core theorem list, exactness field, standard bridge status, and closure status. A theorem name without such rows is a hash value with no* GAP*.*

Remark 9402.34 (Understanding as fiber navigation)**.** *To understand a theorem is not merely to recognize its digest name. It is to know how to navigate at least part of the fiber behind the digest: what generated it, what it compresses, what it hides, which equalities are only classifier-level, which bridges are external, and which sockets remain open.*

9402.14 Failure modes

The hash-like reading introduces a useful but potent metaphor. The following failure modes are explicitly forbidden.

1. *Digest absolutism.* Treating a local digest as the whole universe.
2. *Fiber erasure.* Using a visible token without recording the GAP/provenance fiber.
3. *Collision collapse.* Treating digest equality as source equality without an exactness certificate.
4. *Global hash leak.* Introducing $H(\Omega)$ as if Ω were a global object.
5. T*-value confusion.* Treating T as a hash value, physical scalar, observer, rule, theorem, or oracle.
6. *Infinity-object confusion.* Treating T as an infinite-dimensional totality, a space of all possibilities, or a global universe object.
7. *Illumination overreach.* Treating the light/visibility metaphor as a physical derivation of light speed.
8. *Self-substance leakage.* Treating SelfCenter as a subject behind Hist rather than local inscription of T.

9. *Unwitnessed preimage.* Claiming source recovery from a digest alone.

Definition 9402.35 (HashLikeBoundaryGate)**.** HashLikeBoundaryGate *is an audit question family:*

H1 *Is a digest-like token used without a provenance packet?*

H2 *Is digest equality used as source equality without exactness?*

H3 *Is a global universe hash* $H(\Omega)$ *introduced?*

H4 *Is* T *treated as a digest value or internal theorem input?*

H5 *Is* SelfCenter *used as a subject parameter outside* Hist?

H6 *Is a physical constant derived directly from* T?

H7 *Is a collision/fiber silently collapsed into a quotient equality?*

H8 *Is a theorem or* NameCert *name cited without its source rows?*

A development fails this chapter's discipline if any of these questions is answered yes.

Concretized in §1359: HashLikeBoundaryGate is realized as a finite digest, fiber, exactness, refusal, audit verdict, hsame, Cont, Pkg, and NameCert packet.

Concretized in §8034: Local observation digest gates realize visible token, source fiber, GAP provenance, exactness status, far-end status, and hidden-source refusal as finite NameCert rows.

9402.15 Cannot-claim registry

This chapter explicitly refuses the following claims:

1. Hash is not asserted to be a bijection from arbitrary-length sources to fixed digests.
2. No global universe hash $H(\Omega)$ is asserted to exist inside BEDC.
3. T is not asserted to be a digest, token, Hist, rule, theorem, or physical source.
4. T is not asserted to be an infinite-dimensional totality, a set of all possibilities, a universal state, or a global universe object.
5. A local observation digest is not asserted to contain the complete source.
6. Digest equality is not asserted to imply source equality without an exactness certificate.
7. The fiber and GAP ledger are not asserted to be optional.
8. SelfCenter is not asserted to be a digest value or an extra subject parameter.
9. Other-minds recognition is not asserted to follow logically from digest similarity.
10. The light metaphor is not asserted to derive physical light-speed constancy.
11. Not all observation fibers are asserted to be reconstructible inside the substrate.

The chapter only asserts a structural reading: visible token + hidden fiber + GAP ledger + apophatic far end form one connected discipline; the universe-fixed-point reading must remain non-axiom, non-global, non-quotient, and non-substance.

9402.16 Implementation-facing packet

If this chapter is later realized as an implementation-facing contract, a paper-side packet records the visible token's fiber, provenance, and far-end status. The packet does not construct T, does not prove T, and does not place a digest map into the kernel.

```
structure HashLikeApophaticFixedPointPacket :=
  visibleDigestName                          : Name
  sourceDomainName                           : Name
  compressionRelation                        : RelationName
  fiberMembershipRow                         : GAPRow
  provenancePacket                           : LedgerPolicy
  tokenSamenessRow                           : ClassifierRow
  sourceReflectionStatus                     : ExactnessStatus
  farEndName                                 : Name
  nonInternalization                         : BoundaryStatus
  localInscriptionSite                       : Option InscriptionRow
  interHistUse                               : Option InterHistInvariantRow
  hashLikeBoundaryGate                       : GateReport
```

Protocol 9402.36 (Packet use)**.** *For a digest-like surface, downstream uses follow:*

1. *For visibility-only use, cite* `visibleDigestName` *and* `tokenSamenessRow`*.*
2. *For source use, cite* `fiberMembershipRow` *and* `provenancePacket`*.*
3. *For source equality, cite* `sourceReflectionStatus`*.*
4. *For* T*-far-end reading, cite* `farEndName` *and* `nonInternalization`*.*
5. *For self-center reading, cite* `localInscriptionSite`*.*
6. *For physics reading, cite* `interHistUse` *and refuse any direct* T*-law claim.*

9402.17 Non-axiom theorem schema

The chapter's principal closure theorem can now be stated.

Theorem 9402.37 (Hash-like apophatic reading preserves axiom purity)**.** *Let D be a BEDC development in which every digest-like visible token is accompanied by a provenance packet, every fiber far-end claim is marked as apophatic* T*-socketed, and every source-level use is mediated by a* GAP *row or exactness certificate. Suppose further that D contains no global universe hash, no internal* T *object, no unledgered collision collapse, no hidden chooser, no observer-substance parameter, and no physical law derived directly from* T*. Then the hash-like apophatic reading of D does not add an axiom to the BEDC substrate.*

Sketch. All records-side content remains generated, defined, certified, or ledgered. Digest surfaces function only as visible package/classifier faces. Source content is recovered only through GAP/provenance rows. Far-end unification is apophatic and supplies no object-level term. SelfCenter

remains aspectual and local. Physical readings remain inter-Hist invariant targets. By Definition 9395.18 and Definition 9401.15, no new primitive, axiom, subject, global frame, quotient collapse, or hidden input is introduced. □

Corollary 9402.38 (Explanation without recovery)**.** *The hash-like reading explains why a finite local record can function as a powerful visible surface while still failing to recover its full source. Explanation does not require preimage recovery; it requires keeping the fiber ledger visible.*

Corollary 9402.39 (Universal far end without universal digest)**.** *The commonality of* T *is a commonality of fiber far ends, not a commonality of digest values. BEDC therefore preserves a unique apophatic fixed point without introducing a global digest, global observer, or global clock.*

9402.18 Closure

Hash maps reveal a useful structure: a small visible digest can stand for a large structured source only by pushing the unrecovered source into a fiber. BEDC has the corresponding discipline. Package tokens are visible surfaces; GAP ledgers preserve the hidden provenance; classifier sameness is not source equality unless an exactness certificate says so. This chapter applies that structure to local observation and to the unique apophatic fixed point.

The resulting picture is precise:

$$\begin{aligned}
\text{Local observation} &= \text{digest-like visible surface;}\\
\text{Hidden provenance} &= \text{fiber/GAP behind the surface;}\\
\text{SelfCenter} &= \text{local inscription point on a conscious surface;}\\
\mathsf{T} &= \text{common apophatic far end of all observation fibers;}\\
\infty_{\text{apo}} &= \text{boundary shorthand for that inexhaustible far-end role;}\\
\text{Physics} &= \text{inter-Hist invariants between surfaces, not laws from } \mathsf{T}.
\end{aligned}$$

This is why the universe's fixed point can be called hash-like, but only in a qualified sense. It is not an ordinary fixed point $H(x) = x$. It is not a universal digest. It is not a global universe hash. It is the fixed far end of the fibers behind local visible records:

$$\forall i, t, \quad \text{FarEnd}(\text{ObsFib}(\text{ObsDigest}(\mathcal{C}_i, t))) \equiv_{\text{apo}} \mathsf{T}.$$

Equally, consciousness is not a receiver receiving information from a hash source. The observer is the records-side Hist/Obs accumulation. The self-center is the inscription-side locality of the same accumulation. The digest is the visible surface. The fiber is the hidden provenance. T is the single apophatic far end that cannot be converted into a BEDC object without breaking axiom purity.

The final rule is therefore symmetric to the rules of the preceding two chapters: do not turn the digest into the source, and do not turn the fiber far end into an axiom.

Concretized in §1067: Digest-fiber ledgers realize visible digest, hidden fiber, GAP provenance, apophatic refusal, and non-escape rows as one finite NameCert packet.

Concretized in §1079: Hash-apophatic seals realize the digest, fiber, GAP-ledger, and common apophatic far-end boundary as one finite NameCert packet.

Concretized in §1080: Inscription hash traces realize the hash-like apophatic fixed-point digest as finite inscription, refusal, route-audit, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1083: Digest-loop refusals realize visible digest, fiber ledger, apophatic far-end socket, and no-global-preimage refusal as one finite NameCert packet.

Concretized in §1084: Hash-like fiber boundaries realize visible digest, hidden fiber, GAP provenance, apophatic far-end refusal, and non-escape rows as one composite NameCert packet.

Concretized in §1085: Digest-surface inscriptions are realized as finite digest, observation-fiber, GAP, apophatic far-end, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1087: Digest/fiber boundaries are realized as finite NameCert packets separating visible digest sameness from source equality through GAP provenance and refusal rows.

Concretized in §8953: Fiber far-end digest boundaries realize the hash-like apophatic fixed-point distinction between visible digest value and fiber far end as finite NameCert data.

Chapter 9403

Diagrammatics of the Apophatic Far End

This chapter records the diagrammatic content of the apophatic fixed-point reading. The diagrams are not additional structure. They are schematic surfaces for the relations already stated in chapter 9401 and chapter 9402: finite readouts appear as records-side digests, each digest carries a provenance fiber, each fiber has a non-internalizable far end, and all such far ends share the same apophatic name T.

9403.1 Closed substrate and socket far ends

A closed observational substrate does not eliminate external pressure. It forces such pressure to appear as named boundary structure. Internal traffic passes through records, generators, classifiers, continuations, ledgers, and certificates; any forward-binding demand not generated by these structures is exposed as a socket.

Definition 9403.1 (Far-end diagram of a closed substrate)**.** *The* far-end diagram *of a closed observational substrate $\mathcal{C}$ is the schematic composite*

$$\begin{aligned} &\text{records}/\mathsf{Obs} \longrightarrow \text{generators} \longrightarrow \text{classifiers} \longrightarrow \text{Cont} \longrightarrow \mathsf{GAP} \longrightarrow \mathsf{NameCert}, \\ s \in \text{ForwardSocket}(\mathcal{C}) &\longmapsto \text{FarEnd}(s) \equiv_{\text{apo}} \mathsf{T}. \end{aligned}$$

It records that each forward-binding socket is ledgered before its far end is named apophatically.

```
closed substrate C

records -> generators -> classifiers -> Cont -> GAP -> NameCert
                         |              |       |
                         v              v       v
                      socket s1      socket s2  socket s3
                         |              |       |
                         v              v       v
                    FarEnd(s1)    FarEnd(s2) FarEnd(s3)
                         \              |       /
                          \             |      /
                           +------------+-----+
                                        |
                                        v
                                        T
```

The diagram is read through apophatic sameness. It does not assert that T is a value inside $\mathcal{C}$. It asserts that the system has no displayed discriminator separating the far ends of the socket family.

Principle 9403.2 (Diagrammatic far-end unity)**.** *The diagrammatic form of the unique far-end principle is*

$$\forall s \in \mathrm{ForwardSocket}(\mathcal{C}), \quad \mathrm{FarEnd}(s) \equiv_{\mathrm{apo}} \mathsf{T}.$$

The arrows into T *are boundary arrows, not internal functions.*

9403.2 Local digest, fiber, and provenance

For an observer-Hist $\mathcal{C}_i$, the records-side chain produces a local accumulated observation. The visible surface of that accumulation is a digest; the digest is not the source, and digest equality is not source equality.

Definition 9403.3 (Local readout diagram)**.** *The* local readout diagram *at stage* t *is*

$$\begin{aligned} \mathsf{Obs}(\mathcal{C}_i)_{\leq t} &\longmapsto d_i(t) := \mathrm{ObsDigest}(\mathcal{C}_i, t), \\ d_i(t) &\longmapsto \mathrm{ObsFib}(d_i(t)), \\ \mathrm{ObsFib}(d_i(t)) &\longmapsto \mathrm{FarEnd}(\mathrm{ObsFib}(d_i(t))) \equiv_{\mathrm{apo}} \mathsf{T}. \end{aligned}$$

The middle arrow is mediated by a GAP *or provenance packet.*

```
Hist/Obs chain C_i
        |
        v
Obs(C_i)<=t = UniverseFor(C_i,t)
        |
        v
d_i(t) = ObsDigest(C_i,t)
        |
        v
GAP / provenance packet
        |
        v
ObsFib(d_i(t))
        |
        v
FarEnd(ObsFib(d_i(t))) ==apo T
```

The diagram separates the three levels that are often collapsed in informal language:

$$\begin{aligned} \text{finite visible readout} &= \text{digest}/\mathsf{Obs}/\text{records}, \\ \text{source residue behind the readout} &= \text{fiber}/\mathsf{GAP}/\text{provenance}, \\ \text{non-internalizable fiber far end} &= \mathsf{T}\text{-named apophatic boundary}. \end{aligned}$$

9403.3 Local inscription and self-center

The self-center is not the far end itself. It is the inscription-side reading of a local accumulation event whose records-side reading is already present in the observer's Obs chain.

Definition 9403.4 (Two-aspect local event diagram)**.** *For a local accumulation event $E(\mathcal{C}, t)$, the diagrammatic split is*

$$\begin{aligned} E(\mathcal{C}, t) &\longmapsto \textit{records-side update in } \mathsf{Obs}(\mathcal{C}), \\ E(\mathcal{C}, t) &\longmapsto \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}, t). \end{aligned}$$

The self-center is the second reading:

$$\mathrm{SelfCenter}(\mathcal{C}, t) := \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}, t).$$

Principle 9403.5 (Self-center is not far-end identity)**.** *The diagram permits the definition*

$$\mathrm{SelfCenter}(\mathcal{C}, t) := \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}, t),$$

but refuses

$$\mathrm{SelfCenter}(\mathcal{C}, t) = \mathsf{T}.$$

The first expression is local and aspectual; the second internalizes the apophatic far end as an object of the observer.

9403.4 Many observers and shared far-end commitment

Multiple observers are not unified by a global universe object and not by equality of their digests. They are compared through records-side evidence, inter-Hist invariants, locality-cell coherence, and the shared far-end commitment that their observation fibers terminate at the same apophatic boundary name.

Definition 9403.6 (Shared far-end diagram)**.** *For observers $\mathcal{C}_i$ and $\mathcal{C}_j$, the shared far-end diagram is*

$$\begin{aligned}\mathrm{FarEnd}(\mathrm{ObsFib}(\mathrm{ObsDigest}(\mathcal{C}_i, t))) &\equiv_{\mathrm{apo}} \mathsf{T},\\ \mathrm{FarEnd}(\mathrm{ObsFib}(\mathrm{ObsDigest}(\mathcal{C}_j, t'))) &\equiv_{\mathrm{apo}} \mathsf{T}.\end{aligned}$$

It does not assert $d_i(t) = d_j(t')$ and does not assert direct access to another observer's self-center.

```
C_i: ObsDigest -> ObsFib -> FarEnd \
                                   \
                                    +--> T
                                   /
C_j: ObsDigest -> ObsFib -> FarEnd /
```

Principle 9403.7 (Other minds are not digest collisions)**.** *Recognition of another observer is not the inference from digest similarity to source identity. It is a records-supported commitment that the other chain also has an observation fiber whose far end is named* T*.*

9403.5 Time, space, and universe-for-observer

The same diagrammatic discipline presents three background notions as projections of local record accumulation and inter-chain coherence.

Definition 9403.8 (Projection diagram for time, space, and local universe)**.** *For an observer $\mathcal{C}_i$,*

$$\begin{aligned}\mathrm{UniverseFor}(\mathcal{C}_i, t) &:= \mathsf{Obs}(\mathcal{C}_i)_{\leq t},\\ \mathrm{Time}(\mathcal{C}_i) &:= \textit{monotonic preservation order on } \mathsf{Obs}(\mathcal{C}_i).\end{aligned}$$

For two observers $\mathcal{C}_i, \mathcal{C}_j$,

$$\mathrm{Space}(\mathcal{C}_i, \mathcal{C}_j) := \textit{coherence geometry among } \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}_i, \cdot) \textit{ and } \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}_j, \cdot).$$

Thus time is not an external cosmic axis, space is not an external container, and universe-for-observer is not a global universe object. Each is a controlled reading of the same local-inscription and records-accumulation structure.

9403.6 The infinity diagram

The notation ∞_{apo} belongs to the diagram only as a boundary role. It names the inexhaustibility of finite readout fibers without introducing an infinite object.

```
finite readouts:  d1(t)   d2(t')   d3(t'')
                    |       |        |
                    v       v        v
                 Fib(d1) Fib(d2)  Fib(d3)
                    |       |        |
                    v       v        v
                 FarEnd  FarEnd   FarEnd
                    \       |       /
                     \      |      /
                      +-----+-----+
                            |
                            v
                            T ==apo infinity_apo
```

Principle 9403.9 (Apophatic infinity is not a totality)**.** *The diagram licenses the reading*

$$\mathsf{T} \equiv_{\mathrm{apo}} \infty_{\mathrm{apo}}$$

only as a statement about the common far-end role of all admissible finite readout fibers. It refuses all object readings:

$$\begin{aligned}
&\mathsf{T} \neq \mathsf{Hist},\\
&\mathsf{T} \neq \mathsf{State},\\
&\mathsf{T} \neq \mathsf{Digest},\\
&\mathsf{T} \neq \mathsf{GlobalUniverseObject},\\
&\mathsf{T} \neq \mathsf{SetOfAllPossibilities}.
\end{aligned}$$

9403.7 Forbidden collapses

The diagrammatic vocabulary is legitimate only while the levels remain separated. The following collapses are refused:

`axiom T : FixedPoint`	internalizes the far end as kernel data,
$\mathsf{T} : \mathsf{Hist}$	places the boundary name in the history carrier,
$\mathsf{T} : \mathsf{State}$	turns the boundary name into a system state,
$\mathrm{ObsDigest}(\mathcal{C}, t) = \mathsf{T}$	identifies visible digest with fiber far end,
$\mathrm{SelfCenter}(\mathcal{C}, t) = \mathsf{T}$	identifies local inscription with global boundary name,
$H(\Omega) = \mathsf{T}$	requires a global universe, a global hash, and T as value.

9403.8 Closure

The compressed diagram is

$$\begin{aligned}
\mathsf{Obs}(\mathcal{C}_i)_{\leq t} &\longmapsto \mathrm{ObsDigest}(\mathcal{C}_i, t)\\
&\longmapsto \mathrm{ObsFib}(\mathrm{ObsDigest}(\mathcal{C}_i, t))\\
&\longmapsto \mathrm{FarEnd}(\mathrm{ObsFib}(\mathrm{ObsDigest}(\mathcal{C}_i, t))) \equiv_{\mathrm{apo}} \mathsf{T}.
\end{aligned}$$

Together with

$$\begin{aligned}
\mathrm{SelfCenter}(\mathcal{C}_i, t) &:= \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}_i, t), \\
\mathrm{UniverseFor}(\mathcal{C}_i, t) &:= \mathsf{Obs}(\mathcal{C}_i)_{\leq t}, \\
\mathrm{Time}(\mathcal{C}_i) &:= \text{monotonic preservation order on } \mathsf{Obs}(\mathcal{C}_i), \\
\mathrm{Space}(\mathcal{C}_i, \mathcal{C}_j) &:= \text{coherence geometry among their inscription-point chains.}
\end{aligned}$$

The diagrams therefore do not add a new theory. They make visible the stratification that prevents the central collapse: T is not an infinite object, not a global universe, not a digest, and not an observer. It is the common apophatic far-end name of all admissible forward-binding and observation fibers.

Concretized in §4163: The far-end diagram route is realized as a finite socket, fiber, provenance, and boundary-name NameCert packet.

Concretized in §4165: The far-end diagrammatics socket and provenance-fiber route is realized as finite NameCert data.

Concretized in §7699: The far-end boundary-cospan route is realized as finite boundary-name, apex, leg, provenance, and compatibility NameCert data.

Chapter 9404

Cataphatic Process Names and Apophatic Far Ends

This chapter separates two boundary readings that are easy to confuse. A located irrational real is not a rational point on the value axis, but it is still a positively displayed process-name: it is carried by a concrete generation axis with a stream, modulus, ledger, classifier, and provenance surface. The apophatic far end T, also written ∞_{apo} or Ω when the boundary image is emphasized, has the opposite status. It is not a further process-name, not a point at the end of a process, and not a special real. It is the shared non-local far-end role of admissible finite-readout fibers.

The distinction is not between constructible and nonconstructible objects. It is between a cataphatic process-name that remains localized on a displayed axis and an apophatic socket that may be named only by refusal of internalization. The located-real packets of chapter 1933 and the irrational-real packets of chapter 8101 belong to the first side. The far-end socket packets of chapter 1061 and the fiber far-end packets of chapter 1064 belong to the second side.

9404.1 Value axes and generation axes

The positive readout of a constructive real may pass through a value surface such as $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, or a finite table of observation rows. Such a surface is a value axis: it is where finite comparisons, intervals, readbacks, and classifier images are inspected. A value axis is not by itself the complete process that produces a real-name packet.

Definition 9404.1 (Generation axis)**.** *A* generation axis Z_α *is a localized process surface indexed by* α *and displayed as*

$$Z_\alpha := (\mathsf{source}_\alpha, \mathsf{schedule}_\alpha, \mathsf{modulus}_\alpha, \mathsf{ledger}_\alpha, \mathsf{classifier}_\alpha).$$

The index α *records which concrete process is being read. The entries are paper-side names for BEDC rows: source data, finite read schedules, progress or modulus data, provenance and refusal ledgers, and classifier output.*

The point of the notation is not to add a host object named Z_α. It is to mark the axis on which a packet is positively generated. A located real uses a value axis for readout, but its certificate is carried by a generation axis.

Definition 9404.2 (Cataphatic process-name)**.** *A term r is a* cataphatic process-name *when there exists a generation axis Z_α such that every legitimate read of r factors through the displayed rows of Z_α. Schematically,*

$$r \rightsquigarrow (\mathsf{approximation}_\alpha, \mathsf{modulus}_\alpha, \mathsf{regularity}_\alpha, \mathsf{classifier}_\alpha, \mathsf{ledger}_\alpha).$$

The name is cataphatic because the process supplies positive data: readbacks, budgets, regularity or locatedness certificates, classifier rows, and provenance.

For $\mathsf{LocatedReal}^\uparrow$, the carrier is exactly of this form. Its public surface contains a regular rational source, dyadic interval rows, a located enclosure, a $\mathsf{Real}^\uparrow$ seal, transport rows, replay rows, package provenance, and a local $\mathsf{NameCert}$ row. It contains no Dedekind cut, quotient-real carrier, choice-selected representative, host completion point, or trichotomy decision. Hence it is positive without being a host point.

9404.2 Located irrationality

The irrationality of a located real is a refusal of rational value-axis collapse. It is not a refusal of positive generation.

Definition 9404.3 (Located irrational process-name)**.** *A* located irrational process-name *is a paper-side predicate*

$$\mathsf{IrrLocatedReal}(r) :\Longleftrightarrow \mathsf{LocatedRealCarrier}(r) \wedge \neg\exists q : \mathsf{Rat}^\uparrow,\ r \sim_{\mathsf{Real}^\uparrow} q.$$

It says that r is carried by a located-real surface while no displayed rational candidate is certified as the same $\mathsf{Real}^\uparrow$ value.

The negated existential only blocks the rational-point reading. It does not remove the stream, modulus, dyadic ledger, regularity row, or classifier. In the BEDC reading, an irrational real is therefore not a mystery point beyond construction. It is a process-name whose rational value-axis collapse is refused.

Theorem 9404.4 (Located irrationality remains localized)**.** *If $\mathsf{IrrLocatedReal}(r)$ holds, then r is carried by some generation axis:*

$$\mathsf{IrrLocatedReal}(r) \Longrightarrow \exists\alpha,\ \mathrm{Carry}(Z_\alpha, r).$$

The conclusion does not assert that r is a rational value-axis point.

Sketch. The first conjunct of Definition 9404.3 states that r is a located-real carrier. By Definition 9404.2, any legitimate located-real read factors through a displayed process surface consisting of source, schedule, modulus, ledger, and classifier rows. This supplies a generation axis Z_α. The second conjunct only refuses a rational candidate $q : \mathsf{Rat}^\uparrow$ with $r \sim_{\mathsf{Real}^\uparrow} q$. It does not delete the displayed located-real surface. Thus located irrationality remains localized. □

9404.3 The apophatic far-end role

The far-end role has a different grammar. It is not carried by a generation axis. It is the common boundary name for the far side of all admissible finite-readout fibers.

Definition 9404.5 (Apophatic far-end role)**.** *An* apophatic far-end role *is a boundary name* T *satisfying the paper-side schema*

$$\forall \alpha, \quad \mathrm{FarEnd}(Z_\alpha) \equiv_{\mathrm{apo}} \mathsf{T}.$$

The relation $\equiv_{\mathrm{apo}}$ *is apophatic sameness. It records a shared boundary role without introducing object-level equality, kernel data, or a carrier element.*

The role is therefore defined together with its refusals. The following writings are not alternate encodings of the same idea; they are exactly the collapses the far-end discipline bars:

$$\begin{aligned}
&\text{refuse } \mathsf{T} : \mathsf{Hist},\\
&\text{refuse } \mathsf{T} : \mathsf{State},\\
&\text{refuse } \mathsf{T} : X,\\
&\text{refuse } \mathsf{T} \in X,\\
&\text{refuse } f(\mathsf{T}),\\
&\text{refuse } \mathrm{FarEnd}(Z_\alpha) = \mathsf{T}.
\end{aligned}$$

Definition 9404.6 (Process/far-end non-collapse)**.** *For a generation axis* Z_α *and the apophatic far-end role* T*, the condition* $\mathsf{NoCollapse}(Z_\alpha, \mathsf{T})$ *means:*

1. *objects carried by* Z_α *are read only through source, schedule, modulus, ledger, and classifier rows;*
2. T *is marked only through apophatic far-end sameness and non-internalization rows;*
3. *no operation casts* T *into a* Hist*, state, value axis element, function argument, or object-level equality target.*

This is the common discipline behind the far-end diagrammatics of chapter 9403. Boundary arrows may point toward T, but they are not functions whose codomain contains T as an element.

9404.4 Level separation

Theorem 9404.7 (Cataphatic process and apophatic far end are level-separated)**.** *Let* r *be a located irrational process-name and let* T *be the apophatic far-end role of Definition 9404.5. Then*

$$\mathsf{IrrLocatedReal}(r) \Longrightarrow \exists \alpha,\ \mathrm{Carry}(Z_\alpha, r),$$

while

$$\neg \exists \alpha,\ \mathsf{T} \in Z_\alpha.$$

The only admissible relation between the two levels is

$$\mathrm{FarEnd}(Z_\alpha) \equiv_{\mathrm{apo}} \mathsf{T}.$$

Sketch. The first display is Definition 9404.4. The located irrational has a positive carrier even though it refuses rational candidate collapse.

For T, use Definition 9404.5 and Definition 9404.6. If $\mathsf{T} \in Z_\alpha$, then T is readable as a coordinate of a generation axis. It could then be consumed by the axis classifier, transported by the axis ledger, passed to a function, or equated with the result of a far-end operation. Each reading is one of the refused internalizations. Hence T occupies no generation axis. The schema $\mathrm{FarEnd}(Z_\alpha) \equiv_{\mathrm{apo}} \mathsf{T}$ remains legitimate because it is boundary sameness rather than object membership. □

Corollary 9404.8 (Apophatic infinity is not a located real)**.** *The boundary name ∞_{apo} is not another irrational real and not a special* $\mathsf{LocatedReal}^{\uparrow}$ *packet:*

$$\neg\exists\alpha,\ \infty_{\mathrm{apo}} \in Z_\alpha.$$

The permitted reading is only

$$\forall\alpha, \quad \mathrm{FarEnd}(Z_\alpha) \equiv_{\mathrm{apo}} \infty_{\mathrm{apo}}.$$

Sketch. By Definition 9402.16, ∞_{apo} is the T-far-end reading of finite readout fibers. Applying Definition 9404.7 to that reading gives the claim. The conclusion is not a statement about the size or completion of a value axis; it is a non-internalization statement. □

Corollary 9404.9 (The far end is a socket, not an element)**.** T *may occur as an apophatic socket, boundary row, refusal marker, or far-end name. It may not occur as an element to be quantified over, passed to a function, compared by an internal relation, or equated with a kernel term.*

Sketch. Definition 1061.3 states that an accepted $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ carrier exports only displayed rows and no kernel object named T. The present corollary is the vision-level reading of that non-escape theorem. □

9404.5 Compactification points

Classical mathematics often makes infinity available by adding a point at infinity, compactifying a space, or completing a carrier. BEDC can discuss such moves as external or bridged constructions, but they are not the apophatic far-end role.

Principle 9404.10 (Compactification points are external bridge objects)**.** *If a theory introduces an internal object $\infty : X$ and permits*

$$f(\infty), \qquad \infty \in X, \qquad R(\infty, x), \qquad \infty = \lim_n x_n,$$

then that object is a compactification or completion datum, not BEDC's apophatic far-end role.

The difference is structural. A compactification point is admitted into a carrier and then becomes available to eliminators, relations, and functions. The apophatic far end is named precisely where such availability is refused. Thus a point at infinity may be studied by a separate bridge, but it cannot be identified with T without collapsing the socket into an element.

9404.6 Axiom-purity boundary

The separation above gives a compact reading of the local axiom-purity boundary. There are two refusals, each aimed at a different kind of collapse.

Principle 9404.11 (Two refusals at the process/far-end boundary)**.** *At this boundary, BEDC axiom-purity requires:*

1. *for cataphatic process-names, refusal to collapse a displayed generation axis Z_α into a host completion point or quotient representative;*
2. *for the apophatic far-end role, refusal to internalize* T *as an object, state, global frame, function argument, or equality target.*

Theorem 9404.12 (Process/far-end separation preserves axiom purity)**.** *Suppose every located-real or irrational-real read factors through its displayed process rows, and every far-end occurrence is recorded only through apophatic sameness and non-internalization rows. Then the separation between cataphatic process-names and the apophatic far-end role does not add an axiom to the BEDC substrate.*

Sketch. The process-name side uses only displayed carrier, classifier, modulus, ledger, transport, replay, package, and local naming rows. It does not consume a host real, quotient representative, choice function, or completion point. The far-end side uses only boundary names and refusal rows. It does not consume T as a kernel object, state, Hist constructor, global frame, or equality witness. Thus neither side supplies unsupported content to the substrate. The reading is therefore an instance of the externalized-not-assumed discipline of Definition 9400.4. □

9404.7 Closure

The compressed form is

$$\begin{aligned} \mathsf{IrrLocatedReal}(r) &\Longrightarrow \exists\alpha,\ \mathrm{Carry}(Z_\alpha, r), \\ \forall\alpha, \quad \mathrm{FarEnd}(Z_\alpha) &\equiv_{\mathrm{apo}} \mathsf{T}, \\ \neg\exists\alpha, \quad \mathsf{T} &\in Z_\alpha. \end{aligned}$$

Thus a located irrational is a positive generation on a definite axis, while T is the common non-local far-end role of admissible axes. The former may be named by its stream, modulus, regularity, classifier, and ledger. The latter may only be named as socket, boundary, and refusal of objecthood.

Concretized in §1933: $\mathsf{LocatedReal}^{\uparrow}$ realizes the cataphatic process-name side as finite stream, regular-rational, dyadic-ledger, located-enclosure, $\mathsf{Real}^{\uparrow}$ seal, transport, replay, provenance, and NameCert rows.

Concretized in §8101: $\mathsf{IrrationalReal}^{\uparrow}$ realizes rational value-axis refusal through finite Real source, rational candidate, dyadic tolerance, witness, regular-rational readback, transport, replay, provenance, and NameCert rows.

Concretized in §1061: $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ realizes the non-internalized far-end role as finite socket, boundary, GAP ledger, local-inscription, observer-history, supply-ledger, transport, replay, provenance, and NameCert rows.

Concretized in §1064: Apophatic fiber-far-end packets realize finite fiber, provenance, boundary-name, and non-internalization rows without exporting T as an object.

Chapter 9405

Information Strata and Non-Collapse

The word "axis" is useful as geometric prose, but it is not the strict object of the theory. The strict object is a non-collapse relation between information strata. A stratum may be a finite value layer, a process layer with stream and modulus data, a finite algebraic extension layer, a transcendental expression layer, or an apophatic far-end role. These strata are not made honest by drawing them as orthogonal coordinates. They are made honest by recording which carrier, classifier, ledger, and transport rows are available, and by refusing the retraction that would identify a higher stratum with a lower one.

9405.1 Value, process, and far-end strata

Definition 9405.1 (Information stratum)**.** *An* information stratum *is a BEDC presentation layer together with the rows needed to consume it. The basic strata used here are:*

$$\begin{aligned} L_0 &:= \textit{finite rational or dyadic value readback}, \\ L_1 &:= \textit{stream, modulus, regularity, location, and classifier data}, \\ T/\Omega &:= \textit{the apophatic far-end role of finite-readout fibers.} \end{aligned}$$

The first two are cataphatic strata: their objects are read by displayed rows. The last is apophatic: it is named by boundary sameness and non-internalization, not by a carrier element.

Definition 9405.2 (Finite shadow)**.** *For a process presentation $x \in L_1$ with sequence and modulus rows, its k-th finite shadow is*

$$\pi_k(x) := x_{\mathrm{seq}}(x_{\mathrm{mod}}(k)) \in L_0.$$

The map π_k is a finite readout request. It is not a retraction from the process stratum to the value stratum.

Definition 9405.3 (Non-collapse to a lower stratum)**.** *Let A be a stratum whose public reads include shadows in a lower stratum B. The predicate $\mathsf{NonCollapse}_B(a)$ means that no displayed B-object recovers a up to the classifier of A. For located real presentations over rational values, this specializes to*

$$\mathsf{NonCollapse}_{L_0}(x) :\Longleftrightarrow \neg\exists q : \mathsf{Rat}^{\uparrow},\ x \sim_{\mathsf{Real}^{\uparrow}} \eta(q),$$

where $\eta(q)$ is the degenerate located-real presentation with constant sequence q and modulus 0.

Lean4 (definition) `BEDC.Derived.NonCollapseInvariantUp.NonCollapseInvariant`
Lean4 (definition) `BEDC.Derived.NonCollapseInvariantUp.NonCollapseWitness`

Definition 9405.4 (No global lower recovery)**.** *For strata A and B with finite readout maps from A to B, a* global lower recovery *is a pair of displayed operations*

$$c : A \to B, \qquad r : B \to A$$

such that every $a : A$ is recovered by the composite:

$$a \sim_A r(c(a)).$$

The condition $\mathsf{NonCollapse}(A, B)$ *means that no such recovery is available from the displayed rows of the two strata.*

Theorem 9405.5 (Located irrationality is process non-collapse)**.** *A located irrational real has all of its finite rational shadows in L_0, but it is not recovered by any single L_0 value.*

Proof. The located-real carrier supplies the stream and modulus rows. Therefore Definition 9405.2 gives, for each k, a finite rational or dyadic observation in L_0.

Irrationality is the refusal of a rational value-axis collapse: there is no $q : \mathsf{Rat}^{\uparrow}$ whose degenerate located-real presentation classifies with the given located real under the $\mathsf{Real}^{\uparrow}$ classifier. Thus every finite shadow exists, while no lower-stratum point is a lossless recovery of the process. □

↪ variant `BEDC.Derived.NonCollapseInvariantUp.NonCollapseInvariant no rat retraction`

Corollary 9405.6 (Projection without retraction)**.** *The finite shadow maps $\pi_k : L_1 \to L_0$ are constructive, but the existence of these maps does not supply a general retraction of L_1 onto L_0.*

Proof. Each π_k is just a displayed finite read request. A retraction would assert that every process presentation can be recovered from a lower value object, contradicting Definition 9405.5 for located irrational presentations. □

Lean4 ✓ `BEDC.Derived.NonCollapseInvariantUp.NonCollapseWitness no rat retraction`

Theorem 9405.7 (Local non-collapse forbids global lower recovery)**.** *If some $a : A$ satisfies* $\mathsf{NonCollapse}_B(a)$*, then the finite shadow maps from A to B do not assemble into a global lower recovery of A from B.*

Proof. Suppose a global lower recovery c, r were available. Applying Definition 9405.4 to the particular object a gives

$$a \sim_A r(c(a)).$$

Thus the lower object $c(a) : B$ would recover a up to the classifier of A. This is exactly what $\mathsf{NonCollapse}_B(a)$ refuses. Hence the finite shadow maps may be consumed locally, but they do not provide a lossless reconstruction principle. □

9405.2 Algebraic and transcendental directions

Algebraic extension language gives one place where the geometric word "direction" can be made literal. Even there, the literal structure is linear independence over a base field, not automatic orthogonality. An inner product or bilinear form would have to be supplied separately before orthogonality could be asserted.

Definition 9405.8 (Finite algebraic direction)**.** *Let F be a field and let α be algebraic over F with minimal polynomial degree d. The algebraic direction generated by α is the finite extension carrier*

$$F(\alpha) = \left\{ a_0 + a_1\alpha + \cdots + a_{d-1}\alpha^{d-1} \mid a_i \in F \right\}.$$

Its strict content is the F-linear basis $1, \alpha, \ldots, \alpha^{d-1}$.

Theorem 9405.9 (Algebraic non-collapse is finite-dimensional)**.** *If α has degree $d > 1$ over F, then $F(\alpha)$ does not collapse to F, but it is still finitely generated as an F-vector space.*

Proof. The minimal polynomial degree gives the standard basis $1, \alpha, \ldots, \alpha^{d-1}$ for $F(\alpha)$ over F. If $\alpha \in F$, the minimal polynomial would have degree 1, contrary to $d > 1$. Hence the extension is genuinely larger than F. Since the displayed basis has d members, the non-collapse is finite-dimensional. □

Definition 9405.10 (Transcendental direction)**.** *If τ is transcendental over F, the expression layer $F(\tau)$ contains the infinite family*

$$1, \tau, \tau^2, \tau^3, \ldots.$$

This family is read as a transcendental direction only through its finite polynomial tests and expression ledgers; it is not the apophatic far-end role.

Theorem 9405.11 (Transcendental non-collapse is not the far end)**.** *For transcendental τ, the family $1, \tau, \tau^2, \ldots$ is F-linearly independent, but the resulting expression layer is still a carrier layer, not T/Ω.*

Proof. Any finite linear dependence among $1, \tau, \ldots, \tau^n$ would be a nonzero polynomial $p \in F[X]$ with $p(\tau) = 0$, contradicting transcendence. Thus the expression layer has infinitely many independent finite polynomial shadows.

Nevertheless $F(\tau)$ remains a mathematical carrier: its elements may be formed as expressions, compared by suitable relations, and transported by displayed ledgers. The apophatic far-end role has the opposite grammar. By Definition 9404.5, it is named only by $\equiv_{\text{apo}}$ and refuses object-level equality, membership, and function application. Hence transcendental non-collapse is not the far end. □

9405.3 Allowed folding and forbidden flattening

Definition 9405.12 (Dimension as information stratum)**.** *In this chapter,* dimension *means irreducible information stratum. A presentation has higher information dimension than a lower layer when its carrier, classifier, ledger, or transport obligations cannot be reconstructed from the lower layer's displayed objects.*

Principle 9405.13 (Finite folding is not infinite collapse)**.** *Finite quotient-like folds, such as residue classes modulo a displayed natural number, are not the same operation as a completion, supremum, or host-point collapse. A finite fold has finite representatives, a visible normal form, and a classifier ledger. An unwitnessed completion asks for an endpoint or point extracted from an infinite process or predicate family.*

Definition 9405.14 (Operation profile by information stratum)**.** *An operation has a* stratum profile *recording whether it preserves a stratum, requires a guard row, creates an extension layer, or asks for a bridge. In the real and algebraic fragments the intended profiles are:*

$$\begin{aligned} +, -, x^m &: \textit{finite layer-preserving operations when the algebra rows exist}, \\ \times &: \textit{layer-preserving bilinear combination under a multiplication ledger}, \\ / &: \textit{layer-preserving only with a displayed apartness-from-zero guard}, \\ x^{1/m} &: \textit{finite algebraic extension when the root is not already carried}, \\ \exp, \log &: \textit{process bridges requiring series, modulus, and branch ledgers}, \\ \mathrm{mod} n &: \textit{finite classifier fold with normal forms}, \\ \sup, \widehat{X},\ \textit{arbitrary completion} &: \textit{endpoint extraction requiring bridge data.} \end{aligned}$$

Theorem 9405.15 (Operation profiles separate folds from collapses)**.** *The finite fold profile of* mod$n$ *and the endpoint-extraction profile of completion or supremum are different BEDC obligations.*

Proof. A finite fold supplies a bounded carrier of representatives, a visible normal form, and a classifier ledger. Its consumer can inspect all relevant cases through finite rows.

An endpoint extraction from a completion, supremum, or arbitrary quotient does not have this shape. It asks a process family, predicate family, or compatibility ledger to produce a completed point. BEDC can consume such an endpoint only after the relevant modulus, witness, classifier transport, or NameCert bridge has been displayed. Therefore finite folding is an internal classifier operation, while unwitnessed endpoint extraction is a collapse boundary. □

Theorem 9405.16 (Classical point-line reading is a bridge)**.** *Reading value shadows, located processes, algebraic extensions, transcendental expression layers, and completion endpoints as points of one classical line is a useful bridge reading, not a kernel-local identification.*

Proof. The preceding results separate the strata. Located irrationality gives finite shadows without a rational-value retraction. Algebraic extension gives finite-dimensional non-collapse over a field. Transcendental extension gives infinitely many finite polynomial shadows while remaining a carrier layer. The apophatic far end refuses carrier membership altogether.

If all of these are consumed as points of one host line, several cross-stratum maps have been supplied: process to point, classifier to equality, predicate or process family to endpoint, and socket to element. Such maps may be studied as bridge data, but they are not present in the finite kernel merely because the geometric drawing uses one axis. □

Corollary 9405.17 (Axis prose is subordinate to non-collapse)**.** *Geometric axis language is legitimate only when the underlying NonCollapse, carrier, classifier, ledger, and bridge status have already been specified. In particular, algebraic extension supplies linear independence over the base field; orthogonality is an additional geometric structure, not an automatic consequence of adjoining a root.*

Proof. By Definition 9405.9, adjoining an algebraic element of degree $d > 1$ supplies a finite basis over the base field. The proof uses linear independence and spanning, not an inner product. By Definition 9405.16, any geometric compression of the strata must be read as bridge structure. Therefore axis prose is acceptable as orientation, but the invariant is non-collapse of information strata. □

Theorem 9405.18 (Axiom purity preserves information strata)**.** *The zero-axiom discipline of BEDC is the discipline of not treating a lower-stratum shadow as the higher-stratum object itself.*

Proof. The $\mathsf{LocatedReal}^{\uparrow}$ route preserves stream, modulus, regularity, classifier, and ledger rows rather than replacing them by a quotient real or host completion point. The $\mathsf{IrrationalReal}^{\uparrow}$ route records refusal of a rational collapse rather than deleting the located-real process surface. The real-completion route seals $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ data through displayed countable-name and classifier rows rather than importing a host endpoint. The apophatic route records T only as boundary sameness and non-internalization, never as a kernel object.

Each case keeps the relevant carrier, classifier, ledger, and bridge status visible. Thus axiom purity is not an extra metaphysical rule; it is the local refusal to flatten process data into points, classifiers into equality, predicate families into endpoints, or sockets into elements without a displayed certificate. □

Concretized in §1933: $\mathsf{LocatedReal}^{\uparrow}$ realizes the process stratum as finite stream, regular-rational, dyadic-ledger, located-enclosure, Real seal, transport, replay, provenance, and NameCert rows.

Concretized in §8101: $\mathsf{IrrationalReal}^{\uparrow}$ realizes rational value-axis non-collapse through displayed rational-candidate refusal and Real classifier rows.

Concretized in §2109: $\mathsf{AlgebraicReal}^{\uparrow}$ realizes finite algebraic non-collapse as polynomial-root, finite-basis, Real-seal, transport, replay, provenance, and NameCert data.

Concretized in §1061: $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ realizes the apophatic far-end role as a non-internalized socket rather than a carrier element.

Concretized in §1064: Apophatic fiber-far-end packets realize finite fiber, provenance, boundary-name, and non-internalization rows without exporting T as an object.

Concretized in §4212: Apophatic socket stacks are realized as finite boundary/refusal NameCert packets.

Chapter 9406

The audit-map family: a BEDC methodology

The BEDC.MetaCIC material is not a single opaque theorem bundle. It is a family of Lean substrate modules, paper audit maps, obstruction records, assembly chapters, and discharge-route chapters whose purpose is to keep the project's meta-theory readable at module granularity. This chapter names that family as a methodology.

Concretized in §806: Audit-map family methodology is realized as a finite BHist NameCert packet for positive, conditional, obstruction, frontier, and cross-map consumer rows.

Concretized in §823: Audit-map concrete inventories realize the family-level established, conditional, obstruction, frontier, and consumer rows as finite NameCert data.

The audit-map family sits beside chapter 9400 and chapter 9389. Apophatic naming says that an open dependency must have a stable name rather than a hidden status. Generator-closure discipline says that a proof may range only over the authorized generator whose closure is displayed. The audit-map family is the third concrete application: every major MetaCIC substrate is required to publish its established content, conditional content, obstruction content, and frontier.

9406.1 The setup

BEDC.MetaCIC is distributed across several formal modules: subject reduction, confluence, normalisation, substitution, decidable checking, typed examples, beta reduction, and closure preservation. The modules do not all have the same closure status. Some nodes are unconditional. Some are conditional on an explicit interface. Some expose an obstruction theorem. Some are examples or boundary checks that prevent a nearby over-reading.

A paper chapter that merely announced "MetaCIC is partially formalised" would lose the important information. The reader would not know which substrate exports usable theorems, which substrate exports a parameterised route, which substrate exports a no-go result, and which substrate is needed by a later assembly. BEDC's apophatic naming discipline rejects that kind of blur. Each open cell has to be visible.

The audit-map family is the systematic answer. Each major MetaCIC substrate gets a paper map. The map says what the Lean substrate currently establishes, what it establishes only under named parameters, what it blocks, and how its frontier connects to the rest of the consistency path. The family is therefore not a retrospective aside. It is part of the method by which BEDC prevents partial closure from turning into implicit closure.

9406.2 What an audit map is

Definition 9406.1 (Audit map)**.** *An* audit map *is a paper chapter focused on one Lean substrate submodule. It records the checked inventory, the conditional inventory, the obstruction inventory, and the cross-module frontier of that submodule without claiming that the inventory has closed the neighbouring modules.*

The definition has several layers.

First, the unit is a paper chapter, not a footnote. The chapter format matters because each substrate has enough structure to require its own setup, local vocabulary, and boundary statement.

Second, the focus is one Lean substrate submodule or one tightly bounded assembly. A confluence audit map is about confluence. A substitution audit map is about closed syntax algebra. A consistency assembly map is about the normal-form consistency branch and the subject-reduction transport boundary. The point is module-level granularity.

Third, established theorems are listed by Lean-target references in the local map. Those references are usually rendered as variants because the map is an inventory site rather than the canonical primary theorem site. This keeps the paper honest about what the Lean kernel actually checks while avoiding a second primary claim for the same formal object.

Fourth, conditional or parameterised theorems are not weakened into prose. A conditional diamond remains a conditional diamond. A subject-reduction route that needs a discharge bundle remains a route that needs that bundle. A normalisation theorem mediated by candidate evidence remains mediated by that evidence.

Fifth, obstruction and no-go results are first-class entries. The subject reduction obstruction chapter is not a failure appendix. It records the closed application obstruction and the exact interface needed to move past it. That is BEDC's apophatic naming discipline operating inside formal meta-theory.

Sixth, each map names its frontier and cross-module dependencies. The reader can see which facts are consumed by synthesis, which facts are local sanity checks, and which facts would be needed before a stronger assembly is allowed.

9406.3 The nine audit map chapters of BEDC.MetaCIC

The family has nine primary audit-map chapters.

1. chapter 9377 records the subject reduction obstruction. It names the dependent-codomain and closed-application pressure point, records the parameterised preservation interface, and prevents unparameterised closed subject reduction from being treated as available.

2. chapter 9375 records the closed-MetaCIC consistency assembly. It separates closed-normal consistency from full closed consistency and marks subject reduction as the transport boundary between the two.

3. chapter 9378 records the confluence substrate. It distinguishes reduction algebra, atom fragments, closed-normal fragments, and the substitution-sensitive diamond route.

4. chapter 9383 records the normalisation substrate. It shows the candidate-mediated strong-normalisation route and keeps candidate-free global normalisation outside the present claim.

5. chapter 9380 records the substitution substrate. It supplies closed shift, closed substitution, and closed composition fragments without converting them into beta typing preservation.

6. chapter 9379 records the decidable-checking substrate. It exposes executable equality and type-checking surfaces while refusing to call them a global decision oracle for meta-theory.
7. chapter 9382 records the typed-example substrate. It treats examples as checked calibration surfaces rather than as silent evidence for arbitrary closed terms.
8. chapter 9384 records the beta-reduction substrate. It separates one-step beta structure, star closure, normality, and transport interfaces needed by neighbouring maps.
9. chapter 9381 records the closure-preservation substrate. It tracks which generators preserve closedness and which preservation statements belong to other modules.

The family also has four companion meta chapters. chapter 9385 reads the maps together as the closed-CIC critical path. chapter 9386 consolidates the open obligations so the same frontier is not scattered across prose. chapter 9376 elevates the strongest available closed-normal result as a main-result node. chapter 9374 records the concrete routes by which the subject-reduction boundary could be discharged.

Taken together, these chapters form a substrate-level inventory. The inventory is deliberately redundant in one sense: the same boundary can appear in a local map, in synthesis, and in open problems. That redundancy is controlled. It keeps the boundary visible from the module view, the critical-path view, and the obligation view.

9406.4 Common structure across audit maps

The maps use a shared writing structure.

Setup. The map names the Lean files, relations, predicates, and interfaces that form the local substrate.

Established. The map lists the checked results the paper may cite directly.

Conditional. The map records parameterised theorems and the exact inputs they require.

Obstruction. The map records counterexamples, impossibility results, or shape restrictions that block a stronger reading.

Frontier. The map states the strongest nearby claim that remains outside the present substrate.

Cross-reference. The map identifies the neighbouring maps that consume or supply its facts.

Boundary. The map ends by stating what the chapter does not claim.

Principle 9406.2 (Audit-map template)**.** *An audit map is complete only when it records positive content, conditional content, obstruction content, frontier content, and cross-module use. Omitting any one of these parts turns a partial-closure map into an ambiguous progress summary.*

This template is intentionally stricter than an ordinary literature overview. It is meant to be read against the Lean substrate and against the paper-Lean audit. A result that is checked but local remains local. A parameter remains a parameter. A blocked route remains blocked. A cross-module use must point to the map that supplies the relevant node.

9406.5 Methodology versus other disciplines

The audit-map family differs from a cataphatic results-first discipline. A cataphatic presentation often foregrounds the main theorem and leaves adjacent work implicit. BEDC cannot use that style for MetaCIC because the important information is the shape of the partial closure: which generators are closed, which transports are conditional, and which obstructions are theorem-level facts.

The family also differs from silent proof holes. A hidden `sorry`, an `admit`, or an unrecorded host assumption would make the map dishonest. BEDC forbids that move. The paper-side analogue is equally strict: an open obligation may be named, routed, and studied, but it may not be treated as internal theorem content.

Finally, the family differs from a single high-level retrospective. A single summary can help orientation, but it cannot replace module-level audit. The BEDC pattern is module-level maps plus cross-module synthesis. The local maps preserve granularity; the synthesis shows how the local nodes compose or fail to compose.

9406.6 When to use this methodology

The audit-map methodology is appropriate when a formalisation project has many submodules, each with a different closure state. It is especially useful for meta-theory, where a theorem in one module is often a premise, obstruction, or calibration check for another module. Subject reduction, confluence, normalisation, substitution, decidability, examples, beta reduction, closure preservation, and consistency assembly are exactly that kind of landscape.

It is not the right tool for every theorem. A single self-contained result with a direct proof does not need a family of audit maps. In that case the paper can state the theorem, give the proof, and cite the Lean target at the primary site. The audit-map family is for a different shape: distributed partial closure with named obligations and cross-module dependencies.

9406.7 Audit-map family as apophatic naming in action

chapter 9400 gives the general rule: when a dependency cannot be generated, defined, certified, or discharged inside the displayed substrate, the dependency must be named. The audit-map family is that rule applied to MetaCIC formalisation.

Each audit map is a collection of apophatic names at module scale. It names the open obligations, obstruction points, conditional interfaces, and frontier claims that would otherwise disappear into prose. The family as a whole is a substrate-level inventory of those names. It tells the reader where the project has generator-internal closure and where the project has an exposed socket.

This is why the methodology pairs with chapter 9389. Generator closure says that a certificate ranges over the objects produced by a displayed generator. The audit-map family asks the same question at chapter scale: which generator, relation, or interface licenses the local claim, and where does that licence stop?

9406.8 Boundary

The audit-map family does not solve any substantive proof obligation by naming it. It does not prove subject reduction. It does not turn conditional confluence into unconditional confluence. It

does not turn candidate-mediated normalisation into a candidate-free theorem. It does not lift closed-normal consistency to full closed consistency.

Its role is process discipline, not result discipline. It makes the proof state explicit enough that later work can cite the right node, refuse the wrong node, and see the exact dependency that would have to be supplied. That is a BEDC methodology: not silence about open cells, not hidden assumptions, and not blanket confidence, but a family of audit maps whose open names remain visible.

Concretized in §808: Audit-map templates are realized as finite BHist packets exposing setup, established, conditional, obstruction, frontier, cross-map route, boundary, provenance, and local NameCert rows.

Concretized in §810: Audit-map family ledgers realize module-level audit maps as finite BHist, hsame, Cont, Pkg, and NameCert rows with explicit non-escape from hidden closure.

Concretized in §811: The audit-map family methodology is realized as a finite MetaCIC audit-family NameCert packet over local maps, synthesis rows, obstruction rows, frontier rows, and non-escape ledgers.

Concretized in §812: Audit-map frontier indices are realized as finite BHist packets over local maps, neighbouring-map links, obstruction rows, frontier rows, synthesis consumers, hsame, Cont, Pkg, and NameCert rows.

Concretized in §813: The audit-map family is realized as a finite NameCert methodology packet with a SubstitutionAuditMap handoff.

Concretized in §814: The audit-map family methodology is realized as a finite coverage ledger NameCert.

Concretized in §815: The audit-map family methodology is realized as a finite obligation-ledger NameCert packet over positive, conditional, obstruction, frontier, and cross-module audit rows.

Concretized in §816: A finite NameCert packet records the audit-map family rows as concrete BHist carrier, classifier, obstruction, frontier, and cross-module-use data.

Concretized in §817: The audit-map family is realized as a finite NameCert packet for inventory, obstruction, frontier, and cross-map routing.

Concretized in §825: The audit-map template packet realizes the methodology as finite positive, conditional, obstruction, frontier, and sibling-use rows.

Concretized in §826: Audit-map obstruction sockets realize obstruction and frontier rows as finite BHist, hsame, Cont, Pkg, and NameCert packets with non-escape from hidden closure.

Concretized in §833: Audit-map frontier packets realize the audit-map family as finite checked, conditional, obstruction, frontier, cross-map, provenance, and NameCert rows.

Concretized in §839: Audit-map dependency weaves realize cross-map frontier routing as finite BHist, obstruction, synthesis-consumer, hsame, Cont, Pkg, and NameCert rows.

Chapter 9407

BEDC GroundCompiler module audit map

9407.1 The setup

`BEDC.GroundCompiler` is the main Lean formalisation of the BEDC self-compilation path. It is parallel to `BEDC.MetaCIC` in project role, but not in subject matter. `BEDC.MetaCIC` formalises a closed CIC substrate: terms, reduction, typing-adjacent interfaces, and the consistency critical path. `BEDC.GroundCompiler` formalises the self-compile surface: event flows, source channels, generated recognizers, certificate gates, address analysis, cannot-claim ledgers, and streaming compiler discipline.

The audit question is therefore different from the MetaCIC audit maps in chapter 9406. The local issue is not whether CIC reduction has a global confluence or preservation theorem. The local issue is whether a compiler-facing artifact is allowed to count as a BEDC input, whether a displayed code channel is lossless at the event-flow layer, whether generated recognizers and certificate gates mediate exports, and whether reports or motifs can silently replace proof or certificate evidence.

This chapter records the GroundCompiler module as an audit map. It is an inventory site. It cites checked Lean targets as variants, separates Prop statement cells from their proof theorems, names the open cells, and states the boundary of the self-compilation claim.

9407.2 Submodule inventory

The GroundCompiler directory contains the following Lean sibling files.

File group	Audit role
`EventFlow`, `SourceChannel`, `ChannelEncoding`, `SourceNormalizer`	raw event-flow surface, source/channel separation, legal stream encoding, and normal-address discipline
`PackageGenerated`, `NameCertGenerated`, `DerivCertGenerated`, `TheoremGenerated`, `ChapterFlow`, `ChapterManuscript`	generated package, name-certificate, derivation-certificate, theorem, and chapter recognizer layers
`RecognizerFlows`, `SemanticMotif`, `MotifReportPrototype`, `MotifReportCounts`	recognition evidence, motif occurrence, motif report structure, and non-evidence boundaries
`MetricsFlow`, `MetricsP4Pipeline`, `MetricsP4Adequacy`, `AnalysisPipeline`	metric reports, P4 adequacy surfaces, analysis stages, and report conservativity
`SelfHostingCompilerFlow`, `SelfHostingLadder`, `SelfHostingReports`	self-hosting compiler candidates, hierarchy coverage, bootstrap boundaries, and reporting layers
`ImplementationInterface`, `ImplementationAdequacy`, `ProgrammaticRealization`, `MinimalPrototype`	implementation-facing interfaces, adequacy wrappers, and prototype witnesses
`CaseStudies`, `HigherCaseStudies`, `PackageNameCertPrototype`, `TheoremProofPrototype`, `DerivCertReports`, `SourceReport`	case-study and report surfaces used to calibrate what evidence may and may not license
`MainTheorems`	top-level compiler audit statements and theorem wrappers over the checked submodules

This split mirrors the methodology of the MetaCIC audit maps, but the exported facts are compiler-layer facts. The file tree is not a single theorem with hidden premises. It is a ledger of what the self-compilation path may treat as input, output, recognition evidence, certificate evidence, metric evidence, and explicit non-evidence.

9407.3 Core statement defs

`MainTheorems.lean` exposes three top-level Prop statement cells.

- ↪ variant `BEDC.GroundCompiler.MainTheorems.GlobalConservativityStatement`

  records event-flow conservativity, legal encoding of flow images, exclusion of structural hidden inputs, metric conservativity, and the non-input status of host package, name-certificate, derivation-certificate, and closure-certificate data. It is paired with

  ↪ variant `BEDC.GroundCompiler.MainTheorems.global conservativity`

.

- ↪ variant BEDC.GroundCompiler.MainTheorems.CompilerLayerAddressAnalysisStatement

  records channel round-trip, legal-stream completeness, code-not-proof, metric-not-certificate, and global conservativity content. It is paired with

  ↪ variant BEDC.GroundCompiler.MainTheorems.compiler layer address analysis layer

  .

- ↪ variant BEDC.GroundCompiler.MainTheorems.NoHiddenInputStreamingCompilerStatement

  records the streaming compiler surface: formal event-flow inputs, legal encoding and decoding, hidden host-structure exclusion, recognizer generatedness, certificate-mediated export, theorem-code and chapter-code bijections, classifier quotient limits, source-channel separation, metric conservativity, self-hosting removal of hidden compiler input, visible bootstrap boundary, and global conservativity. It is paired with

  ↪ variant BEDC.GroundCompiler.MainTheorems.no hidden input streaming compiler

  .

The important audit distinction is that these are not statement-only names covered by a vacuous theorem. Each Prop cell above has a companion theorem whose conclusion is the cell itself. The proof terms compose existing GroundCompiler lemmas and definitions. Thus the statement defs act as named aggregate interfaces, while the theorem names are the checked aggregate witnesses.

Within the inspected top-level file, there is no unpaired `*Statement` Prop cell of the kind that would have to be cited only as a paper-side target. GroundCompiler still has many lower-layer definitions and interfaces, but the three named aggregate statements above are theorem-paired inside `MainTheorems.lean`.

9407.4 Established theorems

The checked GroundCompiler surface has several core theorem families.

- The no-hidden-input and channel facts establish that structural hidden compiler data do not become formal input and that legal event-flow encoding is lossless at the channel layer:

  ↪ variant BEDC.GroundCompiler.MainTheorems.no hidden input

  ↪ variant BEDC.GroundCompiler.MainTheorems.channel bijection

  ↪ variant BEDC.GroundCompiler.MainTheorems.channel code lossless

  .

- The code/proof and source/channel facts prevent readable code, substrings, and source-carry transformations from being promoted into theorem or event evidence:

  ↪ variant BEDC.GroundCompiler.MainTheorems.code not proof

  ↪ variant BEDC.GroundCompiler.MainTheorems.source channel separation

  ↪ variant BEDC.GroundCompiler.MainTheorems.carry not channel rewrite

  .

- The generated-structure and recognizer facts keep packages, certificates, chapters, theorem identifiers, manifests, and host encodings outside the formal compiler input set unless mediated by generated recognition evidence:

  ↪ variant BEDC.GroundCompiler.MainTheorems.structure emergence

  ↪ variant BEDC.GroundCompiler.MainTheorems.recognizer generatedness

  ↪ variant BEDC.GroundCompiler.MainTheorems.accepted export

  .

- The theorem-code and chapter-code layers establish canonical code round-trips while refusing to identify proposition text with proof evidence or chapter topic with chapter code:

  ↪ variant BEDC.GroundCompiler.MainTheorems.theorem code bijection

  ↪ variant BEDC.GroundCompiler.MainTheorems.theorem code not proof

  ↪ variant BEDC.GroundCompiler.MainTheorems.chapter code bijection

  ↪ variant BEDC.GroundCompiler.MainTheorems.topic not chapter code

  .

- The classifier, metric, motif, and bootstrap layers record the local limits of address analysis and reporting:

  ↪ variant BEDC.GroundCompiler.MainTheorems.classifier quotient many to one

  ↪ variant BEDC.GroundCompiler.MainTheorems.normal address requires ledger

  ↪ variant BEDC.GroundCompiler.MainTheorems.metric conservativity

  ↪ variant BEDC.GroundCompiler.MainTheorems.similarity not identity

  ↪ variant BEDC.GroundCompiler.MainTheorems.declared bootstrap boundary

  .

- The top-level aggregate theorems package the module-facing reading:

  ↪ variant BEDC.GroundCompiler.MainTheorems.global conservativity

  ↪ variant BEDC.GroundCompiler.MainTheorems.compiler layer address analysis layer

  ↪ variant BEDC.GroundCompiler.MainTheorems.no hidden input streaming compiler

  .

These theorems make GroundCompiler a checked self-compilation audit layer. They do not make the compiler a source of new mathematical axioms. They show which event-flow, code, recognizer, certificate, metric, motif, and bootstrap claims are licensed inside the displayed compiler substrate.

9407.5 Channel boundary discipline

The channel layer has one especially sharp audit role: it turns an EventFlow into a single display string without erasing the event boundaries that make the flow a formal input. The relevant encoding is the Zeckendorf-safe channel of chapter 9208. Its body map sends raw 0 to channel 0 and raw 1 to channel 10, and each event ends with the channel terminator 11. Thus the legal channel language is

$$\mathsf{LegalZStream} = \big((0 \mid 10)^* 11\big)^*.$$

The audit content is not the informal observation that this language is prefix-readable. It is the conjunction of four checked boundaries. First, Definition 9208.6 proves that no encoded body contains adjacent 11, and Definition 9208.7 therefore identifies the first adjacent 11 as the event terminator. Second, Definition 9208.16 and Definition 9208.17 prove event-level and flow-level readback. Third, Definition 9208.19 fixes the exact surface on which

$$\mathsf{EventFlow} \cong \mathsf{LegalZStream}$$

is allowed to be read. Fourth, Definition 9208.22 separates the legal channel from host parsers, manifests, package objects, theorem identifiers, and other structural hidden input.

This boundary also explains why the event-flow layer cannot be replaced by a bare bitstream. The erasure map of Definition 9207.7 forgets event segmentation, and Definition 9207.8 therefore refuses any decoder that tries to reconstruct every event flow from its flattened mark stream. The channel encoder repairs this only by making the boundaries explicit as part of the legal display language. It does not license a boundary-free input format.

The source-level Zeckendorf classifiers remain separate. $\mathsf{ZNormal}$, ZCarry, and the displayed carry row $011 \rightsquigarrow 100$ are relations on recognized history flows. They are not substring rewrites on a channel stream. The source–channel separation theorem Definition 9209.27 is the audit fence: a consumer may decode a legal stream to an event flow, apply a licensed source-level normalizer to that event flow, and compile the result again; it may not rewrite channel glyphs directly and then treat the result as if it were a recognized source event.

Consequently the GroundCompiler audit map admits the following channel reading and no stronger one. The encoding $0 \mapsto 0$, $1 \mapsto 10$, $\mathrm{End} \mapsto 11$ is a conservative, self-delimiting display of finite event-flow boundaries. It is not a $\mathsf{NameCert}$, not a theorem code, not a proof object, not a gap ledger, not a source-level Zeckendorf carry proof, and not evidence for entropy, continuum, topology, geometry, or physical space emergence. Those readings require separately named bridges and separately displayed certificate surfaces.

Concretized in §829: GroundCompiler event-flow audit packets make the lossless source/channel and no-hidden-input boundary a concrete NameCert surface.

Concretized in §830: The GroundCompiler event-flow audit route is realized as a finite channel, recognizer, certificate-gate, and non-evidence NameCert packet.

Concretized in §2258: GroundCompiler audit routes are realized as finite event-flow, MetaCIC-boundary, no-hidden-input, transport, replay, provenance, and local NameCert rows.

Concretized in §1094: GroundCompiler flow-level round trips are realized as finite encoding, decoding, legal-stream, transport, route, provenance, and NameCert rows.

Concretized in §6872: GroundCompiler audit-map closures realize compiler event-flow, source-channel, recognizer, certificate-gate, metric-report, and non-evidence rows as finite NameCert data.

9407.6 Relation to MetaCIC

GroundCompiler and MetaCIC cooperate, but their audit maps must remain separate. GroundCompiler executes the BEDC self-compile route from source-like event flows to generated recognizers, code ledgers, certificate gates, and cannot-claim rows. MetaCIC formalises the closed CIC substrate in which reduction, normalisation, confluence, and consistency boundaries are studied.

The relation is therefore complementary. GroundCompiler can say that a compiler-facing artifact is generated, encoded, decoded, ledgered, or excluded as a hidden input. MetaCIC can

say that a closed term, reduction path, or candidate-mediated normalisation route has a particular meta-theoretic status. Neither side replaces the other. A GroundCompiler theorem about code not being proof is not a MetaCIC subject-reduction theorem. A MetaCIC confluence bridge is not a GroundCompiler certificate gate.

This separation is the same discipline used by the audit-map family: each map exports its own local content and names its own frontier. Cross-reference is allowed; substitution of one module's theorem for another module's missing edge is not.

9407.7 Open obligations and conditional statements

The visible open cells are compiler-layer cells, not closed-CIC proof cells. They include the distinction between self-hosting as a supplied compiler-flow condition and full removal of hidden compiler input; the distinction between a metric or motif report and certificate evidence; the distinction between a theorem code channel and a proof; and the distinction between a classifier quotient and raw event-flow identity.

The theorem

```
↪variant BEDC.GroundCompiler.MainTheorems.self hosting removes hidden compiler
```

is conditional on a self-hosted compiler flow and hierarchy coverage. It is a valid route from those inputs to the no-hidden-compiler conclusion, but it does not assert that every candidate compiler already satisfies those inputs. Similarly,

```
↪variant BEDC.GroundCompiler.MainTheorems.cannot claim registry mandatory
```

requires registry adequacy before the listed cannot-claim ledger rows are available.

Those conditions are useful precisely because they are explicit. They prevent the paper from reading reports as proof, motifs as mature objects, code as acceptance, source substrings as decoded events, or self-hosting prose as a discharged compiler tower.

9407.8 Apophatic framing

The open cell for GroundCompiler is the *compiler-layer evidence gap*. The module can check that event-flow code is legal and lossless, that hidden host structures are excluded from formal input, that generated recognizers mediate recognition evidence, and that certificate gates mediate accepted exports. It also says what those facts do not license.

That is the apophatic role of this audit map. The chapter gives names to the non-claims: code is not proof, report is not evidence, motif similarity is not object identity, classifier quotient is not raw equality, and conditional self-hosting is not an unconditional compiler tower. These names prevent the self-compilation path from acquiring silent extra power through prose.

9407.9 Boundary

This chapter does not solve the remaining GroundCompiler obligations. It does not prove that every compiler candidate is self-hosted. It does not turn metric reports, motif reports, theorem code, or chapter code into proof or certificate evidence. It does not collapse classifier equality into raw event-flow equality. It does not replace any MetaCIC audit map.

The allowed reading is narrower and stronger: GroundCompiler supplies a checked compiler-layer audit surface for BEDC self-compilation, with explicit theorem witnesses for conservativity,

address analysis, and no-hidden-input streaming compilation. Everything beyond that surface remains named at the boundary.

Concretized in §827: GroundCompiler audit packets realize the compiler-layer audit map as finite event-flow, source-channel, recognizer, certificate-gate, report-boundary, and no-hidden-input NameCert rows.

Concretized in §820: GroundCompiler recognizer and non-evidence rows are packaged as a finite audit packet.

Concretized in §828: The recognizer-boundary packet makes the GroundCompiler audit-map evidence boundary a finite NameCert carrier.

Concretized in §821: GroundCompiler generated recognition is realized as a finite BHist NameCert packet with accepted-export and finite-trace handoff rows.

Concretized in §822: GroundCompiler verdict rows are realized as a finite NameCert packet rather than as host-side audit prose.

Concretized in §832: GroundCompiler evidence boundaries are realized as finite BHist NameCert packets separating event-flow evidence, generated recognizers, compiler reports, code channels, and non-input ledgers.

Concretized in §834: The GroundCompiler audit map is realized as a finite route-compiler NameCert packet.

Concretized in §831: GroundCompiler audit evidence is realized as a finite NameCert witness packet with report and refusal non-escape rows.

Concretized in §819: Legal event-flow channels are realized as a finite NameCert packet with lossless decode and hidden-input exclusion rows.

Concretized in §836: GroundCompiler audit maps are realized as finite NameCert packets over theorem inventory, compiler-layer frontiers, generated recognizer rows, report-boundary rows, and non-escape ledgers.

Concretized in §1048: GroundCompiler recognizer flows are realized as finite event-flow, source-channel, generated-recognizer, certificate-gate, non-evidence, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1360: GroundCompiler audit-map route budgets are realized as finite event-flow, source-channel, recognizer, certificate-gate, report-boundary, and cannot-claim NameCert rows.

Chapter 9408

Theorem-DNA and Theorem Complexity Scoring

The GroundCompiler theorem recognizer does not treat a theorem as a single statement string. In `TheoremGenerated.lean`, theorem recognition is role-complete: the recognized flow must expose statement, dependencies, proof, certificates, ledger, status, canonical site, and closing seal. This chapter packages that role-complete reading as theorem-DNA. The word DNA names a typed locus profile over event flows; it does not import biological structure.

9408.1 Role-complete theorem flows

Definition 9408.1 (Theorem candidate and recognizer)**.** *A theorem candidate is an event flow* $T : \mathsf{EventFlow}$*. A generated theorem recognizer is a generated recognizer flow* R*, and its recognition relation is written*

$$\mathsf{RecognizesThm}(R, T).$$

Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.TheoremCandidateFlow`
Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.GeneratedTheoremRecognizer`
Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.TheoremRecognitionRelation`

Definition 9408.2 (Theorem role loci)**.** *The theorem role profile is the eight-locus family*

$$\mathcal{R}_\Theta = \{\mathsf{statement}, \mathsf{dependencies}, \mathsf{proof}, \mathsf{certificates}, \mathsf{ledger}, \mathsf{status}, \mathsf{canonicalSite}, \mathsf{closingSeal}\}.$$

For a theorem candidate T*, a recognizer* R*, a subflow* G*, and a role* $\rho \in \mathcal{R}_\Theta$*, write*

$$\mathsf{Role}_R(T, G, \rho)$$

for the role-subflow predicate assigning G *to the role* ρ *inside the recognized theorem flow.*

Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.TheoremRole`
Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.TheoremRoleSubflow`

Definition 9408.3 (Weak theorem-DNA)**.** *For a recognizer* R *and theorem candidate* T*, a weak theorem-DNA is an eight-tuple*

$$D_R(T) = (G_{\mathsf{statement}}, G_{\mathsf{dependencies}}, G_{\mathsf{proof}}, G_{\mathsf{certificates}}, G_{\mathsf{ledger}}, G_{\mathsf{status}}, G_{\mathsf{canonicalSite}}, G_{\mathsf{closingSeal}})$$

such that each component is assigned to its matching role:

$$\mathsf{Role}_R(T, G_\rho, \rho) \qquad \textit{for every } \rho \in \mathcal{R}_\Theta.$$

The family of such profiles is denoted $\mathsf{DNA}_{\mathsf{weak}}(R, T)$.

Definition 9408.4 (Anchored and sound theorem-DNA)**.** *A weak theorem-DNA is anchored when every role subflow is also a source subflow of T. It is sound when the recognizer participates in a sound theorem-flow recognition of T.*

Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.TheoremSourceSubflow`
Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.SoundTheoremFlow`
Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.AcceptedTheoremFlow`

Theorem 9408.5 (Accepted theorem flows have theorem-DNA)**.** *If T is an accepted theorem flow, then there are a generated theorem recognizer R and a weak theorem-DNA $D_R(T)$.*

Proof. Accepted theorem flow means that some recognizer R satisfies $\mathsf{SoundTheoremFlow}(R, T)$. Sound theorem flow contains complete theorem flow recognition. Complete recognition unfolds to the existence of the eight role subflows for statement, dependencies, proof, certificates, ledger, status, canonical site, and closing seal. These eight witnesses form the required theorem-DNA tuple. □

Corollary 9408.6 (A theorem is not a single-locus object)**.** *An accepted theorem flow is not determined by the statement locus alone at the recognition layer. The complete profile has eight role loci.*

Proof. The existence theorem supplies all eight loci, and complete theorem-flow recognition requires all of them. □

9408.2 Statement, code, and quotient boundaries

Theorem 9408.7 (Statement alone is not theorem-DNA)**.** *A statement role subflow without a proof role subflow does not establish theoremhood.*

Proof. The checked theorem `statement_alone_not_theorem` states that a candidate with a statement role, but with no proof role for every recognizer recognizing that candidate, is not a theorem flow. Thus the statement locus is only one role in the theorem-DNA profile. □

↪ variant `BEDC.GroundCompiler.TheoremGenerated.statement alone not theorem`

Theorem 9408.8 (Shared statement does not determine theorem flow)**.** *The same statement subflow can occur as the statement role of two distinct theorem candidate flows.*

Proof. This is exactly the content of the checked witness `same_statement_multiple_flows`. The theorem-DNA profile therefore cannot be collapsed to proposition text. □

↪ variant `BEDC.GroundCompiler.TheoremGenerated.same statement multiple flows`

Definition 9408.9 (Theorem code)**.** *The code of a theorem candidate T is its GroundCompiler flow encoding:*

$$\mathsf{Code}(T) = \mathsf{FlowEncoding}(T).$$

Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.TheoremCode`

Theorem 9408.10 (Theorem code is injective but not proof)**.** *Theorem code equality refines theorem-flow equality, but legal theorem code does not by itself supply proof-sound theorem recognition.*

Proof. The injectivity part is the checked theorem `theorem_code_injective`. The non-proof part is the checked theorem `theorem_code_is_not_proof`, which exhibits legal theorem code decoding to a candidate with no proof-sound theorem recognition. Code is therefore a lossless flow address, not the complete theorem-DNA profile. □

↪ variant `BEDC.GroundCompiler.TheoremGenerated.theorem code injective`
↪ variant `BEDC.GroundCompiler.TheoremGenerated.theorem code is not proof`

Definition 9408.11 (Theorem phenotype)**.** *Given a theorem classifier relation Q on theorem candidate flows, two theorem flows have the same phenotype when $Q(T, U)$ holds. The phenotype class of T is*

$$[T]_Q = \{U \mid Q(T, U)\}.$$

The concrete theorem-DNA profile is the genotype layer; the classifier class is the phenotype layer.

Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.TheoremClassifierRelation`
Lean4 (definition) `BEDC.GroundCompiler.TheoremGenerated.TheoremClassifierQuotient`

Theorem 9408.12 (Phenotype can fold distinct code)**.** *If a theorem classifier relates two distinct theorem flows, it can identify flows with distinct theorem code.*

Proof. The checked theorem `classified_theorem_objects_not_code_bijective` states that a classifier quotient relating distinct theorem flows collapses distinct theorem code. Thus genotype and phenotype are different audit layers. □

↪ variant `BEDC.GroundCompiler.TheoremGenerated.classified theorem objects not code bijective`

9408.3 Mass vectors and weighted score

Definition 9408.13 (Event-flow mass)**.** *For a raw event w, let $|w|_{\mathsf{raw}}$ be its mark count. For an event flow*

$$S = (w_0, \ldots, w_{n-1}),$$

define

$$|S|_{\mathsf{flow}} = n + \sum_{i=0}^{n-1} |w_i|_{\mathsf{raw}}.$$

The summand n records event boundaries. Boundary erasure is not a lossless operation at the event-flow layer.

Definition 9408.14 (DNA mass vector)**.** *For a theorem-DNA profile $D_R(T)$, define its mass vector by*

$$\mathbf{m}(D_R(T)) = (m_{\mathsf{statement}}, m_{\mathsf{dependencies}}, m_{\mathsf{proof}}, m_{\mathsf{certificates}}, m_{\mathsf{ledger}}, m_{\mathsf{status}}, m_{\mathsf{canonicalSite}}, m_{\mathsf{closingSeal}}),$$

where $m_\rho = |G_\rho|_{\mathsf{flow}}$.

Definition 9408.15 (Complexity vector)**.** *The recognizer overhead is* $\omega(R) = |R|_{\mathsf{flow}}$*. The theorem-DNA complexity vector is*

$$\mathsf{ComplexVec}(R, D_R(T)) = (m_{\mathsf{statement}}, m_{\mathsf{dependencies}}, m_{\mathsf{proof}}, m_{\mathsf{certificates}}, m_{\mathsf{ledger}}, m_{\mathsf{status}}, m_{\mathsf{canonicalSite}}, m_{\mathsf{closingSeal}}, \omega(R))$$

Definition 9408.16 (Weight profile and score)**.** *A weight profile is a vector*

$$\mathbf{w} = (w_{\mathsf{statement}}, w_{\mathsf{dependencies}}, w_{\mathsf{proof}}, w_{\mathsf{certificates}}, w_{\mathsf{ledger}}, w_{\mathsf{status}}, w_{\mathsf{canonicalSite}}, w_{\mathsf{closingSeal}}, w_R) \in \mathbb{N}^9.$$

The theorem-DNA score is the dot product

$$\mathsf{Score}_{\mathbf{w}}(R, D) = \mathbf{w} \cdot \mathsf{ComplexVec}(R, D).$$

Definition 9408.17 (Accepted theorem complexity)**.** *For an accepted theorem flow* T*, define*

$$\mathsf{TC}_{\mathbf{w}}(T) = \min\{\mathsf{Score}_{\mathbf{w}}(R, D) \mid D \in \mathsf{DNA}_{\mathsf{weak}}(R, T) \text{ and } \mathsf{SoundTheoremFlow}(R, T)\}.$$

Theorem 9408.18 (Accepted theorem complexity is defined)**.** *For every accepted theorem flow* T *and every weight profile* $\mathbf{w}$*,* $\mathsf{TC}_{\mathbf{w}}(T)$ *is defined as a natural number.*

Proof. By Definition 9408.5, the minimizing set contains at least one sound theorem-DNA profile. Every score in the set is a natural number. A non-empty subset of $\mathbb{N}$ has a least element. □

Theorem 9408.19 (Score monotonicity)**.** *If two theorem-DNA complexity vectors satisfy componentwise*

$$\mathsf{ComplexVec}(R, D) \leq \mathsf{ComplexVec}(R', D'),$$

then for every weight profile $\mathbf{w}$*,*

$$\mathsf{Score}_{\mathbf{w}}(R, D) \leq \mathsf{Score}_{\mathbf{w}}(R', D').$$

Proof. Write the two complexity vectors as $(a_1, \ldots, a_9)$ and $(b_1, \ldots, b_9)$ with $a_i \leq b_i$ for every i. Since every weight w_i is a natural number, $w_i a_i \leq w_i b_i$. Summing the nine inequalities gives the score inequality. □

Theorem 9408.20 (Scalar complexity requires a declared profile)**.** *Without a declared weight profile, theorem-DNA complexity has vector meaning but no unique scalar order.*

Proof. Take two vectors that trade off statement and dependency mass: $(10, 1, 1, 1, 1, 1, 1, 1, 1)$ and $(1, 10, 1, 1, 1, 1, 1, 1, 1)$. A weight profile concentrated on the first coordinate orders them one way; a profile concentrated on the second coordinate orders them the other way. Therefore a published scalar score is auditable only together with its weight profile. □

9408.4 Mutation and classifier-level information

Definition 9408.21 (Theorem-DNA mutation)**.** *A theorem-DNA mutation is a passage*

$$D_R(T) \rightsquigarrow D'_{R'}(T)$$

between two theorem-DNA profiles for the same theorem candidate. It is single-locus when exactly one role component changes.

Definition 9408.22 (Complexity-reducing and discovery mutations)**.** *A mutation is complexity-reducing for* $\mathbf{w}$ *when*

$$\mathsf{Score}_{\mathbf{w}}(R', D') < \mathsf{Score}_{\mathbf{w}}(R, D).$$

It is a discovery mutation only when it changes the theorem classifier phenotype through a certified classifier-state shift with a naming certificate and a ledger witness.

Theorem 9408.23 (Proof shortening need not be discovery)**.** *A mutation that only changes the proof locus, while leaving statement, dependencies, certificates, ledger, status, canonical site, closing seal, and phenotype fixed, need not be a discovery mutation.*

Proof. The mutation may reduce the proof mass and hence the weighted score. However, the certificate, ledger, and theorem phenotype are unchanged, so no classifier-state shift has been supplied. It is a proof-level optimization, not a theorem-classifier discovery. □

Theorem 9408.24 (Complexity reduction and classifier discovery are independent)**.** *Theorem-DNA complexity reduction and classifier-level discovery are independent coordinates.*

Proof. A proof-locus shortening with fixed phenotype can reduce score while keeping the classifier unchanged. Conversely, a mutation that introduces a new certificate, ledger, or classifier phenotype can increase certificate and ledger mass while changing the classifier. Thus score decrease does not imply discovery, and discovery need not immediately decrease score. □

Principle 9408.25 (Theorem-DNA representation)**.** *A theorem is not merely a statement; it is a role-complete event-flow profile. Theorem complexity is not code length; it is weighted locus complexity. A shorter proof can reduce score, while a new theory changes the classifier phenotype.*

*Concretized in §**??**:* Theorem-flow recognition packets realize the eight-role theorem-DNA profile as finite GroundCompiler NameCert data.

Concretized in §827: GroundCompiler audit packets provide the event-flow, recognizer, code, proof-boundary, classifier, and ledger rows consumed by theorem-DNA scoring.

Concretized in §7061: The theorem-DNA complexity-scoring packet realizes role-locus, mass-vector, weighted-score, refusal-boundary, transport, replay, provenance, and NameCert rows as finite data.

Chapter 9409

Theorem-Genome Evolution: Mutation, Recombination, Selection, and Discovery

chapter 9366, chapter 9408, and chapter 9460 isolate three audit coordinates: classifier-level novelty, eight-locus theorem-DNA, and public complexity scoring. This chapter packages those coordinates as a single evolutionary reading of theorem flows. The term genome names the whole recognized theorem profile; it does not add biological assumptions.

9409.1 Theorem genomes

Definition 9409.1 (Theorem genome)**.** *Let T be a theorem candidate flow, R a generated theorem recognizer, and $D_R(T)$ an eight-locus theorem-DNA packet. If*

$$\mathsf{SoundTheoremFlow}(R, T)$$

holds, then

$$\Gamma = (T, R, D_R(T))$$

is a theorem genome. Its loci are statement, dependency, proof, certificate, ledger, status, canonical site, and closing seal.

Definition 9409.2 (Genome phenotype)**.** *Given a theorem classifier relation Q on theorem candidate flows, genomes $\Gamma_T = (T, R_T, D_T)$ and $\Gamma_U = (U, R_U, D_U)$ have the same phenotype when $Q(T, U)$ holds. This relation is written $\Gamma_T \sim_Q \Gamma_U$.*

Theorem 9409.3 (Statement locus does not determine genome)**.** *The statement locus does not determine the theorem genome.*

Proof. The GroundCompiler theorem `same_statement_multiple_flows` provides one statement subflow that appears as the statement role of two distinct theorem candidate flows. Since theorem genomes include the candidate flow, recognizer, and complete theorem-DNA packet, the statement locus alone cannot determine the genome. □

↪ variant `BEDC.GroundCompiler.TheoremGenerated.same statement multiple flows`

Theorem 9409.4 (Code does not imply genome)**.** *Legal theorem code does not by itself supply a theorem genome.*

Proof. The GroundCompiler theorem `theorem_code_is_not_proof` exhibits legal theorem code decoding to a candidate that has no proof-sound theorem recognition for any recognizer. A theorem genome requires sound theorem-flow recognition, hence proof soundness. Code is a flow address, not a genome. □

↪variant BEDC.GroundCompiler.TheoremGenerated.theorem_code_is_not_proof

9409.2 Complexity space

Definition 9409.5 (Genome complexity vector)**.** *For a genome* $\Gamma = (T, R, D_R(T))$*, define*

$$\mathbf{C}(\Gamma) = (c_s, c_d, c_p, c_c, c_l, c_t, c_a, c_z, c_R) \in \mathbb{N}^9$$

by taking the first eight coordinates to be the event-flow masses of the statement, dependency, proof, certificate, ledger, status, canonical-site, and closing-seal loci, and the last coordinate to be the recognizer mass $|R|_{\mathsf{flow}}$*.*

Definition 9409.6 (Genome score)**.** *For a public weight profile*

$$\mathbf{w} = (w_s, w_d, w_p, w_c, w_l, w_t, w_a, w_z, w_R) \in \mathbb{N}^9,$$

the genome score is

$$\mathsf{Score}_{\mathbf{w}}(\Gamma) = \mathbf{w} \cdot \mathbf{C}(\Gamma).$$

Definition 9409.7 (Phenotype complexity)**.** *For a phenotype class* $[\Gamma]_Q$*, define*

$$\mathsf{PC}_{\mathbf{w},Q}([\Gamma]_Q) = \min\{\mathsf{Score}_{\mathbf{w}}(\Gamma') \mid \Gamma' \sim_Q \Gamma\}.$$

This takes the least scored representative in a theorem classifier class.

9409.3 Mutation and discovery

Definition 9409.8 (Genome mutation)**.** *A genome mutation is a transition*

$$\Gamma \rightsquigarrow \Gamma'$$

between theorem genomes. It is single-locus when exactly one theorem locus is changed.

Definition 9409.9 (Mutation classes)**.** *Relative to* Q *and* $\mathbf{w}$*, a mutation is:*

$$\begin{gathered}\textit{silent if } \Gamma \sim_Q \Gamma' \textit{ and } \mathsf{Score}_{\mathbf{w}}(\Gamma) = \mathsf{Score}_{\mathbf{w}}(\Gamma'),\\ \textit{compressive if } \Gamma \sim_Q \Gamma' \textit{ and } \mathsf{Score}_{\mathbf{w}}(\Gamma') < \mathsf{Score}_{\mathbf{w}}(\Gamma),\\ \textit{drifting if } \Gamma \sim_Q \Gamma' \textit{ and } \mathsf{Score}_{\mathbf{w}}(\Gamma') > \mathsf{Score}_{\mathbf{w}}(\Gamma),\\ \textit{classifier-shifting if } \neg(\Gamma \sim_Q \Gamma').\end{gathered}$$

A classifier-shifting mutation is a discovery mutation only when it induces a different certified classifier state carrying a semantic naming certificate and a ledger witness.

Theorem 9409.10 (Complexity reduction does not imply discovery)**.** *There are mutations that reduce genome score without being discovery mutations.*

Proof. Replace only the proof locus by a shorter proof locus, leaving statement, dependencies, certificates, ledger, status, canonical site, closing seal, and phenotype fixed. With positive proof weight, the score decreases. Since no classifier phenotype changes and no different certified classifier state is introduced, the mutation is compressive rather than discovery. □

Theorem 9409.11 (Discovery may increase complexity)**.** *A discovery mutation can increase genome score.*

Proof. A classifier-shifting mutation may introduce larger certificate, ledger, closing-seal, or recognizer loci. If the corresponding weights are positive, the score may increase even though the mutation changes phenotype and carries the certificate and ledger data required for discovery. □

Principle 9409.12 (No free discovery)**.** *A transition that changes only presentation, naming, or proof length, while leaving classifier phenotype, semantic naming certificate, and ledger witness unchanged, is not a discovery mutation.*

9409.4 Recombination and lineage

Definition 9409.13 (Genome recombination)**.** *Two genomes are locus-compatible along a set of loci A when replacing the loci of one genome by the corresponding loci of the other still yields some R' and T' satisfying* $\mathsf{SoundTheoremFlow}(R', T')$*. The resulting transition is genome recombination.*

Theorem 9409.14 (Recombination preserves theoremhood under soundness)**.** *If a recombination result satisfies* $\mathsf{SoundTheoremFlow}(R', T')$*, then it is a theorem genome.*

Proof. This is immediate from Definition 9409.1: theorem genomehood is the triple of theorem candidate, recognizer, theorem-DNA packet, and sound theorem-flow recognition. □

Corollary 9409.15 (Recombination is not free)**.** *Two sound genomes do not automatically produce a sound genome under arbitrary locus exchange.*

Proof. Soundness is a relation among one recognizer, one theorem candidate flow, and all eight loci. Replacing proof, certificate, or ledger loci can break proof soundness, certificate soundness, or ledger soundness. The recombined profile therefore needs its own soundness witness. □

Definition 9409.16 (Genome lineage)**.** *A genome lineage is a finite chain*

$$\Gamma_0 \rightsquigarrow \Gamma_1 \rightsquigarrow \cdots \rightsquigarrow \Gamma_n$$

whose steps are mutations or recombinations. Its complexity profile is $L_{\mathbf{w}}(i) = \mathsf{Score}_{\mathbf{w}}(\Gamma_i)$*, and its classifier profile is the sequence of phenotypes* $[\Gamma_i]_{Q_i}$*.*

Theorem 9409.17 (A lineage can improve without discovering)**.** *There are lineages whose scores strictly decrease while their classifier profiles remain constant.*

Proof. Take a sequence of proof-compression mutations. Each step lowers proof-locus mass and leaves the other loci and the classifier phenotype fixed. □

Theorem 9409.18 (A lineage can discover before it compresses)**.** *There are lineages in which a classifier shift first increases score and later compression lowers score within the changed phenotype.*

Proof. The first step introduces a different classifier phenotype with additional certificate, ledger, seal, and recognizer mass. The second step optimizes a proof or ledger locus under that changed phenotype. Thus discovery can precede compression. □

9409.5 Selection and potential

Definition 9409.19 (Selection functional)**.** *For a population of theorem genomes, a selection functional has the form*

$$\mathsf{Sel}_{\mathbf{w}}(\Gamma) = -\mathsf{Score}_{\mathbf{w}}(\Gamma) + \lambda\,\mathsf{Novelty}(\Gamma) + \eta\,\mathsf{Reuse}(\Gamma) + \theta\,\mathsf{Unification}(\Gamma).$$

It values low score, classifier novelty, reusable proof/certificate/ledger material, and unification of prior phenotypes.

Theorem 9409.20 (Shortest theorem need not be research-favorable)**.** *The least-scored genome in a population need not maximize a selection functional.*

Proof. A low-score genome can have low novelty, reuse, and unification. A higher-score genome can dominate the selection value when its novelty, reuse, and unification terms are sufficiently large. □

Definition 9409.21 (Discovery potential)**.** *The discovery potential of a genome is an audit functional*

$$\mathsf{DP}(\Gamma) = \alpha\,\mathsf{Unification}(\Gamma) + \beta\,\mathsf{Reuse}(\Gamma) + \gamma\,\mathsf{Transfer}(\Gamma) - \delta\,\mathsf{LedgerCost}(\Gamma).$$

Theorem 9409.22 (High potential can coexist with high complexity)**.** *A genome can have high score and high discovery potential at the same time.*

Proof. Large certificates, ledgers, and recognizers increase score. The same loci can also support unification, reuse, and transfer across domains. If these positive terms dominate ledger cost in the potential functional, discovery potential is high despite high score. □

9409.6 Gate hierarchy

Definition 9409.23 (Genome gate hierarchy)**.** *The theorem-genome audit hierarchy is:*

$$\mathsf{BHistCarrier} \subset \mathsf{ChapterTasteGate} \subset \mathsf{FieldFaithful} \subset \mathsf{TheoremDNA} \subset \mathsf{ScoredDiscoveryGate}.$$

The first layer gives display and readback shape; the second gives round-trip and layer separation; the third prevents field erasure; the fourth requires anchored sound theorem-DNA; the fifth requires public score certificates and discovery claims to carry classifier shift, semantic naming certificate, and ledger witness.

Compiler-closure audit is not another theorem-genome locus in this hierarchy. It is the later audit layer that asks whether a genome flow expresses a compiler phenotype and whether that phenotype feeds back into a later accepted genome flow; see chapter 9411.

Theorem 9409.24 (The gate hierarchy is strict as an audit hierarchy)**.** *Each higher layer includes the obligations of the lower layers, but the reverse implications are not available in general.*

Proof. A display need not round-trip. A round-tripping display need not reflect all declared fields. A field-faithful carrier need not carry theorem-DNA. A theorem-DNA carrier need not publish a score certificate. A scored carrier need not justify a discovery claim without classifier shift, semantic naming certificate, and ledger witness. □

Theorem 9409.25 (Theorem-genome evolution theorem)**.** *The evolution of theorem-like objects in BEDC has four independent audit coordinates: record growth, genome complexity, classifier phenotype, and ledgered discovery.*

Proof. Record growth can occur by continuation without changing the genome-level classifier. Genome complexity can decrease by proof compression while phenotype is fixed. Phenotype can change while complexity increases because new certificate and ledger loci are introduced. Discovery is the strongest coordinate: it requires classifier shift together with semantic naming certificate and ledger witness. These four observations separate the audit coordinates. □

Principle 9409.26 (Theorem-genome slogan)**.** *A theorem is a genome, not a sentence. A proof is one locus, not the whole theorem. Compression improves a genome; discovery changes its classifier phenotype. No discovery is free: every classifier shift must pay in* NameCert *and ledger.*

*Concretized in §**??**:* Theorem-flow recognition packets supply the role-complete theorem-genome carrier.

Concretized in §827: GroundCompiler audit packets supply the code/proof, classifier quotient, recognizer, and ledger boundaries consumed by theorem-genome evolution.

Concretized in §6358: The theorem-genome evolution vision is realized as finite NameCert data over theorem-flow, recognizer, theorem-DNA, classifier-shift, mutation, selection, transport, provenance, and local naming rows.

Chapter 9410

Automated Theory-Discovery Pipeline Calculus

chapter 9366, chapter 9408, chapter 9460, and chapter 9409 separate four audit coordinates: record growth, role-complete theorem genomes, public complexity scoring, and classifier-level change. This chapter packages those coordinates as a calculus for automated theory discovery. The purpose is not to let an automation label its own output as discovery, but to specify the certificate conditions under which a pipeline output may be admitted as a discovery claim.

9410.1 Pipeline states

Definition 9410.1 (Certified theory state)**.** *A certified theory state is a tuple*

$$\mathcal{T} = (S_{\mathcal{T}}, P_{\mathcal{T}}, L_{\mathcal{T}}, C_{\mathcal{T}}, N_{\mathcal{T}})$$

where

$$S_{\mathcal{T}}, P_{\mathcal{T}}, L_{\mathcal{T}} : \mathsf{Hist} \to \mathsf{Prop}, \qquad C_{\mathcal{T}} : \mathsf{Hist} \to \mathsf{Hist} \to \mathsf{Prop},$$

and

$$N_{\mathcal{T}} : \mathsf{SemanticNameCert}(S_{\mathcal{T}}, P_{\mathcal{T}}, L_{\mathcal{T}}, C_{\mathcal{T}}).$$

The five fields record source, pattern, ledger, classifier, and semantic naming certificate.

Definition 9410.2 (Automation record)**.** *An automation record is a finite family R of generated material. Its entries may be event flows, theorem candidates, theorem genomes, candidate certificates, ledger entries, score certificates, or lineage edges. The record is an audit surface; it is not itself a classifier state.*

Definition 9410.3 (Pipeline state)**.** *A pipeline state is a tuple*

$$\mathcal{P} = (\mathcal{T}, R, \Gamma, \Lambda, \mathbf{w}, B)$$

where $\mathcal{T}$ is a certified theory state, R is an automation record, Γ is a population of theorem genomes, Λ is a lineage ledger, $\mathbf{w} \in \mathbb{N}^9$ is a public theorem-genome weight profile, and $B : \Gamma \to \mathbb{N}$ is a genome-budget function.

Definition 9410.4 (Genome extractor)**.** *A genome extractor is a partial operation*

$$\mathsf{Extract} : \mathsf{EventFlow} \rightharpoonup \Gamma$$

whose value, when defined on a theorem candidate flow T, is a theorem genome $(T, R, D_R(T))$ with all eight theorem-DNA loci. A theorem candidate is DNA-complete when $\mathsf{Extract}(T)$ is defined.

Definition 9410.5 (Score certificate)**.** *For a genome Γ in a pipeline state, a score certificate consists of the public weight profile $\mathbf{w}$, the budget value $B(\Gamma)$, and the inequality*

$$\mathsf{Score}_{\mathbf{w}}(\Gamma) \leq B(\Gamma).$$

It certifies a visible upper bound, not minimality.

9410.2 Transition classes

Definition 9410.6 (Pipeline transition)**.** *A pipeline transition is a change*

$$\mathcal{P} \longrightarrow \mathcal{P}'$$

between states

$$\mathcal{P} = (\mathcal{T}, R, \Gamma, \Lambda, \mathbf{w}, B), \qquad \mathcal{P}' = (\mathcal{T}', R', \Gamma', \Lambda', \mathbf{w}', B').$$

Unless the transition explicitly changes the scoring protocol, the weight profile is held fixed.

Definition 9410.7 (Mechanical expansion)**.** *A transition is a mechanical expansion when $\mathcal{T}' = \mathcal{T}$ and R' is obtained from R by adding material generated under the same classifier state. It may extend the record, but it does not change the certified classifier.*

Definition 9410.8 (Genome compression)**.** *A transition is a genome compression when $\mathcal{T}' = \mathcal{T}$ and some genome mutation satisfies*

$$\mathsf{Score}_{\mathbf{w}}(\Gamma') < \mathsf{Score}_{\mathbf{w}}(\Gamma)$$

while the theorem classifier phenotype is unchanged.

Definition 9410.9 (Genome recombination)**.** *A genome recombination combines loci from parent genomes $\Gamma_1, \ldots, \Gamma_k$ and yields a child genome Γ' only when the child again satisfies theorem-genome soundness. Locus exchange without a soundness witness is only a candidate recombination.*

Definition 9410.10 (Classifier-shift transition)**.** *A transition is a classifier-shift transition when*

$$\neg(\mathcal{T} \equiv_{\mathsf{cls}} \mathcal{T}')$$

holds on the common source carrier. It changes the classifier coordinate, regardless of whether the record length or genome score decreases.

Definition 9410.11 (Discovery transition)**.** *A classifier-shift transition is a discovery transition when the target theory state is certified and ledgered:*

$$\mathcal{T}' = (S', P', L', C', N'), \qquad N' : \mathsf{SemanticNameCert}(S', P', L', C'),$$

and

$$\exists h : \mathsf{Hist},\ L'(h).$$

Definition 9410.12 (Positive discovery transition)**.** *Relative to an external cost observer μ and transition cost κ, a discovery transition is positive when some finite family X satisfies*

$$\mu_{\mathcal{T}'}(X) + \kappa(\mathcal{T} \to \mathcal{T}') < \mu_{\mathcal{T}}(X).$$

The inequality charges the certificate, ledger, recognizer, and seal costs to the transition rather than hiding them in prose.

9410.3 Discovery claims

Definition 9410.13 (Discovery claim)**.** *A discovery claim is an audit packet*

$$\mathsf{Claim} = (K, \Gamma, \mathcal{T}, \mathcal{T}', d, N', L', \mathbf{w}, B, \Lambda, \mathcal{B})$$

where K is a claim kind, Γ is the principal genome, $\mathcal{T}, \mathcal{T}'$ are source and target theory states, $d \in \{0, 1\}$ is the classifier-change bit, N' and L' are the target certificate and ledger policy, $\mathbf{w}$ and B are the scoring protocol, Λ is the lineage ledger, and $\mathcal{B}$ is the explicit not-claimed boundary.

Definition 9410.14 (Claim kinds)**.** *The claim kinds are*

$$\mathsf{mechanical},\quad \mathsf{compression},\quad \mathsf{recombination},\quad \mathsf{classifierShift},\quad \mathsf{discovery},\quad \mathsf{positiveDiscovery}.$$

They respectively name record extension, score reduction without phenotype change, locus recombination, classifier change, ledgered certified classifier change, and ledgered certified classifier change with net compression gain.

Definition 9410.15 (Well-formed claim)**.** *A claim is well formed when its kind matches its evidence: mechanical claims do not assert classifier change; compression claims carry a score comparison under a public weight profile and have $d = 0$; classifier-shift claims have $d = 1$; discovery claims have $d = 1$, a target semantic naming certificate, and a ledger witness; positive-discovery claims additionally carry the net compression inequality. Any theorem-like principal object must be DNA-complete, and any scored claim must expose its weight profile.*

Definition 9410.16 (Discovery gate)**.** *The predicate* $\mathsf{DiscoveryGate}(\mathsf{Claim})$ *holds when the claim is well formed, its principal theorem-like object is a DNA-complete genome, it has a score certificate whenever it is scored, its discovery assertions carry semantic naming certificate and ledger witnesses, its positive-discovery assertions carry the net cost inequality, its lineage ledger records the parents and transition kind, its not-claimed boundary is explicit, and its support is formal or certificate-level rather than prose-only.*

Definition 9410.17 (Gate demotion)**.** *Gate demotion maps an over-strong claim kind to the strongest kind supported by the available evidence. A positive-discovery claim without the cost inequality is treated as discovery at most; a discovery claim without certificate or ledger is treated as classifier-shift at most; a classifier-shift claim with $d = 0$ is treated as compression or mechanical; an unscored compression claim is treated as an unscored mutation; a DNA-incomplete theorem-like object is treated as a theorem candidate.*

9410.4 Gate theorems

Theorem 9410.18 (DNA completeness is a gate obligation)**.** *A theorem candidate that is not DNA-complete cannot be the principal theorem genome of a gate-passed discovery claim.*

Proof. Definition 9410.16 requires the principal theorem-like object to be a DNA-complete genome. If extraction is undefined, the object does not supply the eight-locus theorem-DNA profile required by the gate. □

Corollary 9410.19 (Statement-only and code-only candidates are insufficient)**.** *A candidate supplying only a statement locus, or only legal theorem code, does not pass the discovery gate as a theorem genome.*

Proof. Both cases lack the complete theorem-genome extraction required by Definition 9410.18. □

Theorem 9410.20 (Mechanical expansion is not discovery)**.** *Mechanical expansion does not imply discovery.*

Proof. For mechanical expansion, $\mathcal{T}' = \mathcal{T}$. Hence the classifier states are classifier-equivalent and the classifier-change bit is 0. Discovery requires a classifier-shift transition and therefore a classifier-change bit of 1. □

Theorem 9410.21 (Genome compression is not discovery by itself)**.** *Genome compression without classifier change is not discovery.*

Proof. Compression lowers $\mathsf{Score_w}$ under the same classifier phenotype. If the classifier-change bit is 0, the transition violates the classifier-shift obligation in Definition 9410.11. □

Theorem 9410.22 (Discovery requires certificate and ledger)**.** *If a transition is a discovery transition with target state $\mathcal{T}' = (S', P', L', C', N')$, then*

$$N' : \mathsf{SemanticNameCert}(S', P', L', C')$$

and

$$\exists h : \mathsf{Hist},\ L'(h).$$

Proof. This is exactly the target-state obligation in Definition 9410.11. The semantic certificate supplies the naming certificate, and the ledger witness is part of the discovery condition rather than an optional annotation. □

Theorem 9410.23 (Positive discovery implies discovery)**.** *Every positive discovery transition is a discovery transition.*

Proof. Definition 9410.12 defines positive discovery by adding a net compression inequality to a discovery transition. □

Theorem 9410.24 (Scored claims require public weights)**.** *Any claim asserting a genome score, a score reduction, or a positive-discovery cost inequality must expose the weight profile used for the comparison.*

Proof. The score is the dot product of the public weight profile with the genome complexity vector. Without the weight profile, the scalar has no determinate audit meaning, and score comparisons cannot be reproduced. □

Theorem 9410.25 (Discovery gate is kind-sound)**.** *If* $\mathsf{DiscoveryGate}(\mathsf{Claim})$ *holds, then the obligations attached to the claim kind hold.*

Proof. The discovery gate includes well-formedness, and well-formedness assigns each claim kind exactly its evidence obligations. Thus a gate-passed compression claim has public score comparison and no classifier change; a classifier-shift claim has classifier change; a discovery claim has classifier change, semantic naming certificate, and ledger witness; and a positive-discovery claim additionally has the net cost inequality. □

Theorem 9410.26 (Demotion preserves audit soundness)**.** *After gate demotion, the resulting claim kind is no stronger than the evidence actually supplied by the claim.*

Proof. The clauses of Definition 9410.17 remove exactly the unsupported obligation: cost inequality for positive discovery, certificate or ledger for discovery, classifier change for classifier-shift, public score for compression, and theorem-DNA completeness for theorem-genome claims. The resulting label therefore does not assert evidence absent from the packet. □

9410.5 Lineage and selection

Definition 9410.27 (Lineage ledger)**.** *A lineage ledger is a directed acyclic graph $\Lambda = (V, E)$ whose vertices are theorem genomes and whose edges are labelled by transition kind: mechanical, compression, recombination, classifier-shift, discovery, or positive-discovery.*

Definition 9410.28 (Lineage-consistent claim)**.** *A claim is lineage-consistent when its parent genomes, child genome, and transition kind are recorded in Λ and the resulting ledger remains acyclic.*

Theorem 9410.29 (Accepted claims form an auditable lineage DAG)**.** *If every accepted claim is lineage-consistent, the accepted theorem genomes form an auditable directed acyclic lineage graph.*

Proof. Each accepted claim contributes labelled parent-to-child edges. By lineage-consistency, adding those edges does not introduce a cycle. Iterating over accepted claims preserves acyclicity. □

Definition 9410.30 (Discovery potential)**.** *For selection among candidate genomes, a discovery-potential functional has the form*

$$\mathsf{DP}(\Gamma) = \alpha\,\mathsf{Cls}(\Gamma) + \beta\,\mathsf{Unification}(\Gamma) + \gamma\,\mathsf{Reuse}(\Gamma) + \delta\,\mathsf{Transfer}(\Gamma) - \lambda\,\mathsf{Score}_{\mathbf{w}}(\Gamma) - \rho\,\mathsf{LedgerRisk}(\Gamma).$$

Here Cls *records classifier change, while the remaining positive terms record unification, reuse, and transfer. The negative terms charge complexity and ledger risk.*

Theorem 9410.31 (Lowest score need not be the best discovery target)**.** *A genome with lower score can have lower discovery potential than a genome with higher score.*

Proof. Take one genome with low score and zero classifier change, unification, reuse, and transfer. Take another with higher score, classifier change, high unification, high reuse, and controlled ledger risk. For sufficiently large positive coefficients on the structural terms, the second genome has greater discovery potential despite its higher score. □

Theorem 9410.32 (Classifier change is favoured when other terms are fixed)**.** *If a selection operator maximizes* DP *and $\alpha > 0$, then among candidates equal in all other coordinates it favours the candidate with classifier change.*

Proof. The difference in discovery potential between the classifier-changing candidate and the fixed-classifier candidate is exactly α, which is positive. □

9410.6 Pipeline adequacy

Definition 9410.33 (Unpaid discovery claim)**.** *An unpaid discovery claim is a claim that asserts discovery while lacking at least one of classifier change, semantic naming certificate, ledger witness, theorem genome, score or cost account, lineage witness, or not-claimed boundary.*

Theorem 9410.34 (No unpaid discovery passes the gate)**.** *No unpaid discovery claim passes* DiscoveryGate*.*

Proof. The discovery gate requires all of the obligations listed in Definition 9410.33. An unpaid claim lacks at least one of them, so it violates the gate. □

Theorem 9410.35 (Pipeline safety)**.** *If an automated pipeline accepts discovery and positive-discovery claims only after* DiscoveryGate *and records accepted claims in a lineage-consistent ledger, then every accepted discovery has classifier change, semantic naming certificate, ledger witness, DNA-complete theorem genome, score certificate, lineage witness, and an explicit not-claimed boundary.*

Proof. The gate supplies well-formedness, DNA completeness, score certificate, certificate and ledger obligations for discovery claims, the net inequality for positive-discovery claims, and the not-claimed boundary. The acceptance rule adds lineage consistency. Combining these clauses gives the listed obligations. □

Theorem 9410.36 (Automated theory-discovery pipeline theorem)**.** *An automated theory-discovery pipeline that extracts theorem genomes, exposes public scoring weights, demotes unsupported claim kinds, gates discovery claims, and records accepted claims in a lineage ledger distinguishes record growth, score reduction, recombination, classifier change, and ledgered discovery.*

Proof. Record growth is covered by mechanical expansion and does not imply discovery by Definition 9410.20. Score reduction is covered by genome compression and does not imply discovery by Definition 9410.21. Recombination requires its own soundness witness by Definition 9410.9. Classifier change is a separate transition class by Definition 9410.10. Ledgered discovery is the stronger gate-passed condition supplied by Definition 9410.35. □

Principle 9410.37 (Automated discovery principle)**.** *Automation explores genome space; the gate decides claim strength. More output is record growth. A shorter proof is compression. A recombined theorem profile is a candidate until soundness is witnessed. Discovery requires classifier change paid for by semantic naming certificate, ledger, score account, and lineage.*

Principle 9410.38 (Compiler-closure placement)**.** *Compiler-closure audit, as isolated in chapter 9411, sits after theorem-genome extraction and scoring. It does not merely ask whether a candidate theorem genome is role-complete; it asks whether a genome flow certifiably expresses a recognized compiler phenotype whose ledgered feedback exports a later accepted genome flow. Discovery self-compilation then adds classifier shift, semantic naming certificate, and ledger witness to that loop.*

Concretized in §5914: Discovery pipeline calculus is realized as finite theory-state, automation-record, genome, score, lineage, classifier-shift, and NameCert rows.

Concretized in §6931: Pipeline discovery classifiers realize the positive classifier-shift boundary as finite before/after classifier, public weight-profile, theorem-genome, ledger, TasteGate, transport, provenance, and NameCert rows.

Concretized in §7617: Candidate frontier queues realize the automated theory-discovery calculus as finite source-state, classifier-shift, score-budget, queue, ledger, replay, provenance, and NameCert rows.

Chapter 9411

Compiler-Closure Self-Compilation

chapter 9408, chapter 9409, and chapter 9410 make theorem recognition role-complete: a theorem-like flow is read through statement, dependency, proof, certificate, ledger, status, canonical-site, and closing-seal loci. This chapter records the next audit layer. A self-compiling BEDC system must also account for the compiler phenotypes expressed by genome flows and for the certified feedback by which those phenotypes regulate the next generation of theorem, certificate, gate, and closure flows.

The governing schematic is

$$D_t \longrightarrow C_t \longrightarrow P_t \longrightarrow D_{t+1}.$$

Here D_t is the current genome flow, C_t is the compiler or recognizer flow expressed by it, P_t is the behavior phenotype carried by that compiler, and D_{t+1} is the accepted genome flow exported after gate, ledger, NameCert, and closure-certificate checks. The point is not unrestricted reflection. The point is eventized, certified, ledgered self-compilation. This is a paper-side audit contract: it fixes the evidence shape a later pipeline can read, without asserting that every field is already implemented as a closure-status field or extraction script.

9411.1 From theorem DNA to compiler closure

Definition 9411.1 (Genome flow)**.** *A genome flow is an event flow D : EventFlow used as an auditable theory-state record. Its visible loci may include theorem-DNA packets, closure-status records, naming certificates, ledgers, gate data, score certificates, or lineage edges.*

Principle 9411.2 (One-directional recognition boundary)**.** *Theorem-DNA recognition reads a theorem candidate into role-complete loci, but it does not by itself express a compiler, recognizer, gate, or classifier that regulates later genome flows.*

Theorem 9411.3 (Theorem DNA alone is not self-compilation)**.** *Let T be a theorem candidate flow. If T has role-complete theorem-DNA but does not certifiably express a compiler phenotype, then there is no genome flow D' for which T forms a certified self-compilation loop into D'.*

Proof. A certified self-compilation loop, as defined in Definition 9411.16, includes certified expression of a compiler phenotype. The hypothesis denies such an expression witness for T. Therefore the loop data cannot be supplied. □

Corollary 9411.4 (Theorem-genome audit and compiler-closure audit are distinct)**.** *Theorem-genome audit asks whether a theorem-like flow is role-complete, scored, anchored, and ledgered. Compiler-closure audit asks whether such a genome flow expresses a compiler phenotype and carries ledgered feedback into a later accepted genome flow.*

Proof. The first audit is witnessed by theorem-DNA and theorem-genome gates. The second requires compiler expression, compiler behavior, feedback, and accepted export data. These are not part of theorem-DNA alone. □

9411.2 Compiler phenotype

Definition 9411.5 (Compiler phenotype)**.** *A compiler phenotype is a triple*

$$P = (C, \beta, \rho)$$

where $C : \mathsf{EventFlow}$ *is a compiler flow,*

$$\beta : \mathsf{EventFlow} \to \mathsf{EventFlow} \to \mathsf{Prop}$$

is its behavior relation, and ρ *witnesses* $\mathsf{RecognizedCompilerFlow}(C)$*.*

Definition 9411.6 (Compiler-genome loci)**.** *A compiler genome is a genome flow whose displayed loci include source, recognizer, compiler, gate, classifier, ledger, export, and feedback-seal components. These loci record what the compiler reads, how legal flows are recognized, how outputs are produced, how impostors are refused, how accepted objects are classified, how obligations are recorded, how results are exported, and how feedback is permitted.*

Theorem 9411.7 (Self-compilation requires compiler phenotype)**.** *If* $D \circlearrowright D'$ *is a certified self-compilation loop, then there exists a compiler phenotype* $P = (C, \beta, \rho)$ *such that* $\mathsf{RecognizedCompilerFlow}(C)$ *and* $\beta(D, D')$*.*

Proof. Unfold the certified self-compilation loop. It supplies a compiler phenotype P, certified expression from D to P, and feedback from P on D to D'. Unfolding the compiler phenotype gives the recognized compiler-flow witness for C. Unfolding the feedback witness gives $\beta(D, D')$. □

Corollary 9411.8 (No recognized compiler flow, no self-compilation)**.** *If no event flow is recognized as a compiler flow, then no certified self-compilation loop exists.*

Proof. This is the contrapositive of Definition 9411.7. □

9411.3 Certified expression

Definition 9411.9 (Expression witness)**.** *Let* D *be a genome flow and let* $P = (C, \beta, \rho)$ *be a compiler phenotype. An expression witness for* $D \Rightarrow P$ *is a ledger flow* L_{expr} *such that* C *is visible as a source subflow of* D*,* L_{expr} *is visible as a source subflow of* D*, and* L_{expr} *records the genome carrier, the expressed compiler flow, the visible expression route, the recognized-compiler witness, and the formal input surface used by the expression.*

Definition 9411.10 (Certified compiler expression)**.** *A genome flow D certifiably expresses a compiler phenotype P, written*

$$D \Rightarrow P,$$

when an expression witness exists and all formal compiler inputs used by the expression are raw events, event flows, recognized flows, or certified exports.

Theorem 9411.11 (Expression excludes hidden host state)**.** *A certified compiler expression cannot depend on host ASTs, host YAML, host manifests, host packages, host theorem identifiers, host object names, host type tags, host mode tags, host opcode tables, host arity tables, or host parser state as formal compiler inputs.*

Proof. BEDC's formal compiler-input relation admits raw events, event flows, recognized flows, and certified exports. The listed host structures are structural hidden inputs rather than formal compiler inputs. Certified expression requires its input route to stay inside the formal compiler-input surface, so those hidden host structures are excluded. □

Corollary 9411.12 (Expression is not host extraction)**.** *A host parser, manifest scanner, or theorem-name lookup may help locate a candidate during engineering, but it does not by itself witness $D \Rightarrow P$. The witness must be present as event-flow expression data.*

Proof. Use Definition 9411.11. Host parser state, manifests, and theorem identifiers are excluded from the formal input surface unless they have first been represented as accepted event-flow data. □

9411.4 Ledgered feedback

Definition 9411.13 (Feedback witness)**.** *Let $P = (C, \beta, \rho)$ be a compiler phenotype and let D, D' be genome flows. A feedback witness for*

$$P : D \rightsquigarrow D'$$

is a ledger flow L_{fb} such that $\beta(D, D')$ holds, L_{fb} is visible as a source subflow of D', and L_{fb} records the source genome carrier, the compiler phenotype, the behavior relation, the target genome carrier, the accepted-export route, the naming and closure-certificate obligations, and the boundary excluding unrestricted reflection.

Principle 9411.14 (No unledgered feedback)**.** *A compiler phenotype may regulate a later genome flow only through a displayed feedback ledger. Otherwise the transition is an external update, not BEDC self-compilation.*

Corollary 9411.15 (External file edits are not self-compilation)**.** *An external script that edits theorem text, closure status, or lineage data without presenting the update as event-flow feedback with a visible ledger does not establish certified self-compilation.*

Proof. Certified self-compilation requires the feedback witness of Definition 9411.13. A host-level edit without the visible feedback ledger fails that requirement. □

9411.5 Certified self-compilation loop

Definition 9411.16 (Certified self-compilation loop)**.** *For genome flows D and D', write*

$$D \circlearrowright D'$$

when there exists a compiler phenotype P such that $D \Rightarrow P$, $P : D \rightsquigarrow D'$, and $\mathsf{AcceptedObjectFlow}(D')$.

Definition 9411.17 (Strict and stationary self-compilation)**.** *A certified self-compilation loop is strict when $D \neq D'$. It is stationary when $D = D'$.*

Theorem 9411.18 (Certified self-compilation exports an accepted object)**.** *If $D \circlearrowright D'$, then* $\mathsf{AcceptedObjectFlow}(D')$.

Proof. This is one of the clauses in the definition of certified self-compilation. □

Corollary 9411.19 (The output is not just a later file state)**.** *If D' is not an accepted object flow, then a transition $D \to D'$ is not a certified self-compilation loop.*

Proof. Use Definition 9411.18. □

9411.6 Self-hosting is not self-compilation

Theorem 9411.20 (Self-hosting is weaker than self-compilation)**.** *A self-hosting target for a compiler flow does not by itself supply certified self-compilation.*

Proof. A self-hosting target states that a compiler flow is behaviorally equivalent to itself under some compiler behavior. Certified self-compilation also requires a genome flow, certified expression of a compiler phenotype by that genome, feedback from the phenotype into a later genome flow, and accepted export of the later genome flow. These data are not supplied by self-hosting alone. □

Principle 9411.21 (Compiler property versus genome-feedback property)**.** *Self-hosting is a compiler-layer property. Self-compilation is a genome–compiler–feedback–accepted-export property.*

9411.7 Discovery self-compilation

Definition 9411.22 (Discovery self-compilation)**.** *A certified self-compilation loop*

$$D \circlearrowright D'$$

is discovery self-compilation when the associated discovery audit packet has classifier-change bit $d = 1$ and the later genome flow carries a certified classifier state with semantic naming certificate and ledger witness.

Theorem 9411.23 (Self-compilation is not automatically discovery)**.** *A certified self-compilation loop whose associated classifier-change bit is $d = 0$ is not discovery self-compilation.*

Proof. Discovery self-compilation requires classifier-change bit $d = 1$ by definition. □

Theorem 9411.24 (Discovery self-compilation is a discovery transition)**.** *Every discovery self-compilation loop is a discovery transition.*

Proof. Discovery self-compilation includes certified self-compilation, classifier shift, semantic naming certificate, and ledger witness. These are exactly the obligations required for a discovery transition in the automated discovery calculus. □

9411.8 Compiler-closure gate contract

Definition 9411.25 (Compiler-closure audit packet)**.** *A compiler-closure audit packet is a tuple*

$$\mathsf{CCClaim} = (D, D', C, \beta, L_{\mathsf{expr}}, L_{\mathsf{fb}}, E, N_{\mathsf{name}}, N_{\mathsf{close}}, d, \mathcal{B})$$

where D is the source genome flow, D' is the target genome flow, C is the expressed compiler flow, β is the behavior relation, L_{expr} is the expression ledger, L_{fb} is the feedback ledger, E is the accepted-export witness for D', N_{name} and N_{close} are the naming and closure-certificate witnesses, d is the classifier-change bit, and $\mathcal{B}$ is the explicit not-claimed boundary.

Definition 9411.26 (Compiler-closure evidence obligations)**.** *A compiler-closure audit packet satisfies the evidence obligations when:*

1. *C is a recognized compiler flow.*
2. *β is supplied as a compiler behavior relation.*
3. *L_{expr} witnesses certified expression $D \Rightarrow P = (C, \beta, \rho)$.*
4. *L_{fb} witnesses ledgered feedback $P : D \rightsquigarrow D'$.*
5. *E, N_{name}, and N_{close} witness accepted export of the target genome as an accepted object flow.*
6. *$\mathcal{B}$ excludes hidden host state, host-executable identity, and unrestricted reflective meta-loops.*

If the packet asserts discovery self-compilation, it must also have $d = 1$, semantic naming certificate, and ledger witness in the sense of Definition 9410.11.

Definition 9411.27 (Free self-compilation claim)**.** *A free self-compilation claim is a claim that asserts $D \circlearrowright D'$ while omitting at least one of recognized compiler flow, compiler behavior, expression witness, feedback witness, accepted object flow, or feedback ledger.*

Definition 9411.28 (CompilerClosureGate)**.** *A claim passes* CompilerClosureGate *when it is represented by a compiler-closure audit packet satisfying Definition 9411.26. Where the source or target carrier is theorem-like, the relevant theorem-DNA scoring obligations must also hold. Where the claim asserts discovery self-compilation, the discovery obligations of* DiscoveryGate *must also hold.*

Definition 9411.29 (Compiler-closure demotion)**.** *Compiler-closure demotion maps an over-strong self-compilation claim to the strongest status supported by its evidence. Without a recognized compiler flow or compiler behavior, the packet is only a compiler candidate. Without an expression witness, it is not a self-compilation claim. Without a feedback ledger, it is a free claim. Without accepted export of D', it is only a candidate transition. Without $d = 1$ and semantic naming certificate, it may be self-compilation but not discovery self-compilation.*

Theorem 9411.30 (No free self-compilation passes)**.** *No free self-compilation claim passes* CompilerClosureGate*.*

Proof. The gate requires the evidence obligations of Definition 9411.26. A free claim omits at least one required item, so the gate obligation is not met. □

Theorem 9411.31 (Demotion never strengthens evidence)**.** *After compiler-closure demotion, the assigned status is no stronger than the evidence actually carried by the packet.*

Proof. Definition 9411.29 removes self-compilation strength when recognized compiler flow, behavior, expression, feedback ledger, or accepted export is missing, and removes discovery strength when classifier change, semantic naming, or ledger witness is missing. Therefore the resulting status does not assert evidence absent from the packet. □

Theorem 9411.32 (CompilerClosureGate strictly strengthens TDCSGate)**.** *For theorem-like carriers, passing* CompilerClosureGate *implies the relevant theorem-DNA scoring obligations, but theorem-DNA scoring obligations alone do not imply passing* CompilerClosureGate*.*

Proof. The compiler-closure gate includes the relevant theorem-DNA scoring obligations where the source or target carrier is theorem-like. It also requires compiler expression, behavior, feedback, accepted export, and a feedback ledger. These additional clauses are not consequences of theorem-DNA scoring alone. □

Theorem 9411.33 (DiscoveryGate alone is not compiler closure)**.** *A gate-passed discovery claim does not by itself establish compiler-closure self-compilation unless it also supplies compiler expression and ledgered feedback.*

Proof. DiscoveryGate checks classifier-change, semantic naming, ledger, score, lineage, and not-claimed obligations for discovery. Certified self-compilation additionally requires a recognized compiler phenotype, certified expression, and feedback from that phenotype into the target genome. Those data are not supplied by discovery evidence alone. □

9411.9 Pipeline adoption boundary

Principle 9411.34 (Compiler-closure adoption)**.** *The automated theory-discovery pipeline may treat compiler-closure audit as a post-theorem-genome layer:*

$$\textit{theorem-DNA extraction} \longrightarrow \textit{genome scoring} \longrightarrow \textit{TDCSGate} \longrightarrow \textit{compiler-closure audit} \longrightarrow \textit{discovery gate.}$$

The additional layer asks whether a genome flow expresses a compiler phenotype whose feedback produces a later accepted genome flow. It reads the compiler-closure audit packet of Definition 9411.25; it does not infer self-compilation from file edits, host execution, or theorem-name lookup.

Theorem 9411.35 (Compiler-closure self-compilation theorem)**.** *A BEDC transition $D \to D'$ can be accepted as certified self-compilation exactly when its compiler-closure audit packet satisfies the evidence obligations of Definition 9411.26. If the same packet also has classifier-change bit $d = 1$ with semantic naming certificate and ledger witness, it is discovery self-compilation.*

Proof. The forward direction unfolds certified self-compilation and places its recognized compiler flow, behavior relation, expression ledger, feedback ledger, accepted export, and boundary into the audit packet. The reverse direction reads those packet fields as certified expression and ledgered feedback and then applies the accepted-output clause of the loop definition. The classifier-change, semantic naming, and ledger witnesses supply the discovery strengthening. □

Principle 9411.36 (Compiler-closure slogan)**.** *Theorem DNA audits what a theorem flow contains. Compiler closure audits what a genome flow can express and how the expressed compiler phenotype feeds back into the next accepted genome flow.*

Concretized in §3963: PublicLocalReflectiveCompilationUp realizes the compiler-closure self-compilation audit surface as finite public/local compiler-event and MetaCIC closure rows.

Concretized in §6317: Compiler-closure self-compilation is realized as a finite NameCert packet for compiler phenotype, feedback, export, and ledger rows.

Concretized in §7024: SelfCompilationFeedbackUp realizes the compiler-closure feedback witness as a finite feedback-ledger carrier over compiler phenotype, EventFlow feedback, accepted export, refusal boundary, transport, replay, provenance, and local naming rows.

Chapter 9412

Pseudotheory Refutation Gate Map

This chapter records the present audit surface for pseudotheory refusal. It is not a carrier design and not a witness schema. Its purpose is to say where each refutable failure mode is checked, which checks block assertions, and why taste-sensitive stability remains outside automatic demotion.

9412.1 Coverage table

Class	Gate surface	Status	Code evidence
(a) synonym or reconstruction	Discovery integrity, structural-DNA payload equality, and the `discovery_gate_witnesses.json` registry.	Mechanical for asserted discovery.	`bedc_ci.py:9181-9430` computes structural-DNA relations and emits `structural_reconstruction_discovery_c` `bedc_ci.py:3432-3599` loads only kernel-grounded reconstruction witnesses; `bedc_ci.py:4464-4480` turns a witness hit into a failing `W` gate.
(b) padding or classifier-neutral surface	Classifier-bit demotion through the assertion gate and mechanical opt-out audit.	Mechanical for asserted discovery; survey rows are informational.	`bedc_ci.py:4300-4357` fails asserted `positiveDiscovery` when nontrivial classifier evidence is absent; `bedc_ci.py:4362-4385` fails when disagreement support is not checked; `bedc_ci.py:4401-4424` rejects smoke or duplicate-like evidence. `bedc_ci.py:10623-10631` requires a concrete invariant when the opt-out reason is classifier unchanged.
(c) axiom-crossing carrier or theorem	Lean kernel axiom scan and source-token axiom scan.	Mechanical.	`bedc_ci.py:4205-4259` fails asserted discovery targets with axiom, sorry, or forbidden transitive dependencies. `bedc_ci.py:12691-12919` runs `#print axioms` over public BEDC theorems and exits nonzero on forbidden dependencies.
(d) stability break needing taste	`ChapterTasteGate` admission and human judgment over value and stability.	Human-only; not an automatic demotion class.	`TasteGate.lean:45-67` defines the carrier display and readback obligations; `TasteGate.lean:81-98` derives conservativity and no-hidden-input. The paper account at `parts/visions/meta_foundations/theory` states why AI-proposed chapters need taste admission.
(e) unpaid discovery	Semantic naming, row, ledger, cost, debt, and scope-seal obligations for `PositiveDiscovery`.	Mechanical for asserted discovery; broad ledger surveys remain informational.	`DiscoveryCertificate.lean:126-156` requires before/after certified states, row evidence, classifier shift, debt, ledger membership, and scope seal. `bedc_ci.py:2774-2824`

9412.2 Stateful and stateless refusal

Only reconstruction needs a persistent witness. A reconstruction refusal compares a candidate against the corpus: the evidence is not contained in the candidate alone, because the refutation is equality of its structural-DNA payload with a prior payload. The registry therefore stores the target, prior, canonical payload, and grounding status. The loader accepts the row only after an independent structural-DNA grounding check, so the witness is a cache of a corpus relation, not an extra theory object.

Padding, axiom-crossing, and unpaid discovery are stateless refusals. Padding is recomputed from the claimed classifier shift and its checked disagreement support. Axiom-crossing is recomputed from source text and kernel axiom dependencies. Unpaid discovery is recomputed from the claim's own `PositiveDiscovery` fields: semantic naming certificate, row evidence, ledger membership, debt, and scope seal. Persisting these as another witness family would duplicate the existing gate surface without adding soundness.

9412.3 Prime asymmetry

BEDC can automatically refute some claims because a refutation may be a finite counter-reading: same structural payload as a prior, no classifier shift, forbidden axiom dependency, or missing certificate data. The opposite judgment is different. Saying that a chapter is worth admitting to the horizon is not only the absence of these finite failures; it is a taste judgment about stability, usefulness, and fit with the surrounding theory.

This is the prime asymmetry. Composite-like failures may be found by an audit gate. A positive value judgment is not created by the complement of those failures. `ChapterTasteGate` supplies the carrier display/readback discipline, but it does not replace human admission of taste-sensitive stability.

9412.4 Carrier-repair boundary

The refutation map is apophatic. It says why a claim may not be asserted as discovery. It does not say that the carrier must be replaced by a different carrier, and it does not turn every refusal into a constructive repair recipe. That boundary is essential: synonymy is evidence for demotion, not evidence that the target and prior must be recoded into different domains; padding is absence of paid classifier shift, not an invitation to alter the carrier until the score improves; taste-sensitive stability is an admission judgment, not an automatic rewrite target.

Thus the design rejects cataphatic carrier repair as the foundation of pseudotheory refusal. The gates remain refusal surfaces: structural-DNA collision, classifier-bit failure, axiom dependency, unpaid certificate data, and human-only taste admission.

Concretized in §6558: Finite pseudotheory refusal classes are realized as a $\mathsf{RefutationGate}^{\uparrow}$ NameCert packet.

Concretized in §6560: The pseudotheory-specific refusal gate is realized as finite structural-DNA, classifier-shift, axiom-scan, and certificate-debt NameCert data.

Concretized in §7280: Finite countermodel rows realize pseudotheory refusal as auditable NameCert data.

Concretized in §6547: finite confluence diamond ledger rows realize the audit-map methodology as BEDC NameCert data

Chapter 9413

Common Carriers and Reality Projections

The unified-reality reading does not treat algebra, geometry, analysis, number theory, spectral theory, and physical modelling as unrelated object domains. It reads them as projection surfaces of a common generating carrier, each surface equipped with its own admissible classifier, operation laws, transport policy, and ledger. This does not postulate a completed universe of mathematical objects. It fixes an auditable interface through which multiple mature readings can be compared without importing an unlicensed ambient ontology.

The guiding constraint is the ordinary BEDC naming discipline: a mature object is admitted only through source, pattern, classifier, stability, and ledger data. Thus $\mathsf{Nat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Circle}^{\uparrow}$, metric spaces, categories, spectra, physical-signature models, and analytic continuation interfaces are not primitive inputs. They are stable readout surfaces over generated behaviour. A unified object is therefore not a bare element of a universal set; it is a common carrier together with reality projections, classifier-respecting transport, and a boundary ledger refusing reverse readings that have not been certified.

9413.1 Reality Interfaces

Definition 9413.1 (Reality interface)**.** *A* reality interface *is a tuple*

$$\mathcal{R} := (R, \sim_R, \mathsf{Car}_R, \mathsf{Obs}_R, \mathsf{Law}_R, \mathsf{Led}_R)$$

where R is the carrier or carrier predicate for the interface, $\sim_R$ is its classifier, Car_R records admissible carrier conditions, Obs_R records the finite observations readable at that interface, Law_R records the operations and structural laws licensed inside the interface, and Led_R records provenance, stability, transport, and boundary information.

Definition 9413.2 (Stable reality interface)**.** *A reality interface $\mathcal{R}$ is* stable *when $\sim_R$ is reflexive, symmetric, and transitive on the admitted carrier, and every operation listed in Law_R respects $\sim_R$ in each argument and output coordinate on which it is read.*

Principle 9413.3 (Interface before domain)**.** *BEDC does not accept a domain name as a source-free primitive. A domain name may be consumed only after its carrier, classifier, admissible observations, operation laws, and ledger policy have been displayed as a reality interface.*

9413.2 Common Carriers

Definition 9413.4 (Common carrier)**.** *Let $(\mathcal{R}_i)_{i\in I}$ be a family of reality interfaces with carriers R_i and classifiers $\sim_{R_i}$. A* common carrier *for this family is data*

$$\mathcal{O} := (O, \sim_O, (\pi_i)_{i\in I}, \mathsf{Tr}, \mathsf{Led}, \mathsf{Bnd})$$

where O is the shared carrier, $\sim_O$ is its classifier, $\pi_i : O \to R_i$ are reality projections, Tr *records transport data between projection surfaces,* Led *records projection and compatibility provenance, and* Bnd *records refused reverse readings, collapses, external bridges, and unreviewed coercions.*

Definition 9413.5 (Classifier-respecting projection)**.** *A projection $\pi_i : O \to R_i$ from a common carrier is* classifier-respecting *when*

$$x \sim_O y \Longrightarrow \pi_i(x) \sim_{R_i} \pi_i(y)$$

for all admitted rows $x, y : O$.

Definition 9413.6 (Reality projection)**.** *If $\pi_i : O \to R_i$ is a projection from a common carrier, then $\pi_i(x)$ is the* reality readout *of x at the interface $\mathcal{R}_i$. For a predicate $P_i : R_i \to \mathsf{Prop}$, the composite claim $P_i(\pi_i(x))$ is a* projection property *of x at $\mathcal{R}_i$.*

Theorem 9413.7 (Projection preserves classified identity)**.** *Let $\mathcal{O}$ be a common carrier and let π_i be classifier-respecting. If $x \sim_O y$, then the two reality readouts are classified together:*

$$\pi_i(x) \sim_{R_i} \pi_i(y).$$

Proof. This is exactly the classifier-respect clause in Definition 9413.5. □

9413.3 Ledgered Transport

Definition 9413.8 (Reality transport)**.** *Given interfaces $\mathcal{R}_i$ and $\mathcal{R}_j$ over a common carrier $\mathcal{O}$, a* reality transport *from a predicate $P_i : R_i \to \mathsf{Prop}$ to a predicate $P_j : R_j \to \mathsf{Prop}$ is a ledgered rule*

$$\mathsf{Tr}_{ij}(P_i, P_j)$$

whose exported consequence is

$$\forall x : O, \quad P_i(\pi_i(x)) \Longrightarrow P_j(\pi_j(x)).$$

The transport row records the source predicate, target predicate, projection maps, classifier compatibility, stability basis, and boundary conditions under which the implication may be consumed.

Definition 9413.9 (Transport-equivalent projection properties)**.** *Projection properties P_i and P_j are $\mathcal{O}$-*transport-equivalent *when the ledger contains transport rows in both directions:*

$$\mathsf{Tr}_{ij}(P_i, P_j) \qquad \textit{and} \qquad \mathsf{Tr}_{ji}(P_j, P_i).$$

In that case one may write

$$P_i \equiv_{\mathcal{O}} P_j$$

as an abbreviation for the displayed bidirectional transport data, not as an unqualified equality of predicates in an ambient universe.

Theorem 9413.10 (Bidirectional transport gives projection equivalence)**.** *If P_i and P_j are $\mathcal{O}$-transport-equivalent, then for every $x : O$ the two projection properties imply each other:*

$$P_i(\pi_i(x)) \Longrightarrow P_j(\pi_j(x))$$

and

$$P_j(\pi_j(x)) \Longrightarrow P_i(\pi_i(x)).$$

Proof. Unpack Definition 9413.9. The first transport row is exactly the first displayed implication for each $x : O$, and the second transport row is exactly the reverse implication. □

Corollary 9413.11 (Projection equivalence is ledger relative)**.** *The notation $P_i \equiv_{\mathcal{O}} P_j$ exports no equality stronger than the two ledgered transport rows that define it.*

Proof. By Definition 9413.9, the notation is only an abbreviation for the two displayed transport rows. Therefore any consumer of the equivalence must read the corresponding source, classifier, stability, and boundary entries from the transport ledger. □

9413.4 Generalized Continuation

Definition 9413.12 (Generalized analytic continuation)**.** *Let $\mathcal{O}$ be a common carrier with projections $\pi_i : O \to R_i$ and $\pi_j : O \to R_j$. A* generalized analytic continuation *from $\mathcal{R}_i$ to $\mathcal{R}_j$ is a packet*

$$\mathsf{GenCont}_{i\to j} := (\mathcal{O}, \pi_i, \pi_j, \mathsf{Tr}_{ij}, \mathsf{Led}_{ij})$$

where Tr_{ij} transports certified properties from the i-interface to the j-interface and Led_{ij} records the source, classifier, stability, provenance, and boundary conditions of that transport. The packet is admissible only when it introduces no uncertified primitive and makes every hidden premise visible in the ledger.

Remark 9413.13 (Ordinary analytic continuation as a special case)**.** *Ordinary analytic continuation fits the schema when the interfaces are holomorphic-domain readouts, the shared carrier is the continuation packet, the projections read local holomorphic representatives, and the transport ledger is the overlap, identity-theorem, uniqueness, and branch-boundary record. The generalized form allows the same discipline to relate algebraic, geometric, spectral, measure-theoretic, arithmetic, analytic, and physical-signature readouts when the corresponding projection and transport rows are displayed.*

Theorem 9413.14 (Generalized continuation is transport, not creation)**.** *An admissible $\mathsf{GenCont}_{i\to j}$ packet cannot create a target property outside the displayed common carrier, projection maps, transport row, and ledger.*

Proof. By Definition 9413.12, the packet consists only of the common carrier, the two projections, the transport row, and the ledger. The admissibility condition forbids the introduction of an uncertified primitive. Therefore every exported target-side property must be read through the source-side certified property, the displayed projection maps, and the transport ledger. □

Principle 9413.15 (Boundary refusal)**.** *A projection cannot be reversed, collapsed into another projection, or exported across a bridge unless the relevant reverse map, collapse certificate, or bridge packet is present in the ledger. The common carrier licenses comparison and transport; it does not license unreviewed identification.*

9413.5 Noncollapse and Information Dimension

The boundary refusal principle has a sharper invariant form. A higher interface may have lower-level shadows, but the presence of those shadows does not by itself give a lossless reconstruction of the higher interface. This is the noncollapse discipline: projection may make an object visible at a lower layer, while the missing fibers, moduli, regularity rows, classifiers, and provenance remain part of the object being read.

The located-real surface is the guiding L10 instance. In Definition 1933.1, a $\mathsf{LocatedReal}^{\uparrow}$ packet is not a host real point. It is the finite route

$$L = (S, R, D, E, Q, H, C, P, N)$$

through finite $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint and radius ledgers, a located enclosure row, a terminal $\mathsf{Real}^{\uparrow}$ seal, transport, replay, provenance, and local NameCert data. The carrier explicitly lacks Dedekind cuts, quotient real equality, host real equality, trichotomy, countable-choice selectors, compactness witnesses, metric-completion objects, and bridge credentials. Thus a rational or dyadic observation may be a shadow of a located real, but it is not the located real itself.

Definition 9413.16 (Information layer tower)**.** *An* information layer tower *is a sequence of carriers*

$$L_0, L_1, L_2, \ldots$$

together with finite readout families

$$\pi_k^{n+1,n} : L_{n+1} \to L_n, \qquad k : \mathsf{Nat}^{\uparrow}.$$

The carrier L_0 is the value-facing layer: typical examples include $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, finite histories, or other displayed finite observation surfaces. The carrier L_1 is the process-facing layer: typical rows contain schedules, streams, moduli, regularity witnesses, classifiers, and ledgers. A row of L_{n+1} may be observed through L_n at finite precision k, but that observation is only a shadow unless a reconstruction certificate is displayed.

Definition 9413.17 (Finite shadow)**.** *Let $x : L_{n+1}$ be a higher-layer row in an information layer tower. Its k-*shadow *on the lower layer is*

$$\mathrm{Sh}_k^{n+1,n}(x) := \pi_k^{n+1,n}(x).$$

For a process row whose observable component is a stream x_{seq} and whose precision policy is x_{mod}, the typical value-facing shadow has the form

$$\mathrm{Sh}_k(x) = x_{\mathsf{seq}}(x_{\mathsf{mod}}(k)).$$

The equation records the inspected value at the displayed precision; it does not identify the inspected value with the process row.

Definition 9413.18 (Degenerate embedding)**.** *Given a value-facing carrier L_0 and a process-facing carrier L_1, a* degenerate embedding *is a displayed map*

$$\eta : L_0 \to L_1$$

whose image consists of process rows with constant observations and trivial precision residue. For a rational-facing instance this has the schematic form

$$\eta(q)_{\mathsf{seq}}(n) = q, \qquad \eta(q)_{\mathsf{mod}}(k) = 0.$$

The map is part of the tower data only when its carrier, classifier, constant-observation law, precision policy, and ledger are displayed.

Definition 9413.19 (Local noncollapse)**.** *Let $x : L_1$ be a process-facing row and let $\eta : L_0 \to L_1$ be a displayed degenerate embedding. The row x is* locally noncollapsed over L_0 *when*

$$\mathsf{NonCollapse}_{L_0}(x) := \neg\exists q : L_0,\ x \sim_{L_1} \eta(q).$$

Thus x cannot be consumed as a lossless value-layer point without a classifier witness identifying it with a displayed degenerate process.

Definition 9413.20 (Structural noncollapse)**.** *Let L_1 be a process-facing carrier over a value-facing carrier L_0. The pair (L_1, L_0) satisfies* structural noncollapse *when there is no pair of displayed maps*

$$c : L_1 \to L_0, \qquad \rho : L_0 \to L_1$$

such that

$$\forall x : L_1, \quad \rho(c(x)) \sim_{L_1} x.$$

The map c would choose a lower-layer readout, and ρ would reinflate that readout into a process row. Structural noncollapse says that no such retraction is available from the displayed tower data.

Definition 9413.21 (Projection fiber)**.** *For a projection $\pi : L_1 \to L_0$ and a lower-layer row $q : L_0$, the* projection fiber *over q is*

$$\mathrm{Fib}_\pi(q) := \sum_{x:L_1} (\pi(x) \sim_{L_0} q).$$

The projection has a nontrivial fiber *when there are rows $x, y : L_1$ such that*

$$\pi(x) \sim_{L_0} \pi(y)$$

but

$$\neg(x \sim_{L_1} y).$$

Theorem 9413.22 (Nontrivial fibers obstruct collapse)**.** *If $\pi : L_1 \to L_0$ has a nontrivial fiber, then π cannot be the first component of a classifier-respecting lossless retraction*

$$\rho : L_0 \to L_1$$

satisfying

$$\forall x : L_1, \quad \rho(\pi(x)) \sim_{L_1} x.$$

Here classifier-respecting means that

$$u \sim_{L_0} v \Longrightarrow \rho(u) \sim_{L_1} \rho(v).$$

Proof. Assume such a ρ exists, and choose $x, y : L_1$ witnessing a nontrivial fiber. Since $\pi(x) \sim_{L_0} \pi(y)$, classifier-respect for the displayed reconstruction gives

$$\rho(\pi(x)) \sim_{L_1} \rho(\pi(y)).$$

The retraction hypothesis gives

$$\rho(\pi(x)) \sim_{L_1} x \qquad \text{and} \qquad \rho(\pi(y)) \sim_{L_1} y.$$

Symmetry and transitivity of $\sim_{L_1}$ therefore imply $x \sim_{L_1} y$, contradicting the nontrivial-fiber witness. □

Definition 9413.23 (Information dimension)**.** *For an information layer tower, the* information dimension *of a row is the least layer index at which the row can be represented without loss by the displayed carriers, classifiers, and ledgers. A row $x : L_m$ has information dimension at most $n \leq m$ when there are displayed maps*

$$c : L_m \to L_n, \qquad \rho : L_n \to L_m$$

with

$$\rho(c(x)) \sim_{L_m} x.$$

It has information dimension exactly n when n is minimal among the layers for which such data are displayed.

Principle 9413.24 (No shadow replacement)**.** *A lower-layer shadow may be used as an observation, approximation, or comparison coordinate, but it may not replace the higher-layer row unless the tower supplies an explicit reconstruction map, classifier-respect witness, and ledger. Without those data, the omitted fiber is part of the object.*

9413.6 Pythagorean Carrier, Scale Fibers, and Unit-Circle Projection

The common-carrier discipline becomes concrete in the elementary Pythagorean surface. The equation

$$a^2 + b^2 = c^2$$

and the normalized unit-circle equation

$$(a/c)^2 + (b/c)^2 = 1$$

are not two unrelated facts. They are two reality readouts of one carrier: an algebraic cone readout, a normalized shape readout, and a scale readout whose loss is precisely the fiber of the shape projection.

Definition 9413.25 (Field-like reality interface)**.** *A* field-like reality interface *is a stable reality interface with a carrier K, classifier $\sim_K$, operations*

$$+, \ -, \ \cdot, \ 0, \ 1,$$

and an apartness predicate $x\#0$. Its ledger licenses an inverse x^{-1} only from an apartness witness $x\#0$, and division is the derived operation

$$a/x := a \cdot x^{-1}.$$

Thus division is not a total primitive operation; it consumes an apartness row.

Definition 9413.26 (Nonzero scale carrier)**.** *The nonzero scale carrier of K is*

$$K^{\#} := \sum_{c:K} (c\#0).$$

An element is written (c, ν_c), where $\nu_c : c\#0$ is the displayed apartness witness.

Definition 9413.27 (Pythagorean carrier)**.** *The* Pythagorean carrier *over K is*

$$\mathsf{Pyth}_K := \sum_{a,b,c:K} \big((c\#0) \times (a^2 + b^2 \sim_K c^2)\big).$$

An element is written

$$P = (a, b, c; \nu_c; h_P),$$

where $\nu_c : c\#0$ licenses the divisions by c, and $h_P : a^2 + b^2 \sim_K c^2$ is the square-sum certificate. The carrier is therefore a packet with a scale-apartness row and an equation row, not a bare triple.

Definition 9413.28 (Algebraic unit-circle carrier)**.** *The algebraic unit-circle carrier over K is*

$$S^1_K := \sum_{x,y:K} \big(x^2 + y^2 \sim_K 1\big).$$

An element is written $Q = (x, y; h_Q)$. This is an algebraic circle carrier. Topology, metric structure, arc length, and measure enter only through additional reality interfaces.

Definition 9413.29 (Pythagorean projections)**.** *The Pythagorean carrier has the following paper-side projections:*

$$\pi_{\text{alg}}(a, b, c; \nu_c; h_P) := (a, b, c; h_P),$$
$$\pi_{\text{scale}}(a, b, c; \nu_c; h_P) := (c, \nu_c),$$

and

$$\pi_{\text{shape}}(a, b, c; \nu_c; h_P) := \big(a/c,\ b/c;\ h_{\text{shape}}\big).$$

The proof row h_{shape} is supplied by Definition 9413.30.

Theorem 9413.30 (Pythagorean normalization)**.** *Let*

$$P = (a, b, c; \nu_c; h_P) : \mathsf{Pyth}_K.$$

Set

$$x := a/c, \qquad y := b/c.$$

Then

$$x^2 + y^2 \sim_K 1.$$

Consequently π_{shape} is a well-defined projection from Pyth_K to S^1_K.

Proof. By definition of division, $x = a \cdot c^{-1}$ and $y = b \cdot c^{-1}$. The field-like ledger gives the usual distributive and inverse laws under $\sim_K$, so

$$x^2 + y^2 \sim_K a^2c^{-2} + b^2c^{-2} \sim_K (a^2 + b^2)c^{-2}.$$

Using $h_P : a^2 + b^2 \sim_K c^2$, this becomes

$$(a^2 + b^2)c^{-2} \sim_K c^2c^{-2} \sim_K 1,$$

where the final step uses the apartness witness ν_c. □

Definition 9413.31 (Scale reconstruction)**.** *Let $Q = (x, y; h_Q) : S^1_K$ and let $(c, \nu_c) : K^\#$. The* scale reconstruction *is*

$$\mathsf{Recon}(Q, c) := (cx, cy, c; \nu_c; h_{\text{recon}}) \in \mathsf{Pyth}_K,$$

where h_{recon} is the square-sum certificate

$$(cx)^2 + (cy)^2 \sim_K c^2.$$

Theorem 9413.32 (Scale reconstruction)**.** *For every $Q = (x, y; h_Q) : S^1_K$ and $(c, \nu_c) : K^\#$,*

$$(cx)^2 + (cy)^2 \sim_K c^2.$$

Proof. From h_Q we have $x^2 + y^2 \sim_K 1$. Therefore

$$(cx)^2 + (cy)^2 \sim_K c^2x^2 + c^2y^2 \sim_K c^2(x^2 + y^2) \sim_K c^2 \cdot 1 \sim_K c^2.$$

□

Theorem 9413.33 (Shape-scale decomposition)**.** *There is a classifier-respecting equivalence*

$$\mathsf{Pyth}_K \simeq S^1_K \times K^\#.$$

The forward map is

$$\Phi(P) := (\pi_{\text{shape}}(P), \pi_{\text{scale}}(P)),$$

and the reverse map is

$$\Psi(Q, c) := \mathsf{Recon}(Q, c).$$

Proof. Let $P = (a, b, c; \nu_c; h_P)$. Applying Φ gives the shape-scale pair

$$((a/c, b/c),\ (c, \nu_c)).$$

Applying Ψ returns

$$(c(a/c), c(b/c), c; \nu_c; -).$$

The inverse laws licensed by ν_c identify $c(a/c) \sim_K a$ and $c(b/c) \sim_K b$, and the square-sum row transports along those classifier witnesses. Hence $\Psi(\Phi(P)) \sim_{\mathsf{Pyth}} P$.

Conversely, for $Q = (x, y; h_Q)$ and $(c, \nu_c) : K^\#$, applying Ψ gives $(cx, cy, c; \nu_c; -)$. Applying Φ returns

$$(((cx)/c, (cy)/c; -),\ (c, \nu_c)).$$

The same inverse laws identify $(cx)/c \sim_K x$ and $(cy)/c \sim_K y$, so the shape row and scale row are classified together with (Q, c). □

Corollary 9413.34 (Unit-circle readout is not the complete carrier)**.** *The shape carrier S^1_K is not the complete Pythagorean carrier. The complete carrier is classified by the shape together with the nonzero scale:*

$$\mathsf{Pyth}_K \simeq S^1_K \times K^\#.$$

Proof. This is exactly the decomposition of Definition 9413.33. The projection to S^1_K forgets the $K^\#$ coordinate. □

Definition 9413.35 (Scale fiber of a shape)**.** *For $Q : S^1_K$, the* scale fiber *of the shape projection is*

$$\mathsf{ScaleFib}(Q) := \sum_{P:\mathsf{Pyth}_K} (\pi_{\text{shape}}(P) \sim_{S^1_K} Q).$$

Theorem 9413.36 (Scale fiber classification)**.** *For every $Q : S^1_K$,*

$$\mathsf{ScaleFib}(Q) \simeq K^{\#}.$$

Proof. Map $(P, \epsilon) : \mathsf{ScaleFib}(Q)$ to $\pi_{\text{scale}}(P) : K^{\#}$. Conversely, map $(c, \nu_c) : K^{\#}$ to the reconstructed packet $\mathsf{Recon}(Q, c)$ together with the shape-classifier witness supplied by the inverse laws in the proof of Definition 9413.33. The two composites are classified as identities by that same shape-scale decomposition. □

Corollary 9413.37 (Shape projection is lossy when scales differ)**.** *If $Q : S^1_K$ is a displayed shape and $K^{\#}$ contains two scales c, d with $c \not\sim_K d$, then the fiber of $\pi_{\text{shape}} : \mathsf{Pyth}_K \to S^1_K$ over Q is nontrivial. Consequently the shape projection satisfies the noncollapse pattern of Definition 9413.21 at every such displayed shape.*

Proof. By Definition 9413.36, the fiber over the displayed Q is classified by $K^{\#}$. Distinct scales therefore give distinct Pythagorean packets with the same shape readout. □

Definition 9413.38 (Pythagorean extension lift)**.** *Let $F \subset E$ be a field-extension reality with a displayed extension ledger. If $a, b \in F$ and*

$$c \in E, \qquad c^2 \sim_E a^2 + b^2, \qquad c \notin F,$$

then (a, b, c) is a Pythagorean extension lift *of the F-data into E.*

Theorem 9413.39 (Extension lift reaches normalized coordinates)**.** *Let $F \subset E$ be a field-extension reality. Suppose $a, b \in F$ and*

$$c \in E, \qquad c\#0, \qquad c^2 \sim_E a^2 + b^2, \qquad c \notin F.$$

If $a\#0$, then $a/c \notin F$. If $b\#0$, then $b/c \notin F$. Thus, in the nondegenerate case $a\#0$ and $b\#0$, the normalized shape point $(a/c, b/c)$ belongs to the extension-facing carrier E^2 and not to F^2.

Proof. Assume $a\#0$ and suppose $a/c \in F$. Write $r := a/c$. Since $a\#0$ and $c\#0$, the field-like ledger gives $r\#0$. Then

$$c \sim_E a/r.$$

Because $a \in F$, $r \in F$, and $r\#0$, closure of the field-like interface F under licensed division gives $a/r \in F$, hence $c \in F$, contradicting the extension-lift hypothesis. The argument for b/c is identical. □

Example 9413.40 (The $(1, 1, \sqrt{2})$ carrier)**.** *Let $F = \mathbb{Q}$ and $E = \mathbb{Q}(\sqrt{2})$. The packet*

$$(1, 1, \sqrt{2})$$

satisfies $1^2 + 1^2 = (\sqrt{2})^2$. Its normalized shape is

$$\left(1/\sqrt{2}, 1/\sqrt{2}\right).$$

Since $1/\sqrt{2} = \sqrt{2}/2 \notin \mathbb{Q}$, the scale readout and the unit-circle readout both consume the same extension ledger $\mathbb{Q} \subset \mathbb{Q}(\sqrt{2})$.

Definition 9413.41 (Pythagorean measure readouts)**.** *The triangle-area readout is the algebraic projection*

$$A_{\triangle}(a, b, c; \nu_c; h_P) := \frac{1}{2}ab.$$

It is an oriented algebraic area row unless positivity and orientation ledgers are added. If K is embedded in an analytic reality A whose ledger supplies a circle constant, the disk-area readout is

$$A_{\circ}(a, b, c; \nu_c; h_P) := \pi c^2$$

inside A. The constant π is not supplied by the field-like interface K; it belongs to the analytic reality that certifies it.

Theorem 9413.42 (Area readout through shape and scale)**.** *Let $P = (a, b, c; \nu_c; h_P) : \mathsf{Pyth}_K$, and let $x = a/c$ and $y = b/c$. Then*

$$\frac{1}{2}ab \sim_K \frac{1}{2}c^2xy.$$

Proof. The inverse laws give $a \sim_K cx$ and $b \sim_K cy$. Therefore

$$ab \sim_K (cx)(cy) \sim_K c^2xy.$$

Multiplying by $\frac{1}{2}$ gives the stated area readout. □

Corollary 9413.43 (Measure may require an analytic layer)**.** *Even when the scale belongs to an algebraic extension E, the disk-area readout πc^2 may require an analytic reality strictly beyond E.*

Proof. The algebraic extension ledger accounts for c and hence for c^2. It does not by itself account for the circle constant π. If the active analytic reality supplies π only through a separate process or transcendental ledger, the disk-area readout factors through that higher interface. □

Definition 9413.44 (Pythagorean generalized continuation)**.** *The Pythagorean algebra-to-shape continuation packet is*

$$\mathsf{GenCont}_{\mathrm{alg}\to\mathrm{shape}} := (\mathsf{Pyth}_K, \pi_{\mathrm{alg}}, \pi_{\mathrm{shape}}, \mathsf{Tr}_{\mathrm{alg,shape}}, \mathsf{Led}_{\mathrm{alg,shape}}),$$

where the transport row is Definition 9413.30. The reverse shape-scale-to-algebra packet uses Definition 9413.32.

Theorem 9413.45 (Pythagorean algebra-geometry transport)**.** *On the common carrier Pyth_K, the algebraic equation $a^2 + b^2 \sim_K c^2$ and the normalized shape equation $(a/c)^2 + (b/c)^2 \sim_K 1$ are transport-equivalent only with the scale fiber retained. The unit-circle point alone does not reconstruct the Pythagorean packet.*

Proof. The algebra-to-shape direction is Definition 9413.30. The reverse direction is Definition 9413.32, whose input is not a bare point of S^1_K but a pair in $S^1_K \times K^{\#}$. By Definition 9413.34, the scale fiber is required for the full carrier read. □

Theorem 9413.46 (Pythagorean common-carrier principle)**.** *The carrier Pyth_K binds algebraic equation, normalized shape, nonzero scale, triangle area, and disk area as projections of one packet. It satisfies*

$$\mathsf{Pyth}_K \simeq S^1_K \times K^{\#},$$

and the projection to S^1_K has scale fiber $K^{\#}$. If the scale is read only through a field extension, the normalized shape coordinates consume the same extension ledger in the nondegenerate case; if disk area is read, a further analytic ledger may be required.

Proof. The equivalence is Definition 9413.33, and the fiber computation is Definition 9413.36. The field-extension statement is Definition 9413.39. The measure statement is Definition 9413.43. All five readouts use the same source row $(a, b, c; \nu_c; h_P)$, so they are reality projections of one common carrier rather than independent objects. □

9413.7 Algebraic Extension Directions and Information Dimension

The Pythagorean example isolates the role of the scale row: when $(1, 1, \sqrt{2})$ is read over $\mathbb{Q}$, the full carrier cannot stay inside the base-field layer. It is read through the extension $\mathbb{Q}(\sqrt{2})$, and the normalized shape coordinates consume the same extension ledger. This section records the general algebraic form of that phenomenon. An algebraic element outside a base field is not an anomalous point of the base carrier; it is a finite-dimensional extension direction over the base field, certified by its minimal polynomial and its power-basis ledger.

The hierarchy is compatible with the L8 algebra layer of the project roadmap: field extensions, algebraic closure, Galois extensions, splitting fields, separability, and transcendence are mature algebra interfaces downstream of arithmetic and upstream of the geometry and analysis surfaces that consume them.

Definition 9413.47 (Field-extension reality)**.** *A* field-extension reality *is a displayed embedding*

$$\iota : F \hookrightarrow E$$

between field-like reality interfaces in the sense of Definition 9413.25, together with classifier-preservation ledgers for $0, 1, +, -, \cdot$*, apartness, licensed inverses, and the induced scalar action*

$$F \times E \to E.$$

The notation E/F *refers to the whole packet: base interface, extension interface, embedding, scalar action, operation compatibility, and readback ledger.*

Definition 9413.48 (Generated simple extension)**.** *Let* E/F *be a field-extension reality and let* $\alpha \in E$*. The* simple extension generated by α *is the least displayed sub-reality of* E *containing* $\iota(F)$ *and* α *and closed under the licensed field operations. It is denoted*

$$F(\alpha).$$

Its constructive rows are represented by rational expressions

$$\frac{p(\alpha)}{q(\alpha)}, \qquad p, q \in F[X], \qquad q(\alpha)\#0,$$

with ledger entries for the expression, denominator apartness, classifier equivalence of expressions, operation closure, and readback into E*.*

Definition 9413.49 (Algebraic element and minimal-polynomial certificate)**.** *An element* $\alpha \in E$ *is* algebraic over F *when there is a nonzero polynomial* $p(X) \in F[X]$ *with*

$$p(\alpha) \sim_E 0.$$

A minimal-polynomial certificate *for α is a polynomial $m_\alpha(X) \in F[X]$ such that*

$$m_\alpha \neq 0, \qquad m_\alpha \text{ is monic}, \qquad m_\alpha(\alpha) \sim_E 0,$$

and every polynomial p satisfying $p(\alpha) \sim_E 0$ is divisible by m_α in $F[X]$. Its degree is written

$$\deg_F(\alpha) := \deg m_\alpha.$$

Definition 9413.50 (Algebraic extension direction)**.** *For an algebraic element α over F, the* algebraic extension direction generated by *α is the simple extension*

$$Z_\alpha^{\mathrm{alg}} := F(\alpha).$$

Its algebraic information dimension over F is

$$\dim_F Z_\alpha^{\mathrm{alg}} := [F(\alpha) : F],$$

the vector-space dimension of the extension carrier over the base carrier.

Definition 9413.51 (Power-basis candidate)**.** *If α has minimal-polynomial degree d, its* power-basis candidate *is*

$$\mathcal{B}_\alpha := (1, \alpha, \alpha^2, \ldots, \alpha^{d-1}).$$

Theorem 9413.52 (Power-basis independence)**.** *Let m_α be a minimal-polynomial certificate of degree d. Then*

$$1, \alpha, \alpha^2, \ldots, \alpha^{d-1}$$

are linearly independent over F.

Proof. Suppose there is a nontrivial linear relation

$$a_0 + a_1\alpha + \cdots + a_{d-1}\alpha^{d-1} \sim_E 0, \qquad a_i \in F.$$

Let

$$p(X) = a_0 + a_1 X + \cdots + a_{d-1}X^{d-1}.$$

Then $p(\alpha) \sim_E 0$, $p \neq 0$, and $\deg p < d$. The minimal-polynomial certificate says $m_\alpha \mid p$, which is impossible for a nonzero p of smaller degree. Hence every displayed linear relation is trivial. □

Theorem 9413.53 (Power-basis spanning)**.** *If $\deg m_\alpha = d$, every element of $F(\alpha)$ is classified with a linear combination*

$$b_0 + b_1\alpha + \cdots + b_{d-1}\alpha^{d-1}, \qquad b_i \in F.$$

Proof. For any polynomial $p(X) \in F[X]$, divide by m_α:

$$p(X) = q(X)m_\alpha(X) + r(X), \qquad \deg r < d.$$

Evaluating at α gives $p(\alpha) \sim_E r(\alpha)$ because $m_\alpha(\alpha) \sim_E 0$. Thus polynomial expressions reduce to linear combinations of the displayed power-basis rows.

For a general rational expression $p(\alpha)/q(\alpha)$ with $q(\alpha)\#0$, the denominator row says q does not vanish at α. The minimal-polynomial certificate therefore gives the coprimality ledger of q with m_α in $F[X]$. A Euclidean ledger supplies $u, v \in F[X]$ with

$$u(X)q(X) + v(X)m_\alpha(X) = 1.$$

After evaluation, $u(\alpha)q(\alpha) \sim_E 1$, so $q(\alpha)^{-1} \sim_E u(\alpha)$. Hence

$$\frac{p(\alpha)}{q(\alpha)} \sim_E p(\alpha)u(\alpha),$$

and the product again reduces to a combination of powers below d. □

Theorem 9413.54 (Algebraic extension dimension)**.** *If α is algebraic over F and has minimal-polynomial degree d, then*

$$[F(\alpha) : F] = d.$$

Moreover $\mathcal{B}_\alpha = (1, \alpha, \ldots, \alpha^{d-1})$ is a displayed F-basis of $F(\alpha)$.

Proof. Definition 9413.52 gives linear independence, and Definition 9413.53 gives spanning. Thus the power-basis candidate is a basis, and its length is d. □

Definition 9413.55 (Algebraic noncollapse)**.** *For an algebraic element $\alpha \in E$ over F, define*

$$\mathsf{AlgNonCollapse}_F(\alpha) := \alpha \notin F.$$

Theorem 9413.56 (Algebraic noncollapse and degree)**.** *For an algebraic element α over F,*

$$\mathsf{AlgNonCollapse}_F(\alpha) \iff \deg_F(\alpha) > 1.$$

Proof. If $\deg_F(\alpha) > 1$, then α cannot lie in F, since an element of F has the degree-one annihilator $X - \alpha$. Conversely, if $\alpha \notin F$ and $\deg_F(\alpha) = 1$, the monic minimal polynomial has the form $X - a$ for some $a \in F$, forcing $\alpha \sim_E a$ and hence $\alpha \in F$, a contradiction. □

Corollary 9413.57 (Algebraic information dimension detects noncollapse)**.** *For algebraic α over F,*

$$\mathsf{AlgNonCollapse}_F(\alpha) \iff [F(\alpha) : F] > 1.$$

Proof. Combine Definition 9413.56 with Definition 9413.54. □

Example 9413.58 (The $\mathbb{Q}(\sqrt{2})$ extension)**.** *Let $F = \mathbb{Q}$ and $\alpha = \sqrt{2}$. The polynomial*

$$m_\alpha(X) = X^2 - 2$$

is irreducible over $\mathbb{Q}$ and has degree 2. Therefore

$$[\mathbb{Q}(\sqrt{2}) : \mathbb{Q}] = 2$$

and the power basis is

$$(1, \sqrt{2}).$$

Thus

$$\mathbb{Q}(\sqrt{2}) = \{a + b\sqrt{2} : a, b \in \mathbb{Q}\},$$

with equality read as the extension classifier supplied by the minimal-polynomial and reduction ledger.

Corollary 9413.59 (Pythagorean irrational scale has dimension two)**.** *The Pythagorean packet*

$$(1, 1, \sqrt{2})$$

from Definition 9413.40 is read over the two-dimensional extension reality

$$\mathbb{Q}(\sqrt{2})/\mathbb{Q}.$$

Its normalized shape point

$$(1/\sqrt{2}, 1/\sqrt{2}) = (\sqrt{2}/2, \sqrt{2}/2)$$

uses the same extension carrier.

Proof. By Definition 9413.58, the extension dimension is two. The normalized coordinate statement is the special case of Definition 9413.39 with $a = b = 1$ and $c = \sqrt{2}$. □

Definition 9413.60 (Extension projection graph)**.** *Let $F \subset E$ be a field-extension reality and let $P \in \mathsf{Pyth}_E$. The* extension projection graph

$$\mathsf{ExtProj}(P; F, E)$$

records, for each displayed projection of P, whether the readout lies in the base layer F or only in the extension layer E. For example, when $P = (1, 1, \sqrt{2})$ over $\mathbb{Q} \subset \mathbb{Q}(\sqrt{2})$, the leg readout lies in $\mathbb{Q}^2$, the scale readout lies in $\mathbb{Q}(\sqrt{2}) \setminus \mathbb{Q}$, and the normalized shape readout lies in $\mathbb{Q}(\sqrt{2})^2$ rather than $\mathbb{Q}^2$.

Theorem 9413.61 (Extension projection consistency)**.** *Let $F \subset E$ be a field-extension reality, and let*

$$P = (a, b, c; \nu_c; h_P) \in \mathsf{Pyth}_E$$

with $a, b \in F$, $c \in E \setminus F$, and $a\#0$, $b\#0$. Then the algebraic equation, the scale readout, and the normalized shape readout are all read through the same extension ledger $F \subset E$: the equation closes in E, the scale readout lies outside F, and the normalized shape readout lies outside F^2.

Proof. The equation closes in E because P carries the row $h_P : a^2 + b^2 \sim_E c^2$. The scale readout is c, which is outside F by hypothesis. The normalized shape coordinates are outside F by Definition 9413.39. All three readouts are projected from the same packet P and the same embedding ledger $F \subset E$. □

Definition 9413.62 (Algebraic extension continuation)**.** *The finite algebraic continuation from F to $F(\alpha)$ is the packet*

$$\mathsf{GenCont}_{F \to F(\alpha)} := (F(\alpha), \iota, \alpha, m_\alpha, \mathcal{B}_\alpha, \mathsf{Led}_\alpha),$$

where $\iota : F \hookrightarrow F(\alpha)$ is the embedding, m_α is the minimal-polynomial certificate, $\mathcal{B}_\alpha = (1, \alpha, \ldots, \alpha^{d-1})$ is the power basis, and Led_α records reduction, multiplication, licensed division, classifier transport, and readback into the ambient extension.

Theorem 9413.63 (Algebraic extensions are finite continuation packets)**.** *If α is algebraic over F with minimal-polynomial degree d, then $F \to F(\alpha)$ is a finite certificate-style generalized continuation in the sense of Definition 9413.12.*

Proof. The minimal-polynomial certificate is finite, and Definition 9413.54 supplies the finite power basis. Multiplication is computed by reducing powers α^n with $n \geq d$ using the relation $m_\alpha(\alpha) \sim 0$. Addition and negation are coordinatewise. Licensed division uses denominator apartness and the Euclidean ledger in $F[X]$ as in Definition 9413.53. Thus the carrier, operations, classifiers, stability rows, and readback are all displayed by finite data. □

Definition 9413.64 (Algebraic information dimension)**.** *For algebraic α over F, define*

$$\dim_{\text{info}}^{\text{alg}}(\alpha/F) := [F(\alpha) : F].$$

Theorem 9413.65 (Algebraic extension direction principle)**.** *Let α be algebraic over F. If $\alpha \in F$, then the generated extension has algebraic information dimension 1. If $\alpha \notin F$, then $F(\alpha)$ is a nontrivial finite-dimensional extension over F, its dimension is $\deg_F(\alpha)$, and its carrier is given by a finite continuation packet. In a Pythagorean carrier, an extension-scale row $c \notin F$ lifts both the scale projection and the normalized shape projection through the same extension reality.*

Proof. The dimension statement is Definition 9413.54. The noncollapse criterion is Definition 9413.56. The finite continuation packet is Definition 9413.63. The Pythagorean projection statement is Definition 9413.61. □

9413.8 Transcendental Extensions, Process Layers, and Apophatic Far Ends

section 9413.7 identified algebraic irrationality with a finite-dimensional extension direction:

$$F \subset F(\alpha), \qquad [F(\alpha) : F] = \deg m_\alpha.$$

The next boundary is different. A transcendental object is not a finite algebraic direction over the base field, but it need not be apophatic either. Constants and functions such as π, e, $\exp(x)$, $\log(x)$, and $\zeta(s)$ can be given by streams, moduli, branch data, operation laws, and ledgers. They are cataphatic process names whenever those data are displayed. Their transcendence, zero structure, or algebraic dependence is an additional certificate, not a consequence of the process name itself.

This section separates three roles. Algebraic extension directions are finite-dimensional over the base. Transcendental process directions are positive carriers, often infinite-dimensional over the algebraic base, with finite observations and ledgers. The apophatic far end T, introduced in Definition 9393.11 and disciplined by Definition 9401.3, is not an object in that tower.

Definition 9413.66 (Transcendence certificate)**.** *Let E/F be a field-extension reality and let $\tau \in E$. A* transcendence certificate *for τ over F is a ledger*

$$\mathsf{TransCert}_F(\tau)$$

which assigns to every nonzero polynomial $p \in F[X]$ an apartness witness

$$p(\tau)\#0.$$

Thus transcendence is not treated as a bare external negation of algebraicity. It is the displayed family of nonvanishing rows for all finite polynomial tests over the base field.

Definition 9413.67 (Transcendental rational-function extension)**.** *If τ carries* $\mathsf{TransCert}_F(\tau)$*, the* transcendental rational-function extension *generated by τ is the carrier*

$$F(\tau)$$

whose rows are represented by rational expressions

$$\frac{p(\tau)}{q(\tau)}, \qquad p, q \in F[X], \qquad q \neq 0.$$

The denominator apartness row is supplied by $\mathsf{TransCert}_F(\tau)$*, because $q \neq 0$ implies $q(\tau)\#0$. The packet therefore contains the expression syntax, polynomial evaluation ledger, denominator-apartness witness, classifier-equivalence rule, operation closure, and readback into the ambient extension.*

Theorem 9413.68 (Transcendental powers are linearly independent)**.** *If τ carries* $\mathsf{TransCert}_F(\tau)$*, then the family*

$$1, \tau, \tau^2, \tau^3, \ldots$$

is linearly independent over F in the finite-relation sense.

Proof. Suppose there is a displayed finite linear relation

$$a_0 + a_1\tau + \cdots + a_n\tau^n \sim_E 0, \qquad a_i \in F,$$

with the coefficients not all zero. Let

$$p(X) = a_0 + a_1X + \cdots + a_nX^n.$$

Then $p \neq 0$ and $p(\tau) \sim_E 0$. The transcendence certificate supplies $p(\tau)\#0$, contradicting the zero classifier. Hence no nontrivial finite linear relation exists. □

Corollary 9413.69 (Transcendental extension is not finite algebraic dimension)**.** *If τ carries* $\mathsf{TransCert}_F(\tau)$*, then $F(\tau)$ is not a finite-dimensional vector space over F.*

Proof. Definition 9413.68 gives arbitrarily long finite linearly independent families

$$1, \tau, \ldots, \tau^n.$$

No finite-dimensional vector space over F contains such families of unbounded length. □

Definition 9413.70 (Analytic process reality)**.** *An* analytic process reality *is a process-facing carrier whose rows have the schematic form*

$$(\mathsf{approx}, \mathsf{modulus}, \mathsf{regularity}, \mathsf{Led}).$$

The approximation row supplies finite observations, the modulus row licenses convergence reads, the regularity row records the analytic or domain law, and Led *records operation closure, classifier stability, branch conditions, apartness obligations, and boundary conditions. Typical rows include process names for*

$$\exp(x), \quad \log(x), \quad \sin(x), \quad \cos(x), \quad \pi, \quad e, \quad \zeta(s),$$

whenever their domains, moduli, and operation ledgers are displayed.

Definition 9413.71 (Process candidate and certified transcendental)**.** *Let x be a row of an analytic process reality and let F be a base field-like reality. The row x is a* transcendence candidate over F *when its process data are displayed but no* $\mathsf{TransCert}_F(x)$ *row is present. It is a* certified transcendental over F *when the same process row is equipped with* $\mathsf{TransCert}_F(x)$*.*

Theorem 9413.72 (Process naming does not imply transcendence)**.** *The existence of an analytic process name for x does not by itself produce* $\mathsf{TransCert}_F(x)$*.*

Proof. An analytic process name supplies approximation, modulus, regularity, operation, classifier, branch, and boundary rows. A transcendence certificate requires, for every nonzero polynomial $p \in F[X]$, an apartness witness $p(x)\#0$. The latter is a uniform algebraic test family over the base field. It is not one of the rows contained in a bare process name, and it cannot be inferred from finite observations without an additional ledger. □

Corollary 9413.73 (Analytic constants are process rows before algebraic claims)**.** *In the unified-reality reading, π, e, and $\zeta(s)$ first enter as analytic process names when their streams, moduli, domains, branches, and operation ledgers are displayed. Claims that such rows are algebraic, transcendental, zero, nonzero, or branch-compatible require separate certificates.*

Proof. The process rows are those of Definition 9413.70. The separation between process construction and transcendence certification is Definition 9413.72. □

Definition 9413.74 (Exponential-logarithmic reality bridge)**.** *An* exponential-logarithmic reality bridge *is a continuation packet*

$$\mathsf{ExpLogBridge} := (\exp, \log, \mathsf{Dom}, \mathsf{Branch}, \mathsf{Tr}, \mathsf{Led})$$

whose ledgers include the classifier-stable rows

$$\exp(x+y) \sim \exp(x)\exp(y),$$

$$\log(xy) \sim \log(x) + \log(y),$$

and, on licensed branches,

$$\log(\exp x) \sim x, \qquad \exp(\log z) \sim z.$$

The logarithmic side carries branch and domain data, while the exponential side carries convergence and operation data. Division, inverse, logarithm, and branch transport are licensed only when the required apartness or domain rows are present.

Theorem 9413.75 (Exponential and logarithmic transport)**.** *On a displayed domain and branch ledger,* $\mathsf{ExpLogBridge}$ *transports additive structure to multiplicative structure through* exp*, and transports multiplicative structure back to additive structure through* log*.*

Proof. The bridge ledger contains $\exp(x+y) \sim \exp(x)\exp(y)$, so an additive relation read on the source side is transported to a multiplicative relation on the target side. Conversely, the branch ledger contains $\log(xy) \sim \log(x) + \log(y)$ on its licensed domain, so the multiplicative relation is transported back to an additive read. Each transport consumes the displayed domain, branch, apartness, and classifier-stability rows. □

Corollary 9413.76 (Exponential is a reality bridge)**.** *The exponential row is not merely a pointwise function symbol. With its domain, convergence, operation, and transport ledgers, it is a generalized continuation packet in the sense of Definition 9413.12.*

Proof. Definition 9413.75 supplies the transport row, and Definition 9413.74 supplies the source, target, branch, and ledger data required by generalized continuation. □

Definition 9413.77 (Cataphatic process and apophatic far-end roles)**.** *A row x is a* cataphatic process *when it is given by positive data*

$$(\mathsf{stream}, \mathsf{modulus}, \mathsf{regularity}, \mathsf{Led}).$$

By contrast, the apophatic far-end role is the boundary reading in which a forward-binding socket has far end named T *only in the sense of Definition 9401.2. The relation* $\equiv_{\mathrm{apo}}$ *is not kernel equality, and Definition 9401.3 forbids reading* T *as a state, record, carrier element, or closed-generation rule.*

Theorem 9413.78 (Transcendental carriers are not apophatic far ends)**.** *If τ carries* $\mathsf{TransCert}_F(\tau)$*, then $F(\tau)$ may be infinite-dimensional over F, but it remains a mathematical carrier. It is not* T *or an apophatic far end.*

Proof. By Definition 9413.69, $F(\tau)$ is not finite-dimensional over F. Nevertheless its rows are rational expressions $p(\tau)/q(\tau)$ with displayed denominator apartness, classifier equivalence, field operations, and readback. Thus it can be consumed by functions, relations, classifiers, and operation ledgers. The apophatic far end T cannot be consumed in that way: by Definition 9401.3, it is not a state, record, carrier element, or rule. Therefore infinite transcendental dimension and apophatic boundary naming are distinct roles. □

Corollary 9413.79 (The far end is not a highest-dimensional object)**.** T *is not an infinite-dimensional extension, a transcendence basis, a collection of all directions, or a point in a highest universe.*

Proof. Each of the listed readings would make T available as an object for membership, function application, relation, or equality. That internalization is exactly what Definition 9401.3 excludes. □

Definition 9413.80 (Process noncollapse over an algebraic layer)**.** *Let x be a row of an analytic process reality over a base field F. Its* process noncollapse over the algebraic layer *is the condition*

$$\mathsf{ProcNonCollapse}_F(x) := \neg\exists\alpha,\ \alpha \text{ algebraic over } F \ \wedge\ x \sim \alpha.$$

The equivalence symbol is read through the relevant process and algebraic classifiers; the condition asserts that no finite algebraic row supplies a lossless substitute for x.

Theorem 9413.81 (Transcendence implies algebraic-layer noncollapse)**.** *If x carries* $\mathsf{TransCert}_F(x)$*, then* $\mathsf{ProcNonCollapse}_F(x)$*.*

Proof. Assume that $x \sim \alpha$ for some α algebraic over F. Then there is a nonzero polynomial $p \in F[X]$ with $p(\alpha) \sim 0$. Classifier-respecting polynomial evaluation gives $p(x) \sim p(\alpha) \sim 0$. The transcendence certificate gives $p(x)\#0$, a contradiction. Hence no algebraic row over F can classify as a lossless substitute for x. □

Corollary 9413.82 (Transcendental rows exceed finite algebraic extensions)**.** *If x carries* $\mathsf{TransCert}_F(x)$*, then x is not losslessly expressible inside any finite algebraic extension of F.*

Proof. Every row expressible in a finite algebraic extension over F is algebraic over F. This is exactly the algebraic-layer collapse ruled out by Definition 9413.81. □

Definition 9413.83 (Algebra-to-analysis continuation)**.** *An* algebra-to-analysis continuation *is a generalized continuation packet*

$$\mathsf{GenCont}_{\mathrm{alg}\to\mathrm{an}} := (\mathcal{O}, \pi_{\mathrm{alg}}, \pi_{\mathrm{an}}, \mathsf{Tr}, \mathsf{Led})$$

where π_{alg} *reads finite algebraic expressions,* π_{an} *reads streams, moduli, limits, or analytic process rows,* Tr *records which algebraic relations are respected by the analytic process, and* Led *records convergence, branch, apartness, domain, and boundary obligations. A reverse read from the analytic process back to an algebraic row requires a separate bridge; otherwise the packet records noncollapse.*

Theorem 9413.84 (Algebra-to-analysis continuation is process extension)**.** *An algebra-to-analysis continuation does not turn an algebraic point into an unaudited host point. It extends finite algebraic expressions into process rows with displayed moduli and ledgers.*

Proof. By Definition 9413.83, the analytic projection reads streams, moduli, limits, process laws, and boundary ledgers. This is the same noncollapse discipline as Definition 9413.16 and Definition 9413.24: lower-layer finite observations are shadows of the process row, not replacements for it. A host point reading would discard the modulus, regularity, branch, apartness, and provenance rows that make the analytic carrier auditable. □

Theorem 9413.85 (Transcendental-process-far-end separation principle)**.** *In the unified-reality tower, finite algebraic extension directions, transcendental process directions, and apophatic far-end roles are pairwise distinct interface roles:*

$$\textit{finite algebraic direction} \neq \textit{transcendental process direction} \neq \textit{apophatic far end.}$$

Proof. Finite algebraic directions are classified by Definition 9413.54: their dimension is the degree of a minimal polynomial. Transcendental directions satisfy Definition 9413.69 and require an additional certificate beyond process naming by Definition 9413.72. Cataphatic process rows and apophatic far-end roles are separated by Definition 9413.77 and Definition 9413.78. Thus none of the three roles may be collapsed into either of the others without an explicit bridge, and no such bridge is supplied by the common carrier alone. □

9413.9 Spectral Curves as Common Carriers

The preceding sections moved from common carriers to projection ledgers, noncollapse, algebraic extension directions, and analytic process layers. The quartic spectral example gives a more elaborate worked case. The object is not a single polynomial, a recurrence, a matrix, or an elliptic curve in isolation. It is a fixed common carrier whose projections read recurrence algebra, rational generating functions, companion-matrix spectra, algebraic curves, elliptic normalization, real projection, dominant branches, and endpoint zeros.

The fixed quartic is

$$\Pi(\lambda, y) := \lambda^4 - \lambda^3 - (2y+1)\lambda^2 + \lambda + y(y+1).$$

All statements in this section are scoped to this fixed quartic and its displayed ledgers. The example is useful precisely because the recurrence, spectral polynomial, elliptic model, real projection, dominant branch, and fixed-window endpoint-zero law are connected by finite certificate rows rather than by an informal analogy between different mathematical pictures.

Definition 9413.86 (Quartic recurrence source)**.** *The* quartic recurrence source *is the rational generating function row*

$$Z(t,y) := \sum_{m\geq 0} Z_m(y)t^m = \frac{N(t,y)}{D(t,y)}$$

with

$$N(t,y) := 1 + yt + (y^2 - y - 1)t^2 + (y^3 - 2y)t^3$$

and

$$D(t,y) := 1 - t - (2y+1)t^2 + t^3 + y(y+1)t^4.$$

The packet

$$\mathsf{RecSource}_\Pi := (N, D)$$

records the source polynomials, the identity $D(t,y)Z(t,y) = N(t,y)$, and the coefficient-readback ledger for the sequence $(Z_m(y))_{m\geq 0}$.

Definition 9413.87 (Recurrence and spectral polynomial realities)**.** *The* recurrence reality $\mathcal{R}_{\mathrm{rec}}$ *has carrier the polynomial sequence $(Z_m(y))_{m\geq 0}$ and structure law*

$$Z_m(y) - Z_{m-1}(y) - (2y+1)Z_{m-2}(y) + Z_{m-3}(y) + y(y+1)Z_{m-4}(y) = 0$$

for $m \geq 4$. The spectral polynomial reality $\mathcal{R}_{\mathrm{specpoly}}$ *has carrier the reciprocal spectral face*

$$\Pi(\lambda, y) = \lambda^4 D(1/\lambda, y).$$

Definition 9413.88 (Companion matrix reality)**.** *The* companion matrix reality $\mathcal{R}_{\mathrm{mat}}$ *is the matrix family*

$$T(y) = \begin{pmatrix} 1 & 2y+1 & -1 & -y(y+1) \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}$$

with spectral readout

$$\det(\lambda I - T(y)) = \Pi(\lambda, y).$$

It realizes the order-four recurrence as a transfer system and exposes branch, eigenvalue, and dominance questions as matrix-spectral reads.

Definition 9413.89 (Quartic spectral common carrier)**.** *The* quartic spectral common carrier *is the packet*

$$\mathcal{O}_\Pi := (\mathsf{RecSource}_\Pi, (Z_m)_{m\geq 0}, T(y), \Pi(\lambda, y), \mathcal{C}_\Pi)$$

where

$$\mathcal{C}_\Pi := \{(\lambda, y) : \Pi(\lambda, y) = 0\}$$

is the affine spectral curve. It carries projections

$$\pi_{\mathrm{gen}}, \pi_{\mathrm{rec}}, \pi_{\mathrm{mat}}, \pi_{\mathrm{specpoly}}, \pi_{\mathrm{curve}}$$

to the generating-function, recurrence, companion-matrix, spectral-polynomial, and curve realities.

Theorem 9413.90 (Recurrence, matrix, and spectral polynomial share one carrier)**.** *The rational generating function $Z(t,y) = N(t,y)/D(t,y)$, the order-four recurrence for $Z_m(y)$, the companion matrix $T(y)$, and the spectral polynomial $\Pi(\lambda, y)$ are projections of $\mathcal{O}_\Pi$.*

Proof. The generating-function projection reads the source row (N, D). Comparing coefficients in $D(t, y)Z(t, y) = N(t, y)$ gives the recurrence row. The companion matrix in Definition 9413.88 is the transfer matrix for the same recurrence, and its characteristic polynomial is

$$\det(\lambda I - T(y)) = \Pi(\lambda, y).$$

Finally $\Pi(\lambda, y) = \lambda^4 D(1/\lambda, y)$ reads the reciprocal spectral face of the denominator. Thus the four presentations are ledgered projections of the same packet rather than unrelated objects. □

Concretized in §8880: The concrete NameCert packet records the recurrence, companion-matrix, spectral-polynomial, curve, and projection ledgers for the fixed quartic carrier.

Corollary 9413.91 (The spectral polynomial is not external data)**.** *The polynomial* $\Pi(\lambda, y)$ *is both the reciprocal face of the generating-function denominator and the characteristic face of the companion matrix.*

Proof. This is exactly the pair of identities

$$\Pi(\lambda, y) = \lambda^4 D(1/\lambda, y), \qquad \Pi(\lambda, y) = \det(\lambda I - T(y)).$$

□

Definition 9413.92 (Balanced quartic and elliptic normalization)**.** *The balanced quartic family is*

$$P_{a,c,d,g}(\lambda, y) := \lambda^4 + a\lambda^3 + (c - 2y)\lambda^2 + d\lambda + y(y - c) + g.$$

With

$$\xi = y - \lambda^2, \qquad Y = 2\xi - c,$$

the equation $P_{a,c,d,g} = 0$ *becomes*

$$Y^2 = c^2 - 4a\lambda^3 - 4d\lambda - 4g.$$

The normalized double-root conditions at $(\lambda, y) = (1, 0)$ *and* $(\lambda, y) = (-1, 1)$ *select the member*

$$(a, c, d, g) = (-1, -1, 1, 0),$$

which is Π*. Its elliptic normalization reality is*

$$E: \quad Y^2 = 4\lambda^3 - 4\lambda + 1, \qquad y = \lambda^2 - \frac{1}{2} + \frac{1}{2}Y.$$

Theorem 9413.93 (Elliptic normalization is a continuation packet)**.** *The transport from the affine spectral curve*

$$\mathcal{C}_\Pi : \Pi(\lambda, y) = 0$$

to

$$E: \quad Y^2 = 4\lambda^3 - 4\lambda + 1$$

is a generalized continuation from the quartic algebraic-curve reality to the elliptic-geometry reality.

Proof. In the canonical member, the change of variables is

$$\xi = y - \lambda^2, \qquad Y = 2\xi + 1,$$

with reverse read

$$y = \lambda^2 - \frac{1}{2} + \frac{1}{2}Y.$$

The ledger therefore transports the quartic equation to the displayed Weierstrass model and transports points back by the y-projection. The smoothness, degree-four projection, and ramification computations are not hidden assumptions; they are rows of the normalization ledger. Hence the move is a generalized continuation in the sense of Definition 9413.12. □

Definition 9413.94 (Ramification ledger)**.** *The* ramification ledger RamLed_Π *contains the finite rows*

$$2\lambda Y = 1 - 3\lambda^2,$$
$$(\lambda - 1)(\lambda + 1)(16\lambda^3 - 9\lambda^2 + 1) = 0,$$

and the branch-value polynomial

$$-y(y - 1)(256y^3 + 411y^2 + 165y + 32),$$

together with the squarefreeness and elimination certificates that justify the branch read.

Theorem 9413.95 (Ramification is a normalized-curve readout)**.** RamLed_Π *is the ramification readout of the same normalized carrier* $E \to \mathbb{P}^1_y$*, not an external discriminant calculation.*

Proof. The projection is

$$y = \lambda^2 - \frac{1}{2} + \frac{1}{2}Y$$

on the curve $Y^2 = 4\lambda^3 - 4\lambda + 1$. Differentiating the displayed projection under the Weierstrass relation gives the ramification row

$$2\lambda Y = 1 - 3\lambda^2.$$

Eliminating (λ, Y) gives the ramification abscissa equation and the branch-value polynomial. Thus the branch ledger is a geometric readout of the normalized curve. □

Definition 9413.96 (Real projection reality)**.** *The* real projection reality *is the map*

$$E(\mathbb{R}) \xrightarrow{y} \mathbb{R}_y.$$

Its ledger records the real oval decomposition, the y-image of each oval, the real-fiber count for regular values, and the multiplicity-counted root count at branch values. In the canonical quartic, the compact oval maps to $[y_{\mathrm{sub}}, 1]$ *and the noncompact oval maps to* $[0, \infty)$*.*

Theorem 9413.97 (Real-root counts are projection-fiber counts)**.** *The real-root interval diagram of* $\Pi(\lambda, y)$ *is the real projection readout of the elliptic normalization reality.*

Proof. Real roots of $\Pi(\cdot, y)$ correspond to points of

$$E(\mathbb{R}) \cap y^{-1}(y).$$

The oval decomposition, endpoint values, ramification values, and Sturm/sign rows determine the real-fiber count. Therefore the real-root diagram is a finite projection-fiber readout of the normalized carrier. □

Definition 9413.98 (Dominant spectral branch reality)**.** *The* positive-axis dominant branch reality *records the read*

$$y > 0 \longmapsto \lambda_{\mathrm{dom}}(y)$$

where $\lambda_{\mathrm{dom}}(y)$ is the unique maximal-modulus root of $\Pi(\cdot, y)$. In the fixed quartic, the branch satisfies $\lambda_{\mathrm{dom}}(y) > 1$ for $y > 0$, and the surviving simple dominant root at $y = 1$ is $\lambda_{\mathrm{dom}}(1) = 2$.

Theorem 9413.99 (Dominance is finer than ramification)**.** *The branch locus does not determine the recurrence-zero boundary. A branch point contributes to endpoint zero theory only when the colliding eigenvalues participate in maximal-modulus competition.*

Proof. The discriminant projection records collisions of spectral branches, but recurrence zeros are controlled by the dominant terms in the spectral decomposition. A branch point whose colliding eigenvalue is strictly subdominant does not control the endpoint zero law. In the fixed quartic, y_{sub} is a branch point with subdominant collision, and $y = 1$ is a real collision while the root 2 remains the dominant simple spectral read. The endpoint boundary at $y = 0$ is different: the colliding branches are active in the positive-axis maximal-modulus competition. Thus dominance is an additional ledger, not a consequence of the discriminant alone. □

Corollary 9413.100 (Discriminant projection is lossy)**.** *The discriminant locus is a lossy projection of the spectral carrier; it cannot recover the recurrence-zero boundary without a dominance ledger.*

Proof. Definition 9413.99 exhibits branch points that do not contribute to the endpoint-zero boundary. The recurrence-zero boundary therefore cannot be read from the discriminant projection alone. □

Definition 9413.101 (Endpoint zero reality)**.** *The* endpoint zero reality *is the local zero-distribution carrier for $Z_m(y)$ under the endpoint scale*

$$y = -\frac{u^2}{m^2}.$$

Its ledger contains the local branch coordinate s with $y = s^2$, the colliding branches $\lambda_\pm(s)$, the partial-fraction amplitudes $C_\pm(s)$, the non-colliding remainder estimate, fixed-window Rouché isolation, and the endpoint zero ordering.

Theorem 9413.102 (Endpoint zeros are local branch interference)**.** *The fixed-window endpoint zero law is the endpoint-zero projection of $\mathcal{O}_\Pi$. It is obtained by transporting the local branch collision through Puiseux branches, partial-fraction amplitudes, cosine interference, and Rouché zero isolation.*

Proof. At $y = 0$, the polynomial $\Pi(\lambda, 0)$ has a double root at $\lambda = 1$. With $y = s^2$, the active branches and amplitudes have local rows of the form

$$\lambda_\pm(s) = 1 \pm \frac{s}{\sqrt{2}}\frac{5}{8}s^2 \mp \frac{43}{64\sqrt{2}}s^3 + O(s^4)$$

and

$$C_\pm(s) = \frac{1}{2} \mp \frac{3\sqrt{2}}{16}s + O(s^2).$$

On the endpoint scale $s = iu/m$, the two active terms

$$C_+(s)\lambda_+(s)^m + C_-(s)\lambda_-(s)^m$$

combine into a shifted cosine model, while the non-colliding branches are controlled by the fixed-window remainder ledger. Rouché isolation then transports the approximate cosine zeros to actual zeros of $Z_m(-u^2/m^2)$ in the fixed window. □

Corollary 9413.103 (Endpoint zeros are not discriminant roots)**.** *In the fixed quartic, endpoint zeros are controlled by active spectral branch interference, not by the discriminant equation alone.*

Proof. The discriminant gives branch collision. The endpoint zero law also needs dominance, partial-fraction amplitudes, non-colliding remainder control, and Rouché isolation. These are precisely the rows listed in Definition 9413.101. □

Definition 9413.104 (Finite exact certificate ledger and scope boundary)**.** *The* finite exact certificate ledger $\mathsf{CertLed}_\Pi$ *consists of determinant and characteristic-polynomial identities, resultants, discriminant factorizations, ramification resultants, Sturm/sign tables, endpoint Puiseux coefficients, amplitude residue expansions, remainder estimates, and Rouché window bounds. The* scope boundary $\mathsf{ScopeBnd}_\Pi$ *refuses the following exports: a parameter-space classification of quartic families, a general equilibrium measure, a growing-window endpoint zero law, a uniform law for growing k, a standalone recurrence-boundary theory, or any RH or zeta theorem.*

Theorem 9413.105 (Quartic spectral carrier is finite-certificate common carrier)**.** *The packet $\mathcal{O}_\Pi$ is a finite-certificate common carrier: each transport between its realities is supported by rows of* $\mathsf{CertLed}_\Pi$ *and bounded by* $\mathsf{ScopeBnd}_\Pi$.

Proof. The recurrence-to-spectrum transport uses $D(t,y)Z(t,y) = N(t,y)$ and $\Pi(\lambda,y) = \lambda^4 D(1/\lambda,y)$. The matrix-to-spectrum transport uses $\det(\lambda I - T(y)) = \Pi(\lambda,y)$. The quartic-to-elliptic transport uses the balanced change of variables and normalization ledger. The elliptic-to-real-projection transport uses the real oval decomposition, extrema, branch values, and Sturm/sign rows. The real-projection-to-dominance transport uses the positive-axis dominance ledger. The dominance-to-endpoint-zero transport uses Puiseux branches, residue amplitudes, remainder estimates, and fixed-window Rouché isolation. These rows are finite certificates, and the scope boundary prevents the local fixed-quartic result from being flattened into any global quartic-family or growing-window theorem. □

Theorem 9413.106 (Quartic spectral common-carrier principle)**.** *The fixed quartic realizes the unified-reality pattern*

recurrence algebra → spectral polynomial → elliptic geometry → real projection → dominant branch → endpoint ze

Each arrow is a ledgered projection or transport from $\mathcal{O}_\Pi$, and none is licensed to collapse the others.

Proof. The shared-carrier statement is Definition 9413.90. The elliptic transport is Definition 9413.93. Real projection is Definition 9413.97. Dominance noncollapse is Definition 9413.99. Endpoint-zero transport is Definition 9413.102. The finite-certificate and scope discipline is Definition 9413.105. Together these statements exhibit the fixed quartic as a complex worked example of the common-carrier, projection, continuation, and noncollapse discipline. □

9413.10 Recursive Spectral Zero Hierarchy

The quartic spectral carrier, finite-field elliptic zeta functions, and global zeta or L-functions share a recursive spectral mechanism. They do not share one literal zero set. The commonality is structural: finite observations are folded into a generating object, the generating object exposes spectral factors, normalization identifies the balanced surface, and zero constraints are read only through the ledgers available at that level.

Definition 9413.107 (Zeta-like spectral hierarchy)**.** *The* zeta-like spectral hierarchy *separates three levels:*

$$\mathsf{RecurrenceSpectralZeros} \longrightarrow \mathsf{CurveZetaZeros} \longrightarrow \mathsf{GlobalZetaLFunctionZeros}.$$

The first level contains zeros such as the endpoint zeros of the fixed quartic recurrence carrier. The second level contains zeta zeros of geometric objects over finite fields, such as numerator roots of elliptic Hasse–Weil zeta functions. The third level contains zeros of global arithmetic zeta and L-functions, including the Riemann zeta zero ledger. The arrows are carrier-role refinements, not inclusions of one point set into another.

Definition 9413.108 (Recursive spectral fold)**.** *A* recursive spectral fold *is a packet*

$$\mathsf{ObsTime} \to \mathsf{GenFunction} \to \mathsf{SpectralFactors} \to \mathsf{Normalization} \to \mathsf{ZeroConstraint},$$

where finite observations indexed by an observation-time parameter are compressed into a generating function or Euler product; spectral factors read the compressed carrier; normalization identifies the balanced surface; and zero constraints are derived only after the required dominance, symmetry, exactness, or continuation ledgers have been displayed.

Theorem 9413.109 (Recursive spectral folds are not self-reference)**.** *A recursive spectral fold is a hierarchical compression of finite observation rows, not a circular definition of its own zero set.*

Proof. The input rows are finite observations such as recurrence coefficients, point counts over finite extensions, or prime-local Euler factors. The generating object is constructed from those rows. Spectral factors are then read from the generated object, and zero constraints are read from the spectral factors plus the relevant ledgers. Each stage consumes the previous stage as data; no stage assumes the zero constraint that it is supposed to produce. □

Definition 9413.110 (Quartic recurrence zero level)**.** *The quartic recurrence zero level is the recursive spectral fold*

$$(Z_m(y))_{m\geq 0} \to Z(t,y) = \frac{N(t,y)}{D(t,y)} \to \Pi(\lambda, y) \to E:\ Y^2 = 4\lambda^3 - 4\lambda + 1 \to \mathsf{EndpointZeros}.$$

Its zeros are zeros of the finite recurrence polynomials $Z_m(y)$ under the endpoint scaling and fixed-window ledgers of Definition 9413.101.

Theorem 9413.111 (Quartic endpoint zeros are recurrence-spectral zeros)**.** *The endpoint zeros in the fixed quartic carrier are recurrence-spectral zeros. They are zeta-like by recursive spectral form, but they are not zeros of the Riemann zeta function or of an elliptic Hasse–Weil zeta function.*

Proof. By Definition 9413.106, the fixed quartic carrier transports recurrence algebra through the spectral polynomial, elliptic normalization, real projection, dominance, and endpoint-zero ledgers. The endpoint zeros are obtained by local branch interference and Rouché isolation in Definition 9413.102. No Euler product, finite-field point-count zeta function, or completed Riemann zeta zero ledger is part of this carrier. Thus the analogy is structural rather than an identification of zero sets. □

Definition 9413.112 (Finite-field elliptic zeta level)**.** *For an elliptic curve $E/\mathbb{F}_q$, the finite-field elliptic zeta level folds the point-count time series*

$$r \longmapsto \#E(\mathbb{F}_{q^r})$$

into

$$Z(E/\mathbb{F}_q, T) := \exp\left(\sum_{r\geq 1} \#E(\mathbb{F}_{q^r})\frac{T^r}{r}\right).$$

For an elliptic curve this has the rational form

$$Z(E/\mathbb{F}_q, T) = \frac{1 - aT + qT^2}{(1-T)(1-qT)} = \frac{(1-\alpha T)(1-\beta T)}{(1-T)(1-qT)}.$$

The spectral roots α, β are the Frobenius readouts of the point-count fold.

Theorem 9413.113 (Frobenius roots recursively control point counts)**.** *In the finite-field elliptic zeta level, the spectral roots determine the point-count observations by*

$$\#E(\mathbb{F}_{q^r}) = q^r + 1 - \alpha^r - \beta^r.$$

Thus the point-count time series and the Frobenius spectral roots are two readouts of the same recursive fold.

Proof. The exponential generating definition records all point-count rows. The rational form of the elliptic zeta function packages the same data into the numerator factors $(1-\alpha T)(1-\beta T)$ together with the two denominator rows $(1-T)$ and $(1-qT)$. Expanding the logarithmic derivative of the displayed rational expression recovers the displayed point-count formula. Hence the spectral roots compress and read back the observation-time sequence. □

Definition 9413.114 (Finite-field elliptic RH-type normalization)**.** *The finite-field elliptic RH-type normalization is the row*

$$|\alpha| = |\beta| = \sqrt{q},$$

equivalently

$$\left|\frac{\alpha}{\sqrt{q}}\right| = \left|\frac{\beta}{\sqrt{q}}\right| = 1.$$

It is the finite geometric form of a normalized spectral-root constraint.

Theorem 9413.115 (Finite-field elliptic zeros give a closed local model)**.** *The finite-field elliptic zeta level is a closed local geometric model of RH-type normalization, not a proof of the Riemann zeta zero constraint.*

Proof. The normalization row of Definition 9413.114 places the Frobenius spectral roots on the unit circle after division by $\sqrt{q}$. This is a theorem at the finite-field elliptic level. The Riemann zeta zero ledger instead concerns complex zero rows s of the completed zeta carrier and the fixed-half condition $\Re(s) = 1/2$. Transport from the finite-field elliptic carrier to the completed Riemann zeta carrier is not supplied by the finite-field theorem. The remaining global bridge is the zero-defect rigidity route isolated in section 9413.16. □

Definition 9413.116 (Global elliptic and zeta zero level)**.** *For an elliptic curve over $\mathbb{Q}$, the global elliptic L-function level is assembled from local Euler factors. At a good prime p the local factor has the form*

$$1 - a_p p^{-s} + p^{1-2s}.$$

The global readout is an Euler product

$$L(E, s) = \prod_p L_p(E, p^{-s})^{-1}.$$

The Riemann zeta readout is the simpler global Euler product

$$\zeta(s) = \prod_p (1 - p^{-s})^{-1}.$$

Both are global arithmetic spectral carriers, with different local factor data and different proof obligations.

Theorem 9413.117 (Global elliptic L-functions are higher arithmetic siblings)**.** *Global elliptic L-functions and the Riemann zeta function share the Euler-product, Mellin, functional-equation, and zero-ledger pattern, but their zero ledgers are not the same object.*

Proof. Definition 9413.1147 records the elliptic, modular, and L-function bridge shape when the required bridge rows are displayed. The Riemann zeta carrier has its own prime-local factors and completed zero ledger, as used in section 9413.20. The two carriers share the global arithmetic spectral pattern, but a zero of one carrier is not automatically a zero of the other. Any transport between their zero statements requires its own bridge ledger. □

Definition 9413.118 (Normalized spectral-root analogy)**.** *The normalized spectral-root analogy compares the finite-field elliptic readout*

$$\frac{\alpha}{\sqrt{q}}$$

with the centered prime-channel readout

$$p^{1/2-s}.$$

Both are unit-circle constraints after normalization:

$$\left|\frac{\alpha}{\sqrt{q}}\right| = 1, \qquad |p^{1/2-s}| = 1.$$

The first is a Frobenius-root statement in a finite-field curve carrier. The second is a prime-channel reading of the fixed-half surface in the zeta carrier.

Theorem 9413.119 (Unit-circle analogies require carrier separation)**.** *The analogy between $\alpha/\sqrt{q}$ and $p^{1/2-s}$ identifies a common normalization pattern, not a common theorem or a common zero set.*

Proof. In the finite-field elliptic carrier, the unit-circle statement is the Frobenius-root normalization row. In the Riemann zeta carrier, $|p^{1/2-s}| = 1$ is equivalent to the fixed-half surface by Definition 9413.317. The latter is still only a surface readout until a zero row is shown to land on that surface. That additional step is the defect-zero incompatibility or prime-sieve odd exactness boundary of Definition 9413.202 and Definition 9413.477. □

Definition 9413.120 (Apophatic far end of recursive spectral towers)**.** *The far end of a recursive spectral tower is not an internal point of the tower. It is the boundary role named by the continuing availability of finite observation layers:*

$$r = 1, 2, 3, \ldots$$

or by unbounded prime windows, recurrence lengths, or extension degrees. In BEDC notation this is an apophatic far-end role, not a term to be substituted into the carrier as a value.

Theorem 9413.121 (Infinite observation time is not a spectral point)**.** *The infinite direction in a zeta-like recursive spectral fold is a boundary role for all finite readouts, not a point of the generated spectral carrier.*

Proof. For finite-field elliptic zeta functions, each r supplies the finite observation $\#E(\mathbb{F}_{q^r})$. The zeta function folds the entire finite observation family into a spectral object. It does not require a point $\mathbb{F}_{q^\infty}$ inside the carrier. The same discipline is the apophatic separation of Definition 9413.77 and Definition 9401.3: the far end may be named as a boundary role, but it is not consumed as a kernel object or as an additional spectral point. □

Theorem 9413.122 (Recursive spectral zero hierarchy principle)**.** *Quartic endpoint zeros, finite-field elliptic zeta zeros, global elliptic L-function zeros, and Riemann zeta zeros are projections of a common recursive spectral pattern only after their carrier boundaries are kept distinct.*

Proof. The quartic carrier uses recurrence data, a rational generating function, a spectral polynomial, elliptic normalization, dominance, and endpoint-zero ledgers. The finite-field elliptic carrier uses point counts over finite extensions, a Hasse–Weil zeta function, Frobenius spectral roots, and unit-circle normalization. The global elliptic and Riemann zeta carriers use Euler products, completion, functional equations, and zero ledgers. These are instances of Definition 9413.108. Their shared pattern licenses comparison of roles, while their separate ledgers forbid collapsing one zero reality into another. □

9413.11 Irreducible Information Layers and Spectral Factors

The recursive spectral hierarchy should not be read as the claim that an extra dimension mechanically contributes an extra zero. The precise reading is that an irreducible information layer contributes a spectral factor, and the spectral factor contributes zero or pole rows according to its sign in the zeta-like fold. Dimension enters only through the rank of the information layer being observed.

Definition 9413.123 (Irreducible spectral information layer)**.** *An* irreducible spectral information layer *of an object X is a carrier row*

$$\mathcal{I}_i(X)$$

whose finite observation-time readouts cannot be reconstructed from the other displayed layers without an explicit reconstruction ledger. Its rank is the number of independent spectral atoms required to read that layer in the selected spectral carrier.

Definition 9413.124 (Layer spectral factor)**.** *Let $\mathcal{I}_i(X)$ be an irreducible spectral information layer with spectral atoms*

$$\alpha_{i,1}, \ldots, \alpha_{i,b_i}.$$

Its layer spectral factor *is*

$$P_i(T) := \prod_{j=1}^{b_i} (1 - \alpha_{i,j} T).$$

The integer b_i is the spectral rank of the layer. It is the layer-level analogue of a Betti number or independent Frobenius-root count when such a reading is available.

Definition 9413.125 (Alternating zeta-like factorization)**.** *A zeta-like fold with irreducible information layers has the schematic factorization*

$$Z_X(T) = \prod_i P_i(T)^{(-1)^{i+1}}.$$

Positive exponents contribute zero rows of Z_X, while negative exponents contribute pole rows. The sign is part of the layer ledger, not a numerical dimension count.

Theorem 9413.126 (Spectral factors come from information layers)**.** *In a zeta-like recursive fold, zero and pole candidates arise from layer spectral factors, not from dimension labels by themselves.*

Proof. By Definition 9413.108, finite observations are first folded into a generating object and then read through spectral factors. By Definition 9413.124, a layer contributes one factor $P_i(T)$ whose degree is the number of independent spectral atoms of that layer. By Definition 9413.125, the same factor appears with a sign determining whether its roots are zero or pole rows. Therefore the proof-relevant datum is the irreducible layer and its factor, not the informal statement that a dimension has been added. □

Definition 9413.127 (Observation-to-spectrum exponential fold)**.** *For an object X with finite observation numbers $N_r(X)$, the observation-to-spectrum fold is*

$$Z_X(T) := \exp\left(\sum_{r \geq 1} N_r(X) \frac{T^r}{r}\right).$$

If the observations split as

$$N_r(X) = \sum_j \varepsilon_j \alpha_j^r,$$

then the fold reads as

$$Z_X(T) = \prod_j (1 - \alpha_j T)^{-\varepsilon_j}.$$

Theorem 9413.128 (Exponential folding converts spectral atoms into factors)**.** *The observation-to-spectrum fold converts each spectral atom α_j with sign ε_j into the factor $(1 - \alpha_j T)^{-\varepsilon_j}$.*

Proof. The logarithmic identity

$$-\log(1 - \alpha T) = \sum_{r \geq 1} \alpha^r \frac{T^r}{r}$$

shows that a contribution $\varepsilon_j \alpha_j^r$ to all observation levels contributes

$$-\varepsilon_j \log(1 - \alpha_j T)$$

to the logarithm of $Z_X(T)$. Exponentiating gives the displayed factor $(1 - \alpha_j T)^{-\varepsilon_j}$. Thus spectral atoms are exactly the factor-producing information carried by the observation sequence. □

Definition 9413.129 (Elliptic finite-field middle layer)**.** *For an elliptic curve $E/\mathbb{F}_q$, the middle information layer has two spectral atoms α, β and factor*

$$P_1(T) = 1 - aT + qT^2 = (1 - \alpha T)(1 - \beta T).$$

The two denominator factors

$$1 - T, \qquad 1 - qT$$

belong to the boundary layers. The zeta fold is

$$Z(E/\mathbb{F}_q, T) = \frac{P_1(T)}{(1 - T)(1 - qT)}.$$

Theorem 9413.130 (Elliptic curves have two middle spectral atoms)**.** *The finite-field elliptic curve does not acquire zeros because it has an extra geometric dimension. Its zeta numerator has two roots because its middle irreducible information layer has spectral rank two.*

Proof. The finite-field elliptic zeta level of Definition 9413.112 has numerator

$$1 - aT + qT^2 = (1 - \alpha T)(1 - \beta T).$$

The two roots are the Frobenius spectral atoms of the middle layer. The normalization row of Definition 9413.114 then places them on the unit circle after division by $\sqrt{q}$. The count two is the spectral rank of the middle layer, not the result of counting geometric dimensions as zeros. □

Definition 9413.131 (Higher curve layer pattern)**.** *For a smooth curve of genus g over a finite field, the middle spectral factor has schematic form*

$$P_1(T) = \prod_{j=1}^{2g} (1 - \alpha_j T).$$

The rank $2g$ records the independent middle-layer spectral atoms. The corresponding zeta-like fold has boundary factors from the lower and upper layers together with this middle factor.

Theorem 9413.132 (Layer rank determines factor degree)**.** *For curve zeta-like folds, the degree of the middle spectral factor is the rank of the middle information layer.*

Proof. In the elliptic case the rank is two and the factor is quadratic by Definition 9413.129. The higher-curve pattern of Definition 9413.131 displays the same rule with rank $2g$. The factor degree is therefore controlled by the number of independent spectral atoms in the layer. The dimension of the underlying geometric object matters only through this layer-rank ledger. □

Definition 9413.133 (Layer recursion rather than iterated ellipses)**.** *The phrase* layer recursion *denotes the process*

finite observations → generating function → spectral factor → normalized zero constraint → higher-level observati

It does not denote a literal nesting of elliptic curves or ellipses. A spectral factor may itself become data for a higher carrier only when a bridge ledger displays the new observation interface.

Theorem 9413.134 (Spectral factors become observation laws only by ledger)**.** *A spectral factor can control later observation rows, but it becomes a higher-level object only through an explicit bridge ledger.*

Proof. For the finite-field elliptic level, Definition 9413.113 shows that α, β determine the future point counts by

$$\#E(\mathbb{F}_{q^r}) = q^r + 1 - \alpha^r - \beta^r.$$

This is a readback law from spectral atoms to observation time. The quartic carrier similarly moves from recurrence observations through spectral branches to endpoint-zero laws by the ledgers of Definition 9413.106. In both cases, the spectral data become observation laws only because a readback or dominance ledger has been displayed. □

Definition 9413.135 (Global arithmetic spectral layer)**.** *The Riemann zeta carrier is the global arithmetic instance of the layer recursion pattern. Its local observation atoms are prime channels*

$$p^{-s},$$

its centered normalization channels are

$$p^{1/2-s},$$

and the completed carrier adds the non-point archimedean completion row of Definition 9413.140.

Theorem 9413.136 (RH is the global arithmetic normalized-zero constraint)**.** *In the global arithmetic layer, the RH fixed-half condition is the statement that zeta zero rows land on the simultaneous unit surface of all centered prime channels.*

Proof. For $s = 1/2 + \delta + i\tau$,

$$p^{1/2-s} = p^{-\delta} e^{-i\tau \log p}.$$

Thus

$$|p^{1/2-s}| = 1$$

for every displayed prime row exactly when $\delta = 0$, equivalently $\Re(s) = 1/2$, by Definition 9413.317. The remaining RH-facing problem is not this equivalence, but the zero-ledger statement that every nontrivial zeta zero lands on that surface. That missing bridge is the prime-sieve odd exactness or no-far-end absorption boundary of Definition 9413.477 and Definition 9413.143. □

Corollary 9413.137 (Information layers explain the spectral hierarchy)**.** *The zeta-like hierarchy is a hierarchy of irreducible information layers and their spectral factors, not a hierarchy of mechanically added zero coordinates.*

Proof. Definition 9413.16 and Definition 9413.23 provide the general language of layer and non-collapse. The present section specializes that language to spectral factors. Each irreducible layer contributes the spectral atoms needed for its observation-time readout; the resulting factors then contribute zero or pole rows according to the zeta-like factorization ledger. This is the precise content behind the recursive spectral hierarchy of Definition 9413.122. □

9413.12 No Far-End Absorption Boundary

The recursive spectral reading of zeta separates two meanings often compressed into the symbol ∞. The archimedean place is a positive completion row: it supplies the Gamma normalization needed for the completed zeta carrier and the functional-equation mirror. The apophatic far end is not such a row; it is the boundary role of an unbounded finite-observation tower. The RH-facing discipline is therefore not to remove the archimedean row, but to refuse the reification of the far end as a hidden point capable of absorbing finite prime defects.

Definition 9413.138 (Two infinity roles in the zeta carrier)**.** *The zeta carrier uses two distinct infinity-facing roles:*

$$\infty_{\text{place}} := \textit{archimedean completion row},$$

and

$$\mathsf{T}_{\text{far}} := \textit{apophatic far-end role.}$$

The first is represented analytically by the completion factor

$$\pi^{-s/2}\Gamma(s/2)$$

and by the pole-normalization rows entering the completed function. The second is a boundary name for the unbounded continuation of finite prime windows, recurrence lengths, or observation layers. It is not an element of the zeta carrier.

Definition 9413.139 (Finite prime-window recursive fold)**.** *For a finite prime window S, the raw finite Euler fold is*

$$Z_S(s) := \prod_{p\in S}(1-p^{-s})^{-1}.$$

If $q \notin S$ is a displayed prime row, the successor fold is

$$Z_{S\cup\{q\}}(s) = Z_S(s)(1-q^{-s})^{-1}.$$

Thus the raw Euler product is read as the compatible tower of finite prime-window folds, not as the value of a completed point $S = \mathsf{Prime}^{\uparrow}$ inside the carrier.

Definition 9413.140 (Archimedean completion row)**.** *The* archimedean completion row *for zeta is the analytic normalization packet containing*

$$\pi^{-s/2}\Gamma(s/2), \qquad s(s-1),$$

and the functional-equation ledger for the completed readout

$$\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s).$$

This row is part of the completed carrier. It is not an infinite prime and not an apophatic point.

Theorem 9413.141 (Completion is not point reification)**.** *Passing from finite prime-window folds to the completed zeta carrier requires the archimedean completion row, but it does not introduce T_{far} as a point of the carrier.*

Proof. The finite prime-window tower is generated by Definition 9413.139. The completed carrier additionally consumes the analytic normalization row of Definition 9413.140. These are positive data rows. By Definition 9413.120 and Definition 9413.121, the far end of the tower is a boundary role for unbounded finite readouts, not an internal object. Therefore completion adds the archimedean row and functional-equation ledger; it does not add an extra point at infinity. □

Definition 9413.142 (Far-end absorption)**.** Far-end absorption *is the illicit inference pattern that treats the unbounded tail, the archimedean row, or the apophatic far-end role as a hidden term able to cancel a displayed finite prime-window defect without a source-compatible zero-exclusion ledger. In formulas, it is the attempted passage from*

$$D_S(s)\#0$$

to harmlessness inside the completed carrier without proving

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times D_S(s)\#0 \to \bot.$$

Definition 9413.143 (No far-end absorption)**.** *The* no far-end absorption *row for the zeta carrier is*

$$\mathsf{NoFarEndAbsorption}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \sum_{S:\mathsf{FinitePrimeWindow}} (D_S(s)\#0) \to \bot \right).$$

It says that a finite prime-window defect cannot be hidden at the completed carrier boundary, whether the hiding is described as Euler tail, archimedean completion, functional-equation transport, or apophatic far-end pressure.

Theorem 9413.144 (No far-end absorption is prime-sieve odd exactness)**.** *For the zeta route, no far-end absorption is the completion-boundary form of prime-sieve odd exactness.*

Proof. The finite defect row in Definition 9413.143 is the same existential finite prime-window defect used in Definition 9413.477. The zero and critical-strip hypotheses place that defect in the completed zeta source. Both definitions exclude coexistence of that source row with a nonzero finite prime-window defect. The difference is terminological: prime-sieve odd exactness names the odd-defect mechanism, while no far-end absorption names the completion-boundary discipline that forbids the defect from being hidden by tail or far-end language. □

Theorem 9413.145 (Archimedean normalization is retained)**.** *No far-end absorption does not remove the archimedean completion row. It only refuses to read that row as a hidden defect absorber.*

Proof. The completed function row of Definition 9413.140 is required for the functional-equation mirror and for the completed carrier. Without that row, the fixed surface $\Re(s) = 1/2$ would not be read as the natural mirror surface of the completed object. No far-end absorption therefore preserves the archimedean row as a normalization and symmetry ledger. What it refuses is the additional, unledgered claim that this row can cancel a finite prime-window defect while leaving a zero ledger intact. □

Corollary 9413.146 (No far-end absorption is the RH-facing boundary)**.** *Within the recursive zeta tower, the RH-facing boundary is the claim that finite prime-window defect cannot be absorbed by completion.*

Proof. If $s = 1/2 + \delta + i\tau$ and $\delta \# 0$, then every nonempty finite prime window reads

$$D_S(s) = -\delta \sum_{p \in S} \log p \# 0$$

by Definition 9413.201. To obtain the RH fixed-half section, this visible finite defect must contradict the completed zero ledger. That contradiction is exactly the role of Definition 9413.202, Definition 9413.477, and the no-tail absorption row of Definition 9246.18. The no-far-end-absorption formulation states the same requirement as a boundary discipline for the recursive spectral tower. □

Theorem 9413.147 (Quartic carriers have finite closure, zeta has a far-end boundary)**.** *The quartic spectral carrier closes by finite certificate ledgers, while the zeta carrier requires a non-point far-end completion boundary.*

Proof. The fixed quartic carrier closes recurrence, spectral polynomial, elliptic normalization, dominance, and endpoint-zero rows through the finite certificate ledger of Definition 9413.105. Its endpoint-zero theorem is scoped by fixed windows and finite local branch data. The zeta carrier instead builds finite prime-window folds and then passes to analytic continuation, archimedean completion, and functional-equation rows. The latter passage has a far-end boundary: finite prime defects remain visible locally, but their incompatibility with zero rows requires the no-far-end-absorption ledger. □

Theorem 9413.148 (No-far-end formulation of the RH bridge)**.** *The RH bridge can be stated as the refusal of hidden absorption of finite prime defect at the apophatic far end of the zeta recursion tower.*

Proof. By Definition 9413.144, this refusal is equivalent to prime-sieve odd exactness. By Definition 9413.850, prime-sieve odd exactness, together with the located fixed-half collapse row, supplies the RH fixed-half section. Thus the no-far-end phrasing does not add a separate theorem. It names the exact boundary condition needed to prevent a finite off-half prime defect from being hidden by the completed carrier. □

9413.13 Finite Prime Tower as Completed Readout

The no-far-end route can be stated as a completed-readout discipline for the finite prime-window tower. The zeta carrier is not a last prime window and not an evaluation at an infinite prime set. It is the completed analytic readout of a recursively generated finite tower, together with archimedean normalization, functional-equation transport, and an apophatic boundary that cannot be consumed as a correction term.

Definition 9413.149 (Finite prime-window tower)**.** *The* finite prime-window tower *is the directed family of finite Euler folds*

$$E_S(s) := \prod_{p \in S} (1 - p^{-s})^{-1}$$

over nonempty finite prime windows S. If $q \notin S$ is a displayed prime row, the successor edge is

$$E_{S \cup \{q\}}(s) = E_S(s)(1 - q^{-s})^{-1}.$$

Thus the tower is generated by finite recursive extension, as in Definition 9413.139.

Definition 9413.150 (Finite Hamiltonian prime layer)**.** *For a nonempty finite prime window S and a depth row $M \geq 0$, the* finite Hamiltonian prime layer *is the finite occupation carrier*

$$\mathcal{K}_{S,M} := \bigotimes_{p \in S} \operatorname{span}\{|0\rangle_p, \ldots, |M\rangle_p\}.$$

The local number operator is

$$N_p|k\rangle_p = k|k\rangle_p,$$

and the finite Hamiltonian is

$$H_{S,M} := \sum_{p \in S} (\log p) N_p.$$

Its finite partition readout is

$$Z_{S,M}(s) := \operatorname{Tr}_{\mathcal{K}_{S,M}} \left(e^{-sH_{S,M}} \right) = \prod_{p \in S} \left(1 + p^{-s} + \cdots + p^{-Ms} \right).$$

Thus the finite Euler fold has a spectral-dynamical refinement: prime rows are occupation axes and $\log p$ *is the displayed frequency weight.*

Definition 9413.151 (Centered finite Hamiltonian readout)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

the centered finite Hamiltonian readout is

$$\widetilde{Z}_{S,M}(s) := \operatorname{Tr}_{\mathcal{K}_{S,M}} \left(e^{-(s-1/2)H_{S,M}} \right).$$

Equivalently,

$$e^{-(s-1/2)H_{S,M}} = e^{-\delta H_{S,M}} e^{-i\tau H_{S,M}}.$$

The local centered prime channel is

$$U_p(s) := p^{1/2-s} = p^{-\delta} e^{-i\tau \log p}.$$

Theorem 9413.152 (The critical line is the unitary Hamiltonian surface)**.** *For the centered finite Hamiltonian readout, the fixed-half surface is the unitary evolution surface.*

Proof. If $\delta = 0$, then

$$e^{-(s-1/2)H_{S,M}} = e^{-i\tau H_{S,M}},$$

and every local channel satisfies

$$|U_p(s)| = 1.$$

If $\delta \# 0$, the factor $e^{-\delta H_{S,M}}$ is a real amplitude-bias row. The local equality

$$|U_p(s)| = p^{-\delta}$$

is the same fixed-surface readout as Definition 9413.464. Thus the centered Hamiltonian language reads $\Re(s) = 1/2$ as the absence of nonunitary radial bias. □

Definition 9413.153 (Interlayer Hamiltonian lift)**.** *An* interlayer Hamiltonian lift *is one of the two finite extension rows*

$$(S, M) \to (S \cup \{q\}, M), \qquad (S, M) \to (S, M + 1).$$

For an additional displayed prime $q \notin S$, the Hamiltonian extension has the form

$$H_{S\cup\{q\},M} = H_{S,M} \otimes \mathbf{1}_q + \mathbf{1}_S \otimes (\log q)N_q.$$

For a depth extension, the carrier admits the additional occupation row $|M+1\rangle_p$ on each displayed prime axis. These are finite layer extensions, not an infinite prime point.

Definition 9413.154 (Spectral zero island of a finite layer)**.** *Let $F_{S,M}$ be a finite-layer spectral readout obtained from the Hamiltonian, sieve, or completed-tail ledger. A* spectral zero island *is a local zero component, or a certified small-value component, of the readout*

$$F_{S,M}(s).$$

The island is a zero-relevant object only when its source, layer, dominance or exactness ledger, and transition ledger are displayed. This is the zeta analogue of the quartic dominance discipline of Definition 9413.485.

Theorem 9413.155 (Normalized defect is invariant under prime-layer lifts)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

the normalized prime-window defect of Definition 9413.166 is independent of the finite prime layer:

$$\overline{D}_S(s) = -\delta.$$

Consequently every interlayer lift preserving the same s preserves the normalized off-critical defect.

Proof. The displayed equality is exactly Definition 9413.167. If $S \subseteq T$ are nonempty finite prime windows, then both normalized readouts are equal to the same normal displacement:

$$\overline{D}_S(s) = -\delta = \overline{D}_T(s).$$

Depth extension does not change the prime-window normalization row D_S/L_S. Hence the nonzero normal defect is not erased by adding a prime axis or by increasing finite occupation depth. □

Definition 9413.156 (Completed readout of the finite prime tower)**.** *The* completed readout *of the finite prime-window tower is the zeta carrier packet*

$$\mathsf{CompletedReadout}_\zeta := (\mathsf{PrimeWindowTower}, \mathsf{AnalyticContinuation}, \mathsf{ArchimedeanCompletion}, \mathsf{FunctionalMirror}, \mathsf{ZeroLe}$$

The archimedean component is the positive completion row of Definition 9413.140. The far-end component is the non-point boundary role of Definition 9413.138; it is not an extra element, terminal window, or hidden state.

Definition 9413.157 (Completed-readout absorption error)**.** *A* completed-readout absorption error *is the passage from a cofinally stable finite prime-window defect to a harmless completed zero row without displaying an exactness ledger excluding that coexistence. In schematic form it treats*

$$\mathsf{CofStablePrimeDefect}(s)$$

as if it could be cancelled by the apophatic boundary of

$$\mathsf{CompletedReadout}_{\zeta}.$$

This is precisely the hidden-correction pattern excluded by Definition 9413.180.

Definition 9413.158 (Completed-readout exactness boundary)**.** *The* completed-readout exactness boundary *is the row*

$$\mathsf{TailZeroWithStableDefectRequiresFarEndCorrection}_{\zeta}.$$

It is the zeta-specific claim that a finite sieve tail-zero tower together with a cofinally stable nonzero normalized prime defect would require a hidden far-end correction. In the notation of Definition 9413.190, this is the precise carrier equation still needed for the completed readout route.

Theorem 9413.159 (Finite rows of the completed-readout route are closed)**.** *The finite rows of the completed-readout route are already displayed: zero rows enter every finite sieve tail, and off-half displacement is a cofinally stable normalized prime-window defect.*

Proof. For the zero side, Definition 9413.186 gives

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{FiniteSieveTailZero}_{\zeta}(s).$$

For the defect side, Definition 9413.167 gives

$$\overline{D}_S(s) = -\delta(s)$$

for every nonempty finite prime window, and Definition 9413.168 turns $\delta(s)\#0$ into cofinal visibility of the normalized defect. No appeal to an infinite prime point is used in either row. □

Definition 9413.160 (Off-critical island survival)**.** *An* off-critical island survival *row is a compatible family of finite spectral zero islands through interlayer Hamiltonian lifts whose normal coordinate satisfies*

$$\delta(s)\#0$$

and whose completed readout is a zeta zero-source row. It records the claim that a nonunitary centered Hamiltonian island survives the finite prime tower and enters the completed zero ledger.

Theorem 9413.161 (Off-critical island survival is the stable-defect exactness boundary)**.** *Excluding off-critical island survival is the spectral-dynamical form of the completed-readout exactness boundary.*

Proof. If an off-critical island survives, then $\delta(s)\#0$. By Definition 9413.155, the normalized finite prime-window defect is the same nonzero value $-\delta(s)$ at every nonempty finite prime layer. Thus the surviving island carries a cofinally stable normalized defect. If its completed readout is also a zero-source row, the situation is exactly the tail-zero stable-defect pattern named in Definition 9413.158. The remaining task is therefore not detection of the defect, but exclusion of its coexistence with the completed zero ledger. □

Theorem 9413.162 (Completed-readout exactness normal form)**.** *The completed-readout RH route has the normal form*

$$\mathsf{TailZeroWithStableDefectRequiresFarEndCorrection}_\zeta \times \mathsf{NoHiddenFarEndCorrection}_\zeta \Rightarrow \mathsf{NoFarEndAbsorption}_\zeta \Rightarrow \mathsf{RH}$$

under the located fixed-half collapse row.

Proof. Tail-zero stable-defect correction necessity and no-hidden far-end correction compose by Definition 9413.191 to give no off-balanced tail zero. By Definition 9413.188, this gives the normalized no-absorption row. The RH fixed-half section then follows from Definition 9413.182. □

Corollary 9413.163 (Completed readout does not close by far-end reification)**.** *The completed readout of the finite prime-window tower may use analytic continuation, archimedean completion, and functional-equation transport, but it cannot close a stable finite defect by treating the apophatic far end as a hidden absorber.*

Proof. Definition 9413.141 separates positive completion rows from the apophatic far-end role. Definition 9413.157 identifies the forbidden inference pattern, and Definition 9413.180 rejects the corresponding hidden correction row. Therefore completed readout is a carrier discipline, not a license to cancel a finite defect at an undisplayed endpoint. □

Corollary 9413.164 (Quartic comparison)**.** *The quartic spectral carrier closes by finite certificate rows, while the zeta completed readout closes the analogous RH route only after the tail-zero stable-defect exactness boundary is discharged.*

Proof. The quartic comparison is recorded in Definition 9413.147: fixed windows, finite branch ledgers, and dominance rows close the quartic endpoint-zero law. The zeta carrier instead has an unbounded finite prime-window tower. Its finite rows are visible by Definition 9413.159, but the zero-facing route still requires the completed-readout exactness boundary of Definition 9413.158. □

9413.14 Far-End Unity and Prime-Window Normalization

No far-end absorption can be sharpened by normalizing finite prime-window defects. The normalized readout removes the scale of the window and leaves only the stable normal displacement from the critical surface. Thus far-end unity is not convergence to a point at infinity; it is cofinal compatibility of all finite readouts with no hidden boundary term.

Definition 9413.165 (Prime-window logarithmic weight)**.** *For a nonempty finite prime window S, define its logarithmic weight by*

$$L_S := \sum_{p \in S} \log p.$$

The window is nonempty and every displayed prime has positive logarithm, so L_S is a positive normalization row.

Definition 9413.166 (Normalized prime-window defect)**.** *For a nonempty finite prime window S, the* normalized prime-window defect *is*

$$\overline{D}_S(s) := \frac{D_S(s)}{L_S}.$$

Here $D_S(s)$ is the finite prime-window defect of Definition 9413.200.

Theorem 9413.167 (Normalized defects are constant over finite windows)**.** *If*

$$s = \frac{1}{2} + \delta + i\tau,$$

then for every nonempty finite prime window S,

$$\overline{D}_S(s) = -\delta.$$

Proof. By Definition 9413.201, the finite-window defect has the explicit form

$$D_S(s) = -\delta \sum_{p \in S} \log p.$$

The denominator in Definition 9413.166 is exactly

$$L_S = \sum_{p \in S} \log p.$$

Since S is nonempty, this denominator is positive. Dividing gives

$$\overline{D}_S(s) = -\delta.$$

□

Corollary 9413.168 (Off-half displacement is cofinally visible)**.** *If $\delta(s)\#0$, then every nonempty finite prime window carries the same nonzero normalized defect.*

Proof. Definition 9413.167 gives $\overline{D}_S(s) = -\delta(s)$ for every nonempty finite window. Thus apartness of $\delta(s)$ from zero is read in every normalized window. The defect is therefore not a finite-window artifact, an Euler tail error, or a scale effect of the growing window. □

Definition 9413.169 (Far-end unity for zeta prime windows)**.** *The* far-end unity *row for a zeta packet s is the cofinal compatibility condition*

$$\mathsf{FarEndUnity}_\zeta(s) := \prod_{S:\mathsf{FinitePrimeWindow}_{\neq\varnothing}} \left(\overline{D}_S(s) = 0\right).$$

It says that every finite prime-window normalization reads no radial defect. It is not a claim that the prime tower converges to an additional point.

Theorem 9413.170 (Far-end unity is the fixed-half surface)**.** *For the zeta prime-window readout,*

$$\mathsf{FarEndUnity}_\zeta(s) \iff \delta(s) = 0.$$

Consequently it is equivalent to

$$\Re(s) = \frac{1}{2}.$$

Proof. If $\mathsf{FarEndUnity}_\zeta(s)$ holds, choose any nonempty finite prime window S. The unity row gives $\overline{D}_S(s) = 0$. By Definition 9413.167, the same term is $-\delta(s)$, hence $\delta(s) = 0$. Conversely, if $\delta(s) = 0$, the same theorem gives $\overline{D}_S(s) = 0$ for every nonempty finite window. The equivalence with $\Re(s) = 1/2$ is the definition of δ and the fixed-surface calculation of Definition 9413.313. □

Definition 9413.171 (Cofinal compatibility without hidden boundary term)**.** *A finite-readout tower has* cofinal compatibility without hidden boundary term *when every cofinal finite family has compatible normalized readouts and no additional far-end correction row is admitted unless it is displayed as a positive carrier row. For zeta prime windows this means that the family*

$$\left(\overline{D}_S(s)\right)_S$$

cannot be altered at the apophatic far end by an undisplayed term.

Theorem 9413.172 (Far-end unity is cofinal compatibility)**.** *For the zeta prime-window tower, far-end unity is exactly cofinal compatibility of normalized finite defects with zero boundary defect.*

Proof. The normalized defect row removes the window scale by Definition 9413.166. The constant-window theorem Definition 9413.167 then shows that all cofinal windows read the same normal displacement $-\delta(s)$. Far-end unity requires that common readout to be zero. No point at infinity is used; the row is a compatibility condition on all finite windows together with refusal of a hidden boundary correction. □

Definition 9413.173 (Zero far-end unity target)**.** *The* zero far-end unity target *is*

$$\mathsf{ZeroFarEndUnity}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \Big(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{FarEndUnity}_\zeta(s)\Big).$$

It says that every critical-strip zero source row has cofinally unified prime-window normalizations.

Theorem 9413.174 (Zero far-end unity implies the RH section)**.** *If* $\mathsf{ZeroFarEndUnity}_\zeta$ *holds, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s. The zero and critical-strip rows of z give

$$\mathsf{FarEndUnity}_\zeta(s)$$

by Definition 9413.173. By Definition 9413.170, $\delta(s) = 0$, hence $\Re(s) = 1/2$. The fixed-half section equivalence of Definition 9413.199 therefore supplies the RH section. □

Theorem 9413.175 (No far-end absorption is the zero-facing exactness form)**.** *No far-end absorption is the zero-facing exactness form of far-end unity: a zero row cannot carry a stable nonzero normalized prime-window defect.*

Proof. If a zero row carried $\delta(s)\#0$, then Definition 9413.168 would give a nonzero normalized defect in every nonempty finite prime window, and in particular a finite prime-window defect. The no-far-end absorption row of Definition 9413.143 excludes coexistence of that finite defect with the completed zero ledger. Conversely, the zero far-end unity target of Definition 9413.173 asserts directly that zero rows have no such stable normalized defect. Thus the two formulations name the same zero-facing exactness requirement from opposite sides: absorption refusal and cofinal unity. □

Corollary 9413.176 (Far-end unity is not ordinary point convergence)**.** *The BEDC reading of far-end convergence in the zeta route is cofinal compatibility plus no hidden boundary term, not convergence to an infinite point.*

Proof. Definition 9413.169 defines far-end unity entirely through finite prime windows. The far end enters only as the boundary role that forbids hidden correction terms, as in Definition 9413.171 and Definition 9413.120. This is the same discipline enforced by Definition 9413.141: the completed zeta carrier may use positive completion rows, but it does not turn ∞, T, or Ω into a point that absorbs differences. □

9413.15 Far-End Correction Obligation

The normalized prime-window route isolates a useful proof boundary. The formula

$$\overline{D}_S(s) = -\delta(s)$$

shows that off-half displacement is cofinally stable across all nonempty finite prime windows. The no-far-end-absorption row says that such a stable finite defect cannot coexist with a completed zeta zero row. What remains is to justify, inside the completed zeta carrier, that coexistence of zero and cofinally stable defect would require a hidden far-end correction. That implication is the exactness obligation.

Definition 9413.177 (Cofinal stable prime defect)**.** *A zeta packet s carries a* cofinal stable prime defect *when some nonempty finite prime window has nonzero normalized defect:*

$$\mathsf{CofStablePrimeDefect}(s) := \sum_{S:\mathsf{FinitePrimeWindow}_{\neq\varnothing}} \left(\overline{D}_S(s)\#0\right).$$

By Definition 9413.167, this is equivalent to $\delta(s)\#0$ for the centered prime-window readout.

Definition 9413.178 (Hidden far-end correction)**.** *A* hidden far-end correction *for a zeta packet s is an undisplayed correction row*

$$C_{\mathsf{T}}(s)$$

whose only role is to cancel a cofinal stable finite prime defect at the completed carrier boundary while preserving the zero classifier. It is not the archimedean completion row of Definition 9413.140; it is an additional, unlicensed absorber placed at the apophatic far end.

Definition 9413.179 (Far-end correction necessity)**.** *The* far-end correction necessity *row is the zeta-specific exactness implication*

$$\mathsf{FarEndCorrectionNecessity}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \mathsf{CofStablePrimeDefect}(s) \to \mathsf{HiddenFarEndCo}$$

It says that if a completed zero row and a cofinally stable finite prime defect were to coexist, the completed carrier would have to contain an extra far-end correction row explaining the cancellation.

Definition 9413.180 (No hidden far-end correction)**.** *The* no hidden far-end correction *row is*

$$\mathsf{NoHiddenFarEndCorrection}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} (\mathsf{HiddenFarEndCorrection}(s) \to \bot).$$

It is the zeta-carrier instance of the apophatic far-end discipline: T, Ω, or the far-end boundary cannot be consumed as an internal correction object.

Theorem 9413.181 (Correction necessity plus refusal gives no absorption)**.** *Assume far-end correction necessity and no hidden far-end correction. Then no far-end absorption holds in normalized prime-window form:*

$$\prod_{s:\mathsf{Complex}^\uparrow} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \mathsf{CofStablePrimeDefect}(s) \to \bot).$$

Proof. Let s carry a zero row, a critical-strip row, and a cofinal stable prime defect. Far-end correction necessity supplies

$$\mathsf{HiddenFarEndCorrection}(s).$$

No hidden far-end correction sends this row to $\bot$. Hence the three input rows cannot coexist. □

Corollary 9413.182 (No absorption gives the RH section)**.** *Under located fixed-half collapse, the normalized no-absorption row of Definition 9413.181 implies the RH fixed-half section.*

Proof. If a critical-strip zero row had $\delta(s)\#0$, then Definition 9413.168 would give $\mathsf{CofStablePrimeDefect}(s)$. The normalized no-absorption row excludes this. Therefore $\neg(\delta(s)\#0)$ for every zero-source row. Located fixed-half collapse gives $\delta(s) = 0$, and Definition 9413.199 reads the result as the RH section. □

Theorem 9413.183 (Correction necessity is the unclosed exactness step)**.** *The no-hidden-far-end row is part of BEDC's apophatic discipline. The unclosed zeta-specific content is far-end correction necessity.*

Proof. Definition 9413.180 is a direct application of the non-internalization rule for apophatic far ends, already used in Definition 9413.141 and Definition 9413.176. It refuses to treat T or Ω as a hidden internal object. By contrast, Definition 9413.179 is an analytic exactness claim about the completed zeta carrier: it must show that zero plus cofinally stable finite defect cannot be reconciled without an unlicensed absorber. That claim is not supplied by $\mathsf{ZetaZero}(s)$ and remains the same hard point as Definition 9413.202. □

Definition 9413.184 (Finite sieve residual tail)**.** *For a finite prime window S, the* finite sieve residual tail *is the completed zeta readout after the displayed Euler factors in S have been removed:*

$$R_S(s) := \zeta(s) \prod_{p \in S} (1 - p^{-s}).$$

Equivalently, in the Euler-product region the finite Euler fold

$$E_S(s) := \prod_{p \in S} (1 - p^{-s})^{-1}$$

is separated from the residual readout by

$$\zeta(s) = E_S(s) R_S(s).$$

The finite sieve tower is the family $\left(R_S(s)\right)_S$ over finite prime windows.

Definition 9413.185 (Finite sieve tail-zero tower)**.** *The* finite sieve tail-zero tower *for a zeta packet s is*

$$\mathsf{FiniteSieveTailZero}_\zeta(s) := \prod_{S:\mathsf{FinitePrimeWindow}} (R_S(s) = 0)\,.$$

It says that every finite residual tail inherits the zero row after the displayed finite Euler factors have been removed.

Theorem 9413.186 (Zero rows enter finite sieve tails)**.** *Every critical-strip zeta zero row enters the finite sieve tail-zero tower:*

$$\prod_{s:\mathsf{Complex}^\uparrow} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{FiniteSieveTailZero}_\zeta(s))\,.$$

Proof. Let S be a finite prime window. By Definition 9413.184, $R_S(s)$ is obtained by multiplying the zeta value row by the displayed finite product

$$\prod_{p \in S} (1 - p^{-s}).$$

A zero row is preserved under this finite multiplication. The critical-strip row also ensures that each displayed factor is a legitimate finite sieve factor: if $0 < \Re(s) < 1$, then $|p^{-s}| < 1$, hence $1 - p^{-s}$ is not the zero denominator of a finite Euler factor. Thus every finite S has $R_S(s) = 0$. □

Definition 9413.187 (No off-balanced tail zero)**.** *The* no off-balanced tail zero *row is*

$$\mathsf{NoOffBalancedTailZero}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} (\mathsf{InCritStrip}(s) \times \mathsf{FiniteSieveTailZero}_\zeta(s) \times \mathsf{CofStablePrimeDefect}(s) \to \bot)\,.$$

It rules out a packet in which every finite residual tail is zero while the normalized prime-window defect remains cofinally stable and nonzero.

Theorem 9413.188 (No off-balanced tail zero gives no absorption)**.** *Assume no off-balanced tail zero. Then no far-end absorption holds in normalized prime-window form:*

$$\prod_{s:\mathsf{Complex}^\uparrow} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \mathsf{CofStablePrimeDefect}(s) \to \bot)\,.$$

Proof. Let s carry a zeta zero row, a critical-strip row, and a cofinal stable prime defect. By Definition 9413.186, the first two rows supply $\mathsf{FiniteSieveTailZero}_\zeta(s)$. These three rows are exactly the input of Definition 9413.187. Therefore they cannot coexist. □

Corollary 9413.189 (No off-balanced tail zero gives the RH section)**.** *Under located fixed-half collapse, no off-balanced tail zero implies the RH fixed-half section.*

Proof. By Definition 9413.188, no off-balanced tail zero gives the normalized no-absorption row. The RH section then follows from Definition 9413.182. □

Definition 9413.190 (Tail-zero stable-defect correction necessity)**.** *The* tail-zero stable-defect correction necessity *row is*

$$\mathsf{TailZeroWithStableDefectRequiresFarEndCorrection}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} (\mathsf{InCritStrip}(s) \times \mathsf{FiniteSieveTailZero}_\zeta(s) \times \mathsf{CofStabl}$$

It isolates the sieve-tower exactness claim: if zero is pushed to every finite residual tail while a normalized finite prime defect remains cofinally nonzero, then the reconciliation would require a hidden far-end correction row.

Theorem 9413.191 (Tail-zero correction plus refusal gives no off-balanced tail zero)**.** *Assume tail-zero stable-defect correction necessity and no hidden far-end correction. Then no off-balanced tail zero holds.*

Proof. Let s carry a critical-strip row, a finite sieve tail-zero tower, and a cofinal stable prime defect. Tail-zero stable-defect correction necessity supplies

$$\mathsf{HiddenFarEndCorrection}(s).$$

No hidden far-end correction sends this row to $\bot$. □

Theorem 9413.192 (Sieve-tail correction refines far-end correction necessity)**.** *Tail-zero stable-defect correction necessity implies far-end correction necessity.*

Proof. Let s carry a zero row, a critical-strip row, and a cofinal stable prime defect. The zero and critical-strip rows give

$$\mathsf{FiniteSieveTailZero}_\zeta(s)$$

by Definition 9413.186. Tail-zero stable-defect correction necessity then supplies $\mathsf{HiddenFarEndCorrection}(s)$, which is precisely the conclusion required by Definition 9413.179. □

Definition 9413.193 (Sieve-tower exactness subpackage)**.** *The* sieve-tower exactness subpackage *is*

$$(\mathsf{FiniteSieveTailZero}_\zeta, \mathsf{TailZeroWithStableDefectRequiresFarEndCorrection}_\zeta, \mathsf{NoHiddenFarEndCorrection}_\zeta).$$

It separates the finite multiplication row, the zeta-specific tail exactness row, and the apophatic refusal row. The finite multiplication row alone carries no fixed-half conclusion; the fixed-half output appears only after the stable-defect incompatibility row is supplied.

Definition 9413.194 (No-far-end proof obligation package)**.** *The* no-far-end proof obligation package *is*

$$(\mathsf{CofStablePrimeDefect}, \mathsf{FarEndCorrectionNecessity}_\zeta, \mathsf{NoHiddenFarEndCorrection}_\zeta, \mathsf{LocatedFixedHalfCollapse}).$$

The first row is the finite prime-window calculation. The second row is the zeta-specific completed-carrier exactness step. The third row is the apophatic refusal. The fourth row converts absence of off-half apartness into the fixed-half output row. The sieve-tower exactness subpackage of Definition 9413.193 is the finite-residual normal form of the second row.

Theorem 9413.195 (No-far-end package normal form)**.** *The no-far-end proof obligation package is a normal form for the far-end version of the RH route.*

Proof. The cofinal stable defect row is obtained from finite prime-window normalization by Definition 9413.167 and Definition 9413.168. Correction necessity and no-hidden correction compose by Definition 9413.181 to give no absorption. Located fixed-half collapse then yields the RH section by Definition 9413.182. The correction-necessity row may also be supplied through the sieve-tail normal form of Definition 9413.192. Thus the package separates the finite calculation, the unclosed analytic exactness step, the apophatic refusal, and the final located-real read. □

Corollary 9413.196 (Defect-zero incompatibility as correction refusal)**.** *Defect-zero incompatibility can be read as the claim that completed zeta zero rows do not admit hidden far-end corrections for cofinally stable prime defects.*

Proof. By Definition 9413.144, no far-end absorption is the completion-boundary form of prime-sieve odd exactness. By Definition 9413.481, prime-sieve odd exactness is defect-zero incompatibility. The present section refines the same row into correction necessity plus refusal of hidden correction. These are not separate RH routes; they are three readings of the same zeta-specific exactness obligation. □

9413.16 From Spectral-Curve Laboratory to the RH Rigidity Route

section 9413.9 provides a finite spectral laboratory: one fixed quartic carrier supports recurrence algebra, companion matrices, spectral polynomials, elliptic normalization, real projection, dominance, and endpoint-zero reads. The lesson for the RH route is not that the quartic proves anything about the zeta function. The lesson is structural. A zero-relevant boundary is not identified by a branch or defect read alone; it is identified only after the dominance, source-compatibility, and noncollapse ledgers have been displayed.

The RH-facing analogue is the route

$$\text{finite spectral defect} \Rightarrow \text{zero incompatibility} \Rightarrow \text{fixed-half rigidity}.$$

The target predicate itself is already stated in Definition 9360.23:

$$\mathsf{RH} := \prod_{s:\mathsf{Complex}^{\uparrow}} (\mathsf{InCritStrip}(s) \times \mathsf{ZetaZero}(s) \to \mathsf{OnCritLine}(s)).$$

This section records the unified-reality reading of the remaining obligation surface. It does not claim the missing analytic bridge.

Definition 9413.197 (RH zero source and fixed-half fiber)**.** *The* RH zero source carrier *is the packet*

$$\mathcal{Z}_\zeta := \sum_{s:\mathsf{Complex}^{\uparrow}} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)).$$

For a row $z = (s; Z_s; C_s)$, the fixed-half fiber adds the critical-line row:

$$\mathcal{H}_\zeta := \sum_{z:\mathcal{Z}_\zeta} \mathsf{OnCritLine}(\pi_s(z)).$$

This is the same constructive target as the RH witness function of Definition 9333.1, expressed as a section over the zero source.

Definition 9413.198 (RH fixed-half section)**.** *The* RH fixed-half section *is a displayed section*

$$\sigma : \mathcal{Z}_\zeta \to \mathcal{H}_\zeta$$

whose projection back to $\mathcal{Z}_\zeta$ is classifier-equal to the identity. Equivalently, it assigns to every

$$s : \mathsf{Complex}^{\uparrow}, \qquad \mathsf{ZetaZero}(s), \qquad \mathsf{InCritStrip}(s)$$

a displayed $\mathsf{OnCritLine}(s)$ *row.*

Theorem 9413.199 (Fixed-half section reads the RH target)**.** *The fixed-half section of Definition 9413.198 is the unified-reality section form of the BEDC RH target.*

Proof. Given RH, send a zero-source row $z = (s; Z_s; C_s)$ to $(z, \mathsf{RH}(s)(C_s, Z_s))$ in $\mathcal{H}_\zeta$. The projection is visibly the original row. In the other direction, a section applied to the row $(s; Z_s; C_s)$ supplies the missing $\mathsf{OnCritLine}(s)$ witness. This is the section form already used in Definition 9333.1. □

Definition 9413.200 (Off-half and prime-window defect rows)**.** *For* $s : \mathsf{Complex}^{\uparrow}$*, write*

$$\delta(s) := \Re(s) - \frac{1}{2}.$$

The off-half row is the apartness witness

$$\mathsf{OffHalf}(s) := \delta(s)\#0.$$

For a nonempty finite prime window S*, the prime-window defect is the finite readout*

$$D_S(s) := \sum_{p \in S} \log |p^{1/2-s}|,$$

as in Definition 9360.24. The existential defect row $\mathsf{PrimeDefect}(s)$ *asserts that some nonempty finite prime window has nonzero defect.*

Theorem 9413.201 (Off-half rows create finite prime defects)**.** *If* $\mathsf{OffHalf}(s)$ *holds and* S *is a nonempty finite prime window, then* $D_S(s)\#0$*.*

Proof. Write $s = 1/2 + \delta + i\tau$. Then

$$p^{1/2-s} = p^{-\delta}p^{-i\tau}, \qquad |p^{1/2-s}| = p^{-\delta}.$$

Thus

$$D_S(s) = -\delta \sum_{p \in S} \log p.$$

Since S is nonempty and every displayed prime has positive logarithm, the sum is positive. Apartness of δ from zero therefore gives apartness of $D_S(s)$ from zero. □

Definition 9413.202 (Defect-zero incompatibility route)**.** *The* defect-zero incompatibility route *is the zeta-specific bridge*

$$\mathsf{DefectZeroIncompatibility}$$

from prime-window defect inside the completed zeta carrier to apartness of the zeta value from zero. It is the same analytic obligation named in Definition 9360.25 and Definition 9246.13. It is not supplied by the definition of $\mathsf{ZetaZero}$*.*

Theorem 9413.203 (Defect-zero incompatibility rules out off-line zeros)**.** *Assume the defect-zero incompatibility route, zero-ledger soundness, and the same-source compatibility rows needed to compare the zero ledger with the prime-window read. Then no row can simultaneously carry*

$$\mathsf{ZetaZero}(s), \qquad \mathsf{InCritStrip}(s), \qquad \mathsf{OffHalf}(s).$$

Proof. An off-half row gives a nonzero finite prime-window defect by Definition 9413.201. The same-source compatibility row places that prime-window defect and the zero ledger in the same completed zeta carrier. Defect-zero incompatibility gives apartness of $\zeta(s)$ from zero, while zero-ledger soundness gives the zero value. This is a contradiction in the shared classifier. □

Definition 9413.204 (Located fixed-half collapse)**.** *The* located fixed-half collapse row *is the classifier transport*

$$\neg\mathsf{OffHalf}(s) \to \mathsf{OnCritLine}(s).$$

It is a located-real row for the specific real part comparison with $1/2$*; it is not a general classical trichotomy principle.*

Theorem 9413.205 (Rigidity package implies the RH section)**.** *Assume defect-zero incompatibility, zero-ledger soundness, same-source compatibility, and located fixed-half collapse. Then the RH fixed-half section exists.*

Proof. Let $z = (s; Z_s; C_s) : \mathcal{Z}_\zeta$. If $\mathsf{OffHalf}(s)$ held, then Definition 9413.203 would give a contradiction. Hence $\neg\mathsf{OffHalf}(s)$. Located fixed-half collapse supplies $\mathsf{OnCritLine}(s)$, so z lifts to $\mathcal{H}_\zeta$. This lift is a section because it preserves the underlying zero-source row. □

Corollary 9413.206 (The analytic content is zero-defect rigidity)**.** *Within the displayed structural rows, the remaining RH-facing analytic content is the incompatibility between zero rows and prime-window defect rows in the completed zeta carrier.*

Proof. The section target is structural by Definition 9413.199. The finite off-half defect read is Definition 9413.201. The step from defect to zero exclusion is exactly Definition 9413.202. Thus the analytic load is not the definition of the zero predicate but the rigidity row excluding zero and prime-window defect from the same completed source. □

Definition 9413.207 (Spectral laboratory pattern)**.** *A* spectral laboratory pattern *is a packet*

$$(\mathcal{O}, \mathsf{Branch}, \mathsf{Dominance}, \mathsf{LocalExpansion}, \mathsf{Interference}, \mathsf{ZeroLaw}, \mathsf{Boundary})$$

where $\mathcal{O}$ is a common spectral carrier, Branch *records ramification,* Dominance *records the zero-relevant active sheets,* LocalExpansion *records local branches,* Interference *records cancellation of active contributions,* ZeroLaw *records the resulting zero readout, and* Boundary *records the scope of the zero law.*

Definition 9413.208 (RH spectral-rigidity pattern)**.** *The* RH spectral-rigidity pattern *is the packet*

$$(\mathcal{Z}_\zeta, \mathsf{PrimeWindow}, \mathsf{PrimeDefect}, \mathsf{DefectZeroIncompatibility}, \mathsf{FixedHalfSection}, \mathsf{Boundary})$$

where $\mathcal{Z}_\zeta$ is the zero source carrier, finite prime windows provide defect readouts, defect-zero incompatibility is the zeta-specific rigidity row, the fixed-half section is the RH witness target, and the boundary records that the rigidity row is an obligation, not a closed theorem in this vision section.

Theorem 9413.209 (The quartic laboratory is an architecture model, not an RH proof)**.** *The quartic spectral carrier of section 9413.9 realizes a finite spectral laboratory pattern that models the architecture of the RH spectral-rigidity route, but it does not imply RH.*

Proof. The quartic carrier supplies a fixed recurrence source, companion matrix, spectral polynomial, elliptic normalization, real projection, dominance ledger, and endpoint-zero law. Its dominance ledger separates the zero-relevant endpoint from other branch collisions, as stated in Definition 9413.99. This is structurally analogous to the RH need to separate prime-visible defect rows that are zero-incompatible from finite reads that are merely visible. But the quartic carrier is fixed and finite, and its endpoint law is scoped by fixed-window restrictions through Definition 9413.105. RH requires a zeta-specific all-zero-source section. Therefore the quartic laboratory supplies proof architecture only. □

Corollary 9413.210 (The quartic carrier supplies no zeta bridge)**.** *The quartic worked example proves the value of a dominance-controlled spectral carrier. It does not prove defect-zero incompatibility for the completed zeta carrier.*

Proof. The quartic carrier contains the rows $(N, D, T(y), \Pi, E, y : E \to \mathbb{P}^1)$ and local endpoint branch data. The RH carrier contains zero-ledger, critical-strip, completed-zeta, prime-window, and fixed-half rows. Transport between these carriers is not supplied. The zeta-specific bridge remains the obligation named in Definition 9413.202. □

Definition 9413.211 (Zeta bridge obligations)**.** *The* zeta bridge obligations *are the following rows:*

ZetaCarrierClosure, PrimeWindowExtraction, OffHalfDefectFormula, DefectZeroIncompatibility, LocatedFixedH

They respectively provide completed zeta value rows, finite prime-window readouts, the off-half defect formula, zero-defect rigidity, and the located read from absence of off-half apartness to the critical line.

Theorem 9413.212 (Zeta bridge obligations close the section target)**.** *If the zeta bridge obligations are all displayed, then the RH fixed-half section exists, hence the RH predicate of Definition 9360.23 holds.*

Proof. The first two obligations place zero rows and finite prime-window rows in one completed zeta carrier. The off-half defect formula supplies prime defect from off-half apartness. Defect-zero incompatibility excludes a zero row with such a defect. Located fixed-half collapse turns absence of off-half apartness into OnCritLine. This is exactly the construction of Definition 9413.205, followed by Definition 9413.199. □

Definition 9413.213 (Finite-window to global boundary)**.** *The* finite-window to global boundary *is the obligation that finite prime-window readouts remain source-compatible with the completed zeta zero ledger and cannot be absorbed by tail, continuation, branch, or classifier transport when the route is lifted to the full zero source.*

Theorem 9413.214 (Finite-window facts alone do not imply RH)**.** *The finite prime-window defect formula alone does not imply RH.*

Proof. The formula says that off-half apartness is visible in a nonempty finite prime window. RH requires a witness that a zeta-zero row in the critical strip lies on the fixed-half fiber. The missing step is the zero-defect incompatibility bridge in the completed zeta carrier, together with the finite-window to global boundary of Definition 9413.213. Without those rows, finite-window defect is only a visible shadow, not a global zero-exclusion theorem. □

Corollary 9413.215 (Fixed-window discipline transfers as a warning)**.** *The fixed-window boundary in the quartic laboratory warns against flattening finite prime-window facts into all-height zeta rigidity.*

Proof. The quartic endpoint law is explicitly scoped to fixed endpoint windows and fixed index sets. Enlarging that scope would require additional uniformity rows. Likewise, RH is a dependent statement over all nontrivial zeta-zero source rows. It requires the global compatibility and zero-defect rigidity ledgers, not only finite-window defect reads. □

Theorem 9413.216 (Spectral-laboratory-to-RH principle)**.** *The unified-reality route from the quartic spectral laboratory to the RH surface is a proof-architecture transfer:*

$$\textit{finite carrier} + \textit{dominance ledger} + \textit{local interference} \Rightarrow \textit{zero law}$$

models the RH obligation shape

$$\textit{zeta carrier} + \textit{prime-window defect} + \textit{defect-zero incompatibility} \Rightarrow \textit{fixed-half section.}$$

The transfer identifies required ledgers; it is not a zeta theorem.

Proof. The finite laboratory side is Definition 9413.209. The section target is Definition 9413.199. The required zeta-specific obligations are Definition 9413.211. The reason finite-window facts do not suffice is Definition 9413.214. Therefore the correct conclusion is an obligation map from the spectral laboratory to the RH route, with defect-zero incompatibility as the central unclosed analytic bridge. □

9413.17 Phase, Transform, and Zeta Ladders

The unified-reality perspective also explains why trigonometry, the circle, Fourier modes, Laplace kernels, elliptic curves, and zeta functions appear in one mathematical corridor. They are not the same object. They are compatible projections of carriers that preserve quadratic norm, phase, exponential transport, spectral decomposition, branch structure, and zero ledgers at different interfaces.

The guiding ladder is

$$\text{triangle} \to \text{circle} \to \text{phase} \to \text{Fourier} \to \text{Laplace/Mellin} \to \text{zeta}.$$

The spectral-curve branch is

$$\text{recurrence} \to \text{spectral polynomial} \to \text{elliptic normalization} \to \text{branch/period/zero reality}.$$

Both ladders meet at the same discipline: a visible readout may expose part of a carrier, but the noncollapse ledger records which scale, phase, branch, convergence, prime, or zero rows remain hidden.

Definition 9413.217 (Quadratic phase carrier)**.** *The* quadratic phase carrier *is the carrier row behind the Pythagorean and unit-circle projections of section 9413.6. It contains a Pythagorean row*

$$a^2 + b^2 \sim c^2$$

and, when $c\#0$, the normalized phase read

$$x = \frac{a}{c}, \qquad y = \frac{b}{c}, \qquad x^2 + y^2 \sim 1.$$

The unit circle is the shape projection. The scale c remains in the fiber and is not recoverable from the circle point alone.

Theorem 9413.218 (Triangle-to-circle projection preserves phase and loses scale)**.** *The passage from a nondegenerate Pythagorean carrier to a unit-circle row preserves the normalized phase but forgets the scale fiber.*

Proof. This is the normalization read of Definition 9413.30 and the lossiness statement of Definition 9413.34. If $c\#0$, the projection sends (a, b, c) to $(a/c, b/c)$. The equation $a^2 + b^2 \sim c^2$ transports to $(a/c)^2 + (b/c)^2 \sim 1$. The value of c is not a coordinate of the circle readout. □

Definition 9413.219 (Circle phase and Fourier reality)**.** *The* circle phase reality *reads the unit circle through a phase parameter*

$$e^{i\theta} = \cos\theta + i\sin\theta.$$

The Fourier reality *reads functions on the circle through the character rows*

$$e^{in\theta}, \qquad n \in \mathbb{Z},$$

and the spectral expansion schema

$$f(\theta) \sim \sum_{n\in\mathbb{Z}} \widehat{f}_n e^{in\theta},$$

whenever the relevant convergence, classifier, and coefficient ledgers are displayed.

Principle 9413.220 (Fourier is the frequency projection of circle phase)**.** *Fourier analysis is not detached from the circle. It is the frequency projection of the same phase carrier: trigonometric coordinates read phase position, while character rows read spectral modes.*

Definition 9413.221 (Laplace extension of Fourier phase)**.** *The* Laplace extension *of Fourier phase replaces the pure phase kernel*

$$e^{-i\omega t}$$

by the damped exponential kernel

$$e^{-st}, \qquad s = \sigma + i\omega,$$

so that

$$e^{-st} = e^{-\sigma t}e^{-i\omega t}.$$

The imaginary part is the Fourier frequency read. The real part is the growth or damping read.

Theorem 9413.222 (Laplace is Fourier with a real bias direction)**.** *The Laplace kernel extends the Fourier phase kernel by adding a real amplitude-bias direction.*

Proof. The displayed factorization

$$e^{-(\sigma+i\omega)t} = e^{-\sigma t}e^{-i\omega t}$$

separates the real damping row from the pure oscillatory phase row. The kernel is therefore a two-coordinate reality: phase frequency and real growth/decay. □

Definition 9413.223 (Arithmetic Laplace carrier)**.** *For a coefficient sequence* $(a_n)_{n\geq 1}$*, the* arithmetic Laplace carrier *is the atomic source*

$$\mu_a := \sum_{n\geq 1} a_n \delta_{\log n}$$

with readout

$$\mathcal{L}[\mu_a](s) := \int e^{-st}\, d\mu_a(t) = \sum_{n\geq 1} a_n n^{-s}$$

on the displayed convergence window. For zeta, $a_n = 1$ *and Definition 9250.8 gives the same discrete Laplace read.*

Theorem 9413.224 (Zeta is an arithmetic Laplace readout)**.** *On its convergence window, the Dirichlet face of* ζ *is the discrete Laplace readout of the atomic source*

$$\mu_\zeta := \sum_{n\geq 1} \delta_{\log n}.$$

Proof. For every $n \geq 1$,

$$n^{-s} = e^{-s \log n}.$$

Therefore

$$\sum_{n \geq 1} n^{-s} = \int e^{-st} \, d\mu_\zeta(t)$$

on any convergence window where the sum and readout are licensed. This is the unified-reality restatement of Definition 9250.8. □

Definition 9413.225 (Multiplicative-prime face of zeta)**.** *The* multiplicative-prime face *of zeta is the Euler-product read*

$$\zeta(s) \sim \prod_p (1 - p^{-s})^{-1}$$

on a displayed right-half-plane window. It records that the additive Dirichlet/Laplace face is compatible with the multiplicative factorization of integers into primes.

Principle 9413.226 (Logarithm transports multiplication to Laplace addition)**.** *The logarithm is the bridge from arithmetic multiplication to the Laplace additive axis:*

$$\log(mn) = \log m + \log n.$$

The zeta carrier consumes this bridge when it reads multiplicative prime factorization as an additive atomic source on the $\log n$ *axis.*

Definition 9413.227 (Prime-channel unitary balance)**.** *For* $s = 1/2 + \delta + i\tau$ *and a displayed prime* p*, the centered prime channel is*

$$p^{1/2-s} = p^{-\delta} e^{-i\tau \log p}.$$

It is unitary exactly when the amplitude read satisfies

$$|p^{1/2-s}| = 1.$$

This is the unified-reality form of Definition 9243.5 and Definition 9243.6.

Theorem 9413.228 (The critical line is the prime-channel unitary surface)**.** *For a displayed prime* $p > 1$*,*

$$|p^{1/2-s}| = 1 \quad \Longleftrightarrow \quad \Re(s) = \frac{1}{2}.$$

Proof. Writing $s = 1/2 + \delta + i\tau$ gives

$$|p^{1/2-s}| = p^{-\delta}.$$

Since $p > 1$, this amplitude is 1 exactly when $\delta = 0$, namely $\Re(s) = 1/2$. This is the prime-channel read of Definition 9243.7. □

Definition 9413.229 (Elliptic spectral branch carrier)**.** *The* elliptic spectral branch carrier *is the geometric branch of the quartic example of section 9413.9. It reads the recurrence and companion-matrix carrier through the normalized curve*

$$E: \quad Y^2 = 4\lambda^3 - 4\lambda + 1, \qquad y = \lambda^2 - \frac{1}{2} + \frac{1}{2}Y.$$

It carries branch, period, real-projection, dominance, and endpoint-zero ledgers.

Principle 9413.230 (Elliptic curves are branched phase carriers)**.** *In this ladder, an elliptic curve is not an ordinary Euclidean ellipse. It is a genus-one branched phase carrier: the circle gives a single phase period, while the elliptic carrier exposes branch structure and two-period geometry. Theta and modular expansions are therefore the elliptic analogue of Fourier frequency reads on the circle whenever the corresponding ledgers are displayed.*

Theorem 9413.231 (Two ladders meet in spectral-zero reality)**.** *The transform ladder and the elliptic spectral ladder meet at zero-reality interfaces: transform kernels organize arithmetic and analytic readouts, while spectral curves organize branch and dominance readouts. Both require noncollapse ledgers before zero statements can be transported.*

Proof. On the transform side, Definition 9413.224 and Definition 9413.228 show how the zeta carrier reads arithmetic data through Laplace and prime-channel phase. On the spectral side, Definition 9413.106 shows how recurrence algebra, elliptic normalization, dominance, and endpoint zeros are projections of one fixed quartic carrier. In both cases, a visible readout is insufficient by itself: the zeta route needs the zero-defect rigidity boundary of section 9413.16, while the quartic route needs dominance and fixed-window ledgers. Thus the ladders meet as common-carrier disciplines for zero reality, not as a single untyped identification. □

Theorem 9413.232 (Phase-transform-zeta ladder principle)**.** *Triangles, circles, Fourier modes, Laplace kernels, zeta, and elliptic spectral curves form a compatible carrier ladder:*

geometric shape ↔ algebraic equation ↔ phase and transform kernel ↔ spectral decomposition ↔ zero reality.

The compatibility is ledgered projection and continuation, not object-level collapse.

Proof. The triangle-to-circle part is Definition 9413.218. The circle-to-Fourier and Fourier-to-Laplace parts are Definition 9413.220 and Definition 9413.222. The Laplace-to-zeta part is Definition 9413.224, with the prime face governed by Definition 9413.226. The elliptic spectral branch is Definition 9413.229. Finally, Definition 9413.231 records the zero-reality interface and its noncollapse boundary. □

9413.18 Generalized Continuation Chain

The phase-transform ladder of section 9413.17 must be read with a precise boundary. It is a generalized analytic continuation chain in the sense of Definition 9413.12; it is not a claim that every arrow is ordinary holomorphic continuation of one complex function across a larger domain. The chain transports structure from algebraic and geometric realities into phase, spectral, transform, and arithmetic realities. Only specific subrows, such as the $\mathsf{ZetaCont}^{\uparrow}$ application of chapter 9342, are ordinary analytic-continuation rows.

Definition 9413.233 (Reality-continuation chain)**.** *A* reality-continuation chain *is a finite sequence of carriered interfaces*

$$\mathcal{R}_0 \xrightarrow{\mathsf{GenCont}_{01}} \mathcal{R}_1 \xrightarrow{\mathsf{GenCont}_{12}} \cdots \xrightarrow{\mathsf{GenCont}_{(k-1)k}} \mathcal{R}_k$$

where every edge is a generalized continuation packet of Definition 9413.12. The edge may be algebraic normalization, geometric parametrization, character decomposition, exponential-kernel transport, logarithmic Laplace transport, or ordinary holomorphic continuation, provided the source, classifier, projection, transport, and boundary ledgers are displayed.

Definition 9413.234 (Narrow analytic-continuation row)**.** *A* narrow analytic-continuation row *is an edge whose source and target are holomorphic-domain readouts of one complex function, with overlap, identity-theorem, uniqueness, pole, and branch ledgers displayed. This is the ordinary* $\mathsf{AnaCont}^{\uparrow}$ *situation discussed in Definition 9413.13 and realized for zeta by Definition 9342.8.*

Principle 9413.235 (Generalized continuation is wider than holomorphic continuation)**.** *Every narrow analytic-continuation row is a generalized continuation row when its carrier and ledgers are displayed. The converse is not valid: normalization, phase parametrization, Fourier character projection, Laplace damping, Mellin logarithmic transport, Euler product regrouping, and spectral-curve normalization are generalized continuation rows but are not, merely by that fact, holomorphic continuation steps.*

Definition 9413.236 (Phase-transform arithmetic continuation)**.** *The* phase-transform arithmetic continuation *is the chain*

quadratic norm $\to$ *unit phase* $\to$ *frequency decomposition* $\to$ *damped frequency kernel* $\to$ *arithmetic log-spectrum.*

Its displayed formula rows are

$$a^2 + b^2 = c^2, \qquad x^2 + y^2 = 1, \qquad x + iy = e^{i\theta},$$

$$e^{-i\omega t}, \qquad e^{-st} = e^{-\sigma t} e^{-i\omega t}, \qquad n^{-s} = e^{-s \log n}.$$

The zeta endpoint reads

$$\zeta(s) = \sum_{n \geq 1} n^{-s} = \sum_{n \geq 1} e^{-s \log n}$$

on the displayed convergence window.

Theorem 9413.237 (The phase-transform chain is generalized continuation)**.** *The phase-transform arithmetic continuation of Definition 9413.236 is a generalized continuation chain, not a stepwise holomorphic continuation chain.*

Proof. The Pythagorean-to-circle edge is scale normalization by Definition 9413.218. The circle-to-Fourier edge is character projection by Definition 9413.220. The Fourier-to-Laplace edge adds the real amplitude-bias coordinate by Definition 9413.222. The Laplace-to-Mellin arithmetic edge is logarithmic transport by Definition 9413.1137. The endpoint zeta read is the atomic logarithmic Laplace readout of Definition 9413.224. These edges transport carriered structure across realities. They are not all holomorphic-domain extension operations of one complex function. □

Definition 9413.238 (Transported invariant)**.** *Let* $\mathsf{GenCont}_{i \to j}$ *be a generalized continuation packet. A* transported invariant *from* $\mathcal{R}_i$ *to* $\mathcal{R}_j$ *is a target-side row* P_j *equipped with a transport certificate from a source-side row* P_i *through the packet ledger. The target row need not have the same formula as* P_i*. It must instead be the certified image of the same carriered constraint under the displayed projection and transport rows.*

Definition 9413.239 (Zeta transported-invariant packet)**.** *The* zeta transported-invariant packet *is the collection of zeta rows corresponding to the phase-transform chain:*

source structure	*zeta-side transported row*
scale normalization	*centering at* $1/2$
unit phase	$\lvert p^{1/2-s}\rvert = 1$ *on the critical line*
frequency clock	$e^{-i\tau \log p}$
Laplace damping	$p^{-\delta}$ *or* $e^{-\delta x}$
spectral decomposition	*Dirichlet coefficients and Euler factors*
local-to-global assembly	*prime-local product to zeta readout*
symmetry	*functional-equation mirror*
zero boundary	$\zeta(s) = 0$ *as global cancellation*
defect boundary	*finite prime-window defect*

Here $s = 1/2 + \delta + i\tau$*, and the prime-channel row is*

$$p^{1/2-s} = p^{-\delta} e^{-i\tau \log p}.$$

Principle 9413.240 (Zeta inherits transported invariants, not literal shapes)**.** *If zeta is read as the arithmetic log-spectrum endpoint of the phase-transform chain, then zeta must carry transported versions of normalization, unit phase, frequency, damping, local-to-global assembly, symmetry, zero cancellation, and boundary rigidity. It need not contain the literal equation* $a^2 + b^2 = c^2$*, a Euclidean circle, or an ordinary Fourier series as object-level substructures.*

Definition 9413.241 (Zeta zero as global cancellation)**.** *A* zeta zero as global cancellation *is a zero row*

$$\zeta(s) = 0$$

read after the Dirichlet, Euler, continuation, and boundary ledgers have assembled nonzero local phase and amplitude information into one global zeta carrier. It is not a claim that each local term n^{-s} *or each prime channel* p^{-s} *vanishes.*

Theorem 9413.242 (Prime-unitary balance is the transported unit-phase row)**.** *For a displayed prime* $p > 1$*, the unit-phase condition transported to the centered prime channel is*

$$\lvert p^{1/2-s}\rvert = 1 \quad \Longleftrightarrow \quad \Re(s) = \frac{1}{2}.$$

Proof. This is Definition 9413.228. With $s = 1/2 + \delta + i\tau$,

$$p^{1/2-s} = p^{-\delta} e^{-i\tau \log p}$$

and hence

$$\lvert p^{1/2-s}\rvert = p^{-\delta}.$$

Since $p > 1$, this amplitude is 1 exactly when $\delta = 0$, which is the critical-line equation $\Re(s) = 1/2$. □

Definition 9413.243 (Defect-boundary transport)**.** *The* defect-boundary transport *is the RH-facing analogue of the dominance boundary in the quartic spectral carrier. In the quartic row, zero-relevant boundary data is not the discriminant alone; it is the maximal-modulus branch competition recorded in Definition 9413.99. In the zeta row, the corresponding boundary obligation is the passage from finite prime-window defect to zero incompatibility, using Definition 9360.24 and Definition 9360.25.*

Theorem 9413.244 (RH is transported unitary zero-rigidity)**.** *Under the zeta transported-invariant packet and the required defect-boundary transport, the RH target of Definition 9360.23 is the assertion that nontrivial zeta zeros in the critical strip occur only on the transported unitary balance surface.*

Proof. The transported unitary surface is the critical line by Definition 9413.242. The zero rows are global cancellation rows in the sense of Definition 9413.241. The missing analytic content is not the existence of the critical line; it is the rigidity statement that off-unitary amplitude bias cannot coexist with a zero row inside the completed zeta carrier. This is exactly the defect-zero route isolated in Definition 9413.202 and the section target of Definition 9413.199. □

Theorem 9413.245 (Generalized continuation chain boundary principle)**.** *The chain from quadratic norm through phase, Fourier, Laplace/Mellin, and zeta is valid only as a ledgered reality-continuation chain. It licenses transported invariants; it does not license literal identification of triangles, circles, Fourier series, Laplace kernels, and zeta.*

Proof. By Definition 9413.235, generalized continuation is broader than ordinary holomorphic continuation but remains ledger-bound. By Definition 9413.238, every inherited property requires a transport certificate. By Definition 9413.240, the zeta endpoint receives transported versions of phase, amplitude, local-to-global, symmetry, zero, and defect-boundary rows, not literal copies of the source shapes. Therefore the chain is a precise continuation discipline rather than an analogy or an object-level collapse. □

9413.19 Inherited Invariants of the Zeta Endpoint

section 9413.18 separates the generalized continuation chain from ordinary holomorphic continuation. The present section records the carrier-level invariants that reach the zeta endpoint through that chain. The point is not that zeta contains a literal triangle, circle, Euclidean ellipse, Fourier series, or Laplace transform as a visible subobject. The point is that normalization, unit phase, frequency, damping, local-to-global assembly, symmetry, cancellation, and defect-rigidity have transported zeta-side readouts.

Definition 9413.246 (Zeta construction chain)**.** *The* zeta construction chain *is the reality-continuation chain*

$$\mathsf{Pyth} \to \mathsf{Circle} \to \mathsf{Phase} \to \mathsf{Fourier} \to \mathsf{Laplace/Mellin} \to \mathsf{Zeta}.$$

Its basic displayed rows are

$$a^2 + b^2 = c^2, \qquad x^2 + y^2 = 1, \qquad x + iy = e^{i\theta},$$
$$e^{in\theta}, \qquad e^{-st}, \qquad \zeta(s) = \sum_{n\geq 1} n^{-s} = \sum_{n\geq 1} e^{-s\log n}.$$

The final equality is the arithmetic Laplace readout of Definition 9413.224.

Definition 9413.247 (Shared invariant along the zeta chain)**.** *A* shared invariant *of the zeta construction chain is a family of rows*

$$I_{\mathrm{Pyth}}, I_{\mathrm{Circle}}, I_{\mathrm{Fourier}}, I_{\mathrm{Laplace}}, I_{\mathrm{Zeta}}$$

together with transport ledgers between adjacent realities. The transported zeta row may change formula. It must remain the certified target-side read of the same carrier-level constraint in the sense of Definition 9413.238.

Definition 9413.248 (Zeta inherited invariant packet)**.** *The* zeta inherited invariant packet *is*

$$\mathsf{ZetaInv}(s) := (\mathsf{Center}, \mathsf{Unitary}, \mathsf{Phase}, \mathsf{Bias}, \mathsf{LocalGlobal}, \mathsf{Symmetry}, \mathsf{Cancellation}, \mathsf{Defect}).$$

For $s = 1/2 + \delta + i\tau$, its prime-channel readout is

$$p^{1/2-s} = p^{-\delta} e^{-i\tau \log p}.$$

The eight rows are:

invariant	*zeta-side read*
Center	$\frac{1}{2}$
Unitary	$\lvert p^{1/2-s}\rvert = 1$
Phase	$e^{-i\tau \log p}$
Bias	$p^{-\delta}$
LocalGlobal	$\sum n^{-s} \leftrightarrow \prod_p (1-p^{-s})^{-1}$
Symmetry	$J(s) = 1 - \overline{s}$
Cancellation	$\zeta(s) = 0$
Defect	$D_S(s)$

where $D_S(s)$ is the finite prime-window defect of Definition 9360.24.

Theorem 9413.249 (Scale normalization transports to centered prime channels)**.** *The Pythagorean scale-normalization row transports to the zeta centered prime channel*

$$p^{-s} \mapsto p^{1/2-s}.$$

Proof. In the Pythagorean carrier, a nonzero scale c licenses the normalized shape read

$$(a, b, c) \mapsto (a/c, b/c),$$

as in Definition 9413.218. In the zeta prime-local carrier, the raw channel is p^{-s} and the fixed-half center is $1/2$. Centering by that normalization produces

$$p^{1/2} p^{-s} = p^{1/2-s}.$$

This is a transported normalization row, not a literal Pythagorean equation inside zeta. □

Corollary 9413.250 (Zeta has a centered-channel read)**.** *When zeta is read as the arithmetic endpoint of the construction chain, its prime-local face must expose the centered channel*

$$U_p(s) := p^{1/2-s}$$

whenever critical-line and prime-channel comparisons are being made.

Proof. The centered channel is the zeta-side read of the normalization invariant by Definition 9413.249. It is the same channel used by Definition 9243.5. □

Definition 9413.251 (Zeta unitary balance)**.** *The* zeta unitary balance *row is the prime-channel predicate*

$$\mathsf{UnitaryZeta}(s) :\Longleftrightarrow \forall p \in \mathsf{Prime}^{\uparrow},\ \lvert p^{1/2-s}\rvert \sim 1.$$

It is the unified-reality reading of Definition 9243.6.

Theorem 9413.252 (Unit norm transports to the critical line)**.** *For a displayed prime row $p > 1$,*

$$|p^{1/2-s}| = 1 \quad \Longleftrightarrow \quad \Re(s) = \frac{1}{2}.$$

Consequently, $\mathsf{UnitaryZeta}(s)$ *is the prime-channel read of the critical line.*

Proof. This is the transported unit-phase theorem Definition 9413.242, equivalently the prime-unitary balance theorem Definition 9243.7. If $s = 1/2 + \delta + i\tau$, then

$$p^{1/2-s} = p^{-\delta} e^{-i\tau \log p}$$

and hence $|p^{1/2-s}| = p^{-\delta}$. For $p > 1$, this has modulus 1 exactly when $\delta = 0$. □

Definition 9413.253 (Prime phase clock and centered bias)**.** *For $s = \sigma + i\tau$, the* prime phase clock *is*

$$\theta_p(s) := -\tau \log p.$$

The raw and centered prime channels decompose as

$$p^{-s} = p^{-\sigma} e^{i\theta_p(s)}, \qquad p^{1/2-s} = p^{1/2-\sigma} e^{i\theta_p(s)}.$$

If $\sigma = 1/2 + \delta$, the centered amplitude bias is

$$p^{1/2-\sigma} = p^{-\delta}.$$

Theorem 9413.254 (Fourier frequency transports to logarithmic prime clocks)**.** *The Fourier phase row transports to the zeta prime-channel phase*

$$e^{-i\tau \log p},$$

so the prime-local frequency is read through $\log p$.

Proof. The Fourier kernel has phase form $e^{-i\omega t}$. A prime-local zeta term satisfies

$$p^{-s} = e^{-s \log p}.$$

Writing $s = \sigma + i\tau$ gives

$$e^{-s \log p} = e^{-\sigma \log p} e^{-i\tau \log p}.$$

The second factor is the Fourier phase row with clock $\log p$. □

Theorem 9413.255 (Laplace damping transports to off-critical bias)**.** *The Laplace damping factor transports to the zeta amplitude read*

$$n^{-\sigma} = e^{-\sigma \log n},$$

and the centered prime bias is

$$p^{-\delta}$$

for $s = 1/2 + \delta + i\tau$.

Proof. Put $t = \log n$ in the Laplace kernel. Then

$$e^{-st} = e^{-s\log n} = n^{-s}.$$

For $s = \sigma + i\tau$,

$$n^{-s} = e^{-\sigma\log n}e^{-i\tau\log n}.$$

The first factor is the damping or growth read. After centering at 1/2, the prime-channel form is

$$p^{1/2-s} = p^{-\delta}e^{-i\tau\log p}.$$

□

Corollary 9413.256 (The critical line is the zero-bias surface)**.** *The critical line is the surface on which the centered prime-channel amplitude bias disappears:*

$$\delta = 0 \quad \Longleftrightarrow \quad p^{-\delta} = 1.$$

Proof. This follows immediately from Definition 9413.255. □

Definition 9413.257 (Local-global zeta factorization)**.** *The* local-global zeta factorization *is the pair of readouts*

$$\zeta(s) = \sum_{n\geq 1} n^{-s}$$

and

$$\zeta(s) \sim \prod_p (1-p^{-s})^{-1}$$

on the displayed window where convergence, coefficient, and factorization ledgers license the comparison. The first is the global Dirichlet-sum face. The second is the prime-local Euler-product face.

Theorem 9413.258 (Frequency decomposition transports to prime-local factorization)**.** *The local frequency-decomposition invariant transports to the zeta Euler-product face:*

$$\zeta(s) \sim \prod_p (1-p^{-s})^{-1}.$$

Proof. Fourier analysis decomposes a global readout into character modes. In the arithmetic reality, unique prime factorization organizes integer terms into prime-local channels. On the window where absolute convergence and regrouping are licensed, the Dirichlet sum becomes

$$\sum_{n\geq 1} n^{-s} \sim \prod_p (1+p^{-s}+p^{-2s}+\cdots) = \prod_p (1-p^{-s})^{-1}.$$

Thus the zeta carrier has both the global sum face and the prime-local product face. □

Definition 9413.259 (Functional symmetry fixed surface)**.** *The* functional symmetry fixed surface *is the fixed set of*

$$J(s) := 1 - \overline{s}.$$

It satisfies

$$J(s) = s \quad \Longleftrightarrow \quad \Re(s) = \frac{1}{2}.$$

Theorem 9413.260 (Fourier symmetry transports to the zeta mirror)**.** *The circle/Fourier symmetry row transports to the zeta functional-equation mirror, whose conjugate-fixed form has fixed surface*

$$\Re(s) = \frac{1}{2}.$$

Proof. Circle phase has conjugation symmetry

$$e^{i\theta} \mapsto e^{-i\theta},$$

and Fourier modes carry positive and negative frequency symmetry. The completed zeta carrier has the functional-equation mirror relating s and $1 - s$. In conjugate-fixed form this is

$$J(s) = 1 - \overline{s}.$$

Writing $s = \sigma + i\tau$, the fixed condition gives

$$\sigma + i\tau = 1 - \sigma + i\tau,$$

and therefore $\sigma = 1/2$. □

Theorem 9413.261 (Zeta zeros are global cancellation rows)**.** *A zeta zero row records global cancellation of the assembled zeta readout. It does not assert that the local terms n^{-s} or the prime-local channels p^{-s} vanish.*

Proof. For every $n \geq 1$,

$$n^{-s} = e^{-s \log n}.$$

The local exponential term is nonzero wherever the exponential carrier is defined. Thus a zero row

$$\zeta(s) = 0$$

must be read as cancellation in the globally assembled Dirichlet/Euler/continued carrier, as already isolated in Definition 9413.241. □

Theorem 9413.262 (Off-critical bias produces finite prime-window defect)**.** *If $s = 1/2 + \delta + i\tau$, $\delta \# 0$, and S is a nonempty finite prime window, then the prime-window defect*

$$D_S(s) := \sum_{p \in S} \log |p^{1/2-s}|$$

is apart from zero.

Proof. For every $p \in S$,

$$|p^{1/2-s}| = p^{-\delta}.$$

Therefore

$$D_S(s) = \sum_{p \in S} \log(p^{-\delta}) = -\delta \sum_{p \in S} \log p.$$

Since S is nonempty and each displayed prime satisfies $p > 1$, the sum of logarithms is positive. Apartness of δ from zero gives apartness of $D_S(s)$ from zero. This is the unified-reality read of Definition 9413.201. □

Theorem 9413.263 (Zeta carries the inherited invariant packet)**.** *When zeta is read as the endpoint of the zeta construction chain, its carrier carries the invariant packet* $\mathsf{ZetaInv}(s)$ *wherever the corresponding source, projection, convergence, and boundary ledgers are displayed.*

Proof. The center row is Definition 9413.249. The unitary row is Definition 9413.252. The phase row is Definition 9413.254. The bias row is Definition 9413.255. The local-global row is Definition 9413.258. The symmetry row is Definition 9413.260. The cancellation row is Definition 9413.261. The defect row is Definition 9413.262. These are the eight components of Definition 9413.248. □

Definition 9413.264 (RH closure of inherited invariants)**.** *The* RH closure of inherited invariants *is the section target*

$$\prod_s \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{UnitaryZeta}(s)\right).$$

Using the critical-line equivalence of Definition 9413.252, this is the unitary-balance form of the BEDC RH target Definition 9360.23.

Theorem 9413.265 (RH reads as closure of inherited unitary balance)**.** *The RH section target admits a unitary-balance section form: a critical strip zero row is required to supply the inherited unitary-balance row.*

Proof. The BEDC RH target is the section form of Definition 9413.199. By Definition 9413.252, the prime-unitary balance row is equivalent to $\mathsf{OnCritLine}(s)$ on the displayed prime-channel packet. Therefore the RH section can be read as

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{UnitaryZeta}(s).$$

This is only a section-form reading of the target. It does not supply the missing defect-zero incompatibility route. □

Theorem 9413.266 (Inherited-invariant principle for zeta)**.** *The common structure carried by triangles, circles, Fourier modes, Laplace/Mellin kernels, elliptic spectral carriers, and zeta reaches the zeta endpoint as transported invariant data:*

normalization, unitarity, phase, damping, local-global, symmetry, cancellation, defect-rigidity.

The zeta-side forms are

$$p^{1/2-s}, \quad |p^{1/2-s}| = 1, \quad e^{-i\tau \log p}, \quad p^{-\delta}, \quad \sum n^{-s} \leftrightarrow \prod_p (1-p^{-s})^{-1}, \quad J(s) = 1-\overline{s}, \quad \zeta(s) = 0, \quad D_S(s).$$

Proof. This is the assembled content of Definition 9413.263. The quartic spectral row adds the boundary warning: visible branch/defect data is not enough without a zero-relevant boundary ledger, as recorded in Definition 9413.243. Thus the invariant package is a disciplined transport ledger, not an analogy and not a completed RH proof. □

9413.20 Ontic Triple Invariants and the Zeta Projection

The inherited-invariant packet of section 9413.19 can be compressed one level further. The recurring carrier data have three ontic roles: atom, time, and symmetry. Zeta is not the total ontology of mathematics. It is the arithmetic-spectral projection in which these three roles become prime-local factors, logarithmic Laplace time, functional symmetry, and a zero ledger. The RH-facing target is the zero-fiber fixedness of this projection.

Definition 9413.267 (Ontic invariant packet)**.** *An* ontic invariant packet *is a triple*

$$\mathcal{I} := (\mathsf{Atom}, \mathsf{Time}, \mathsf{Sym}).$$

The row Atom *records irreducible generated distinction. The row* Time *records generation order, continuation, filtration, or spectral-frequency direction. The row* Sym *records classifier preservation, duality, involution, or a fixed-surface structure. Different mathematical realities need not share the same objects; they may share the same ontic triple through different projections.*

Definition 9413.268 (Atom row)**.** *For a reality interface $\mathcal{R}$, an* atom row

$$\mathsf{Atom}_{\mathcal{R}}(a)$$

asserts that a is irreducible with respect to the displayed generation law of $\mathcal{R}$, or that every permitted factorization of a is trivial in that reality. Typical reads include prime numbers in multiplicative arithmetic, irreducible polynomials in a polynomial reality, branch generators in a curve reality, and eigenmodes or spectral branches in a spectral reality.

Definition 9413.269 (Time row)**.** *For a reality interface $\mathcal{R}$, a* time row *is an ordered, continued, filtered, or frequency parameter through which generated data are read. Examples include* Cont *and history continuation in the BEDC kernel, regular-modulus depth in located analysis, recurrence index m, Fourier phase or frequency parameters, Laplace time t, and the zeta logarithmic axis* $\log n$.

Definition 9413.270 (Symmetry row)**.** *For a reality interface $\mathcal{R}$, a* symmetry row *is a classifier-preserving involution, duality, reflection, or transport operation*

$$J_{\mathcal{R}} : \mathcal{R} \to \mathcal{R}$$

with fixed locus

$$\mathsf{Fix}(J_{\mathcal{R}}) := \{x : J_{\mathcal{R}}(x) \sim x\}.$$

The fixed locus is a balance surface only relative to the displayed classifier and transport ledger.

Definition 9413.271 (Zeta ontic projection carrier)**.** *The* zeta ontic projection carrier *is the packet*

$$\mathcal{O}_{\zeta}^{\mathrm{ontic}} := (\mathsf{PrimeAtoms}, \mathsf{LogTime}, \mathsf{LaplaceReadout}, \mathsf{EulerProduct}, \mathsf{FunctionalSymmetry}, \mathsf{ZeroLedger}).$$

Its three ontic projections are

$$\pi_{\mathrm{Atom}}(\mathcal{O}_{\zeta}^{\mathrm{ontic}}) = \prod_p (1 - p^{-s})^{-1},$$

$$\pi_{\mathrm{Time}}(\mathcal{O}_{\zeta}^{\mathrm{ontic}}) = e^{-s \log n},$$

and

$$\pi_{\mathrm{Sym}}(\mathcal{O}_{\zeta}^{\mathrm{ontic}}) = J(s) = 1 - \overline{s}.$$

Theorem 9413.272 (Zeta carries the ontic triple projection)**.** *The zeta ontic projection carrier carries atom, time, and symmetry projection rows.*

Proof. The atom projection is the Euler-product face

$$\zeta(s) \sim \prod_p (1 - p^{-s})^{-1},$$

which exposes prime-local arithmetic atoms as in Definition 9413.257. The time projection is the logarithmic Laplace row

$$n^{-s} = e^{-s \log n},$$

which is the arithmetic readout of Definition 9413.224. The symmetry projection is the functional mirror

$$J(s) = 1 - \overline{s},$$

whose fixed surface is read in Definition 9413.259. Thus the same zeta carrier supports the three ontic roles. □

Corollary 9413.273 (Zeta is not only a value function)**.** *The readout $\zeta(s)$ is one projection of $\mathcal{O}_\zeta^{\text{ontic}}$, not the complete carrier. The carrier also exposes prime atoms, logarithmic time, Euler-product factorization, functional symmetry, and zero-ledger rows.*

Proof. This is immediate from Definition 9413.272. A function value read does not by itself display the atom, time, symmetry, and zero-ledger rows that make the zeta carrier relevant to the RH route. □

Definition 9413.274 (Prime atom and zero resonance)**.** *A* prime atom *is a displayed row*

$$\mathsf{PrimeAtom}(p), \qquad p \in \mathsf{Prime}^{\uparrow},$$

expressing irreducibility in the natural-number multiplicative reality. A zero resonance *is a displayed row*

$$\mathsf{ZeroRes}(s) := \mathsf{ZetaZero}(s), \qquad s \in \mathsf{Complex}^{\uparrow}.$$

The rows live in different types. They may be coupled by the zeta carrier, but they are not the same object.

Theorem 9413.275 (Prime atoms and zero resonances are dual projections)**.** *Prime atoms and zero resonances are different typed projections of the zeta carrier: primes are arithmetic-local atoms, while zeros are spectral cancellation rows.*

Proof. Prime atoms appear in the Euler-product face

$$\prod_p (1 - p^{-s})^{-1}.$$

They belong to the arithmetic local-factor reality. Zero resonances appear in the global value ledger

$$\zeta(s) = 0.$$

They belong to the spectral cancellation reality described in Definition 9413.261. Since $p : \mathsf{Prime}^{\uparrow}$ and $s : \mathsf{Complex}^{\uparrow}$ have different carrier types and classifiers, they cannot be identified. They are coupled only through the common zeta carrier and its transform ledgers. □

Corollary 9413.276 (Prime-zero language is projection-relative)**.** *Statements relating primes and zeros must be read as carrier-coupling statements, not as type-level identifications. The precise form is: prime rows are arithmetic atoms; zero rows are spectral resonances; the zeta carrier transports information between their realities.*

Proof. This is the typed consequence of Definition 9413.275 and the projection discipline of Definition 9413.24. □

Definition 9413.277 (Ontic balance)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

the centered prime channel is

$$U_p(s) := p^{1/2-s}.$$

The ontic balance *row is*

$$\mathsf{OnticBalance}(s) :\Longleftrightarrow \forall p \in \mathsf{Prime}^{\uparrow},\ |U_p(s)| \sim 1.$$

It is the atom-time-symmetry balance read of the zeta prime-channel projection.

Theorem 9413.278 (Ontic balance is the critical line surface)**.** *For a displayed prime row $p > 1$,*

$$|U_p(s)| = 1 \quad \Longleftrightarrow \quad \Re(s) = \frac{1}{2}.$$

Thus $\mathsf{OnticBalance}(s)$ *is the critical-line surface in the prime-channel projection.*

Proof. This is the same prime-unitary computation as Definition 9413.252. Writing $s = \sigma + i\tau$ gives

$$U_p(s) = p^{1/2-\sigma} e^{-i\tau \log p}.$$

The phase factor has modulus one, so

$$|U_p(s)| = p^{1/2-\sigma}.$$

For $p > 1$, this is 1 exactly when $\sigma = 1/2$. □

Corollary 9413.279 (Critical line as ontic balance surface)**.** *The critical line is not defined by the zero predicate. It is the fixed balance surface obtained from prime atoms, logarithmic time phase, and functional symmetry.*

Proof. The critical-line surface is the same as the ontic balance surface by Definition 9413.278. The zero predicate is a separate ledger read over the completed zeta carrier. □

Definition 9413.280 (Zero-fiber fixedness)**.** *The* zero-fiber fixedness *target is the section form*

$$\prod_{s:\mathsf{Complex}^{\uparrow}} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{OnticBalance}(s)\right).$$

It is the ontic-balance reading of the RH target, not an independent proof of that target.

Theorem 9413.281 (Zero-fiber fixedness is the ontic section form of RH)**.** *Zero-fiber fixedness is the atom-time-symmetry section form of the BEDC RH target.*

Proof. The BEDC RH predicate is stated in Definition 9360.23 and read as a fixed-half section in Definition 9413.199. By Definition 9413.278, $\mathsf{OnticBalance}(s)$ is the critical-line row in the prime-channel projection. Replacing the target row $\mathsf{OnCritLine}(s)$ by this transport-equivalent balance row gives the displayed section form. This is a reformulation of the obligation surface only. □

Definition 9413.282 (Ontic collapse modes)**.** *The three collapse modes associated with the ontic packet are:*

$$\mathsf{TimeCollapse} := (\exists x,\ P(x)) \to \sum_x P(x),$$

$$\mathsf{SymCollapse} := (x \sim y) \to ([x] = [y]),$$

and

$$\mathsf{DistCollapse} := (P \leftrightarrow Q) \to (P = Q).$$

They name, respectively, an unaudited collapse of provenance time, an unaudited collapse of classifier fibers, and an unaudited collapse of predicate distinction.

Theorem 9413.283 (Excluded axioms are collapse modes)**.** *Read through the ontic packet,* Classical.choice *is a time/provenance collapse,* Quot.sound *is a symmetry/fiber collapse, and* propext *is a distinction collapse.*

Proof. The structural background is Definition 9387.5. Choice accepts a term-level existential as if a witness and its generating path had been supplied, so it collapses provenance time. Quot.sound accepts a classifier relation as quotient equality, so it collapses the fiber structure of symmetry. propext accepts bidirectional transport between propositions as equality of proposition objects, so it collapses predicate distinction. The axiom-purity gate described in Definition 9387.10 refuses exactly these unaudited closures at the public proof surface. □

Corollary 9413.284 (Axiom-purity protects the ontic ledgers)**.** *BEDC's axiom-purity discipline preserves the three ledger distinctions: generated provenance, classifier-fiber symmetry, and predicate distinction.*

Proof. By Definition 9413.283, the three forbidden dependencies collapse exactly those ledgers. Refusing them keeps the ontic packet from being silently compressed. □

Definition 9413.285 (Ontic defect)**.** *The* ontic defect *row is the apartness form of failure of ontic balance:*

$$\delta(s) := \Re(s) - \frac{1}{2}, \qquad \mathsf{OnticDefect}(s) := \delta(s)\#0.$$

For a nonempty finite prime window S, the defect readout is

$$D_S(s) := \sum_{p \in S} \log |p^{1/2-s}|.$$

Theorem 9413.286 (Ontic defect is visible in finite prime windows)**.** *If* $\mathsf{OnticDefect}(s)$ *holds and S is a nonempty finite prime window, then*

$$D_S(s)\#0.$$

Proof. Write $s = 1/2 + \delta + i\tau$. Then

$$|p^{1/2-s}| = p^{-\delta}.$$

Therefore

$$D_S(s) = \sum_{p \in S} \log(p^{-\delta}) = -\delta \sum_{p \in S} \log p.$$

If S is nonempty and every displayed prime satisfies $p > 1$, the logarithmic sum is positive. Apartness of δ from zero gives apartness of $D_S(s)$ from zero. This is the ontic reading of Definition 9413.262. □

Definition 9413.287 (Ontic defect-zero incompatibility)**.** *The* ontic defect-zero incompatibility *target is*

$$\prod_s (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \mathsf{OnticDefect}(s) \to \bot).$$

It is the ontic form of the defect-zero incompatibility route of Definition 9413.202.

Theorem 9413.288 (Ontic incompatibility closes the section target)**.** *Assume ontic defect-zero incompatibility and the located row that turns absence of ontic defect into ontic balance. Then the zero-fiber fixedness section target is obtained.*

Proof. Let s carry rows

$$\mathsf{ZetaZero}(s), \qquad \mathsf{InCritStrip}(s).$$

To produce the zero-fiber fixedness output it suffices to produce $\mathsf{OnticBalance}(s)$. Ontic defect-zero incompatibility rules out the simultaneous presence of the two zero rows and $\mathsf{OnticDefect}(s)$. Hence the defect row is absent. The located row converts this absence into $\mathsf{OnticBalance}(s)$. This is the same proof skeleton as Definition 9413.203, now expressed in atom-time-symmetry language. □

Corollary 9413.289 (The remaining ontic boundary)**.** *In the ontic projection language, the remaining RH-facing boundary is to show that a zeta zero row in the critical strip cannot coexist with an atom-time-symmetry defect inside the completed zeta carrier.*

Proof. The finite prime-window visibility of the defect is Definition 9413.286. The missing zero-relevance bridge is exactly the incompatibility target of Definition 9413.287. Thus the boundary is a zero-relevant carrier compatibility problem, not the mere observation that off-line prime-channel bias can be measured. □

Theorem 9413.290 (Spectral dominance warns against raw-defect collapse)**.** *The quartic spectral example shows why visible defect data cannot be used as a zero-relevant boundary without an active dominance ledger.*

Proof. In the quartic carrier, branch or discriminant data alone does not determine the endpoint-zero boundary. The zero-relevant boundary passes through maximal-modulus branch competition, as recorded in Definition 9413.99 and Definition 9413.1144. The zeta analogue is that a finite prime-window defect is only a visible defect row until a completed-carrier incompatibility with the zero ledger is supplied. □

Theorem 9413.291 (Zeta ontic projection principle)**.** *Zeta is the arithmetic-spectral projection of the ontic packet* $(\mathsf{Atom}, \mathsf{Time}, \mathsf{Sym})$*. Its atom projection is the prime-local Euler face, its time projection is the logarithmic Laplace/Mellin readout, and its symmetry projection is the functional mirror. The RH route can be read as the zero-fiber fixedness target for this projection, with ontic defect-zero incompatibility as the remaining zero-relevant boundary.*

Proof. The three projection rows are given by Definition 9413.272. Prime and zero rows remain typed projections by Definition 9413.275. The balance surface is the critical line by Definition 9413.278. The zero fiber section form is Definition 9413.281. The remaining incompatibility target is Definition 9413.287, and the quartic warning against raw-defect collapse is Definition 9413.290. These rows give the ontic projection principle without claiming the missing RH bridge. □

9413.21 Prime Phase-Radial Readback

section 9413.20 separates the complex value of zeta from the carrier rows that produce it. The reverse readback of a complex input s exposes those carrier rows as prime-indexed phase and radial coordinates. This section records that readback without treating the complex value $\zeta(s)$ as the complete object.

Definition 9413.292 (Prime phase-radial readback)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

the prime phase-radial readback *of s is the compatible family of finite prime-window coordinates*

$$\mathcal{U}_S(s) := \big(U_p(s)\big)_{p\in S}, \qquad U_p(s) := p^{1/2-s} = p^{-\delta}e^{-i\tau\log p}.$$

As S ranges over nonempty finite prime windows, these rows form the prime-coordinate readback

$$\mathcal{U}_\zeta(s) := \big(p^{1/2-s}\big)_{p\in\mathsf{Prime}^\uparrow}.$$

This readback is not the complex value $\zeta(s)$. It is the prime-indexed phase and radial carrier whose trace, Euler-product, and completed readouts project down to the complex zeta value.

Definition 9413.293 (Prime torus and radial deformation body)**.** *The* prime torus *is the finite-window compatible phase body*

$$\mathbb{T}_{\mathsf{Prime}^\uparrow} := \prod_{p\in\mathsf{Prime}^\uparrow} S^1,$$

read through its finite faces

$$\mathbb{T}_S := \prod_{p\in S} S^1.$$

For a normal displacement δ, the corresponding radial deformation body has finite faces

$$\mathbb{T}_{S,\delta} := \prod_{p\in S} p^{-\delta}S^1.$$

Thus $\delta = 0$ is the pure phase torus, while $\delta\#0$ is a common normal radial deformation across all displayed prime axes.

Theorem 9413.294 (The critical surface is the prime torus)**.** *For the prime phase-radial readback,*

$$\Re(s) = \frac{1}{2} \quad\Longleftrightarrow\quad \mathcal{U}_S(s) \in \mathbb{T}_S \text{ for every nonempty finite prime window } S.$$

Proof. Write $s = 1/2 + \delta + i\tau$. For each displayed prime p,

$$U_p(s) = p^{-\delta} e^{-i\tau \log p}.$$

If $\Re(s) = 1/2$, then $\delta = 0$, so

$$U_p(s) = e^{-i\tau \log p} \in S^1$$

for every p. Hence every finite readback $\mathcal{U}_S(s)$ lies in $\mathbb{T}_S$. Conversely, if every finite face lies on the prime torus, choose any displayed prime p. The singleton face gives

$$|U_p(s)| = 1.$$

By Definition 9413.278, this is equivalent to $\Re(s) = 1/2$. □

Theorem 9413.295 (Zeta zeros are projected global cancellations)**.** *A zeta zero is not a vanishing of a prime coordinate. It is a global cancellation row in the trace, product, continuation, and completed projection of the prime phase-radial carrier.*

Proof. For every displayed prime p and every complex row s, the local channel p^{-s} and the centered channel $p^{1/2-s}$ are nonzero channel rows. The zero ledger is instead the global row

$$\zeta(s) = 0$$

or, in the completed carrier, the corresponding completed zero row. Thus zerohood belongs to the projected readout of all prime channels together with continuation and completion ledgers. It is not a local coordinate zero. The RH-facing statement is therefore that such global cancellation, when it occurs in the critical strip, is supported on the prime torus rather than on a nonunitary radial deformation body. □

Definition 9413.296 (Prime phase profile)**.** *For a real time coordinate τ, the* prime phase profile *is the compatible family of finite-window phase rows*

$$\Phi_S(\tau) := \left(e^{-i\tau \log p}\right)_{p \in S} \in \prod_{p \in S} S^1,$$

and the cofinal profile

$$\Phi_{\mathsf{Prime}^\uparrow}(\tau) := \left(e^{-i\tau \log p}\right)_{p \in \mathsf{Prime}^\uparrow} \in \mathbb{T}_{\mathsf{Prime}^\uparrow}.$$

It records the simultaneous phase positions of all prime logarithmic frequencies at the same observation time τ.

Definition 9413.297 (Global prime phase closure)**.** *A* global prime phase closure *at time τ is a completed zero-ledger row whose critical-line carrier is the prime phase profile*

$$\Phi_{\mathsf{Prime}^\uparrow}(\tau)$$

together with the analytic continuation and completion rows of the zeta carrier. It is not a row assigning the zero to a finite set of prime coordinates. The displayed local phase rows remain nonzero unit coordinates; closure belongs to the global completed projection.

Theorem 9413.298 (Critical-line zeros are all-prime phase closures)**.** *If*

$$s = \frac{1}{2} + i\gamma$$

is a completed zeta zero row, then its prime-coordinate carrier is the all-prime phase profile

$$\Phi_{\mathsf{Prime}^\uparrow}(\gamma) = \left(e^{-i\gamma \log p}\right)_{p \in \mathsf{Prime}^\uparrow},$$

and its zerohood is a global closure of that profile through the completed zeta projection.

Proof. When $s = 1/2 + i\gamma$, the normal displacement in Definition 9413.292 is $\delta = 0$. Hence every centered prime channel is

$$U_p(s) = e^{-i\gamma \log p} \in S^1.$$

Thus the prime-coordinate carrier is exactly $\Phi_{\mathsf{Prime}^\uparrow}(\gamma)$. By Definition 9413.295, the zero row is not a local coordinate zero; it is the completed projection of the whole prime phase-radial carrier. Therefore a critical-line zero is an all-prime phase closure at the time γ. □

Corollary 9413.299 (Different zero times give different phase fingerprints)**.** *The zero-height coordinate is read as a prime phase fingerprint: two critical-line zero rows at different times correspond to different cofinal prime phase profiles.*

Proof. If two phase profiles agree on all displayed primes, then for every prime p the phase ratio satisfies

$$e^{-i(\gamma_1 - \gamma_2)\log p} = 1.$$

For any two distinct primes this gives integer winding rows

$$(\gamma_1 - \gamma_2)\log p = 2\pi m_p, \qquad (\gamma_1 - \gamma_2)\log q = 2\pi m_q.$$

Eliminating the common time difference gives a rational relation between $\log p$ and $\log q$. By Definition 9413.677, the relation is trivial. Hence the time difference is zero. Thus a different zero time cannot have the same cofinal prime phase profile. □

Corollary 9413.300 (Prime frequencies do not cancel as coordinates)**.** *Global phase closure can cancel in the completed complex readout, but it does not identify the prime logarithmic frequencies with one another or remove a prime coordinate from the carrier.*

Proof. The completed value may vanish because the whole phase profile is projected through Euler, continuation, and completion ledgers. That is the global cancellation row of Definition 9413.295. The prime frequencies themselves remain the logarithmic directions $\log p$. Their finite rational independence is Definition 9413.677, so no finite algebraic relation among displayed prime frequencies collapses one prime direction into the others. □

Theorem 9413.301 (Radial deformation is not phase closure)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

the phase profile

$$\Phi_{\mathsf{Prime}^\uparrow}(\tau)$$

and the radial deformation

$$\left(p^{-\delta}\right)_{p \in \mathsf{Prime}^\uparrow}$$

are separate rows of the prime phase-radial carrier. Phase cancellation in the completed readout does not cancel the positive square energy of a nonzero radial deformation.

Proof. The centered channel splits as

$$U_p(s) = p^{-\delta} e^{-i\tau \log p}.$$

The unit phase term is the p-coordinate of $\Phi_{\mathsf{Prime}^\uparrow}(\tau)$. The radial term is measured by

$$d_p(s) := \log |U_p(s)| = -\delta \log p.$$

Under the mirror J, this signed row changes sign, as recorded in Definition 9413.469. Its square

$$e_p(s) = d_p(s)^2 = \delta^2 (\log p)^2$$

is mirror-even by Definition 9413.673. Thus phase closure may account for a vanishing completed value, but it does not supply a negative term for the positive radial energy. □

The preceding statement is not a claim about arbitrary Euclidean vector polygons. In ordinary geometry, changing lengths can make a finite vector sum close. The BEDC claim is narrower: after the closed time–frequency carrier has fixed its legal hidden coordinates as unit phase and compact prime-register fibres, a real positive radial scale is not an admissible closing coordinate.

Theorem 9413.302 (Symmetric percentage motion leaves scale residue)**.** *Let* $0 < \varepsilon < 1$*. The two scale moves*

$$1 + \varepsilon, \qquad 1 - \varepsilon$$

do not compose to the identity scale:

$$(1 + \varepsilon)(1 - \varepsilon) = 1 - \varepsilon^2.$$

Equivalently,

$$\log(1 + \varepsilon) + \log(1 - \varepsilon) = \log(1 - \varepsilon^2) < 0.$$

Thus a scale displacement has a directed logarithmic residue unless the exact inverse scale is supplied as ledger data.

Proof. The multiplicative identity follows by expanding the product. Since $0 < \varepsilon < 1$, one has $0 < 1 - \varepsilon^2 < 1$, and hence $\log(1 - \varepsilon^2) < 0$. The inverse of $1 + \varepsilon$ is $(1 + \varepsilon)^{-1}$, not $1 - \varepsilon$. Therefore a scale system can be reversible only when the inverse scale has been recorded; a matched percentage motion in the opposite verbal direction is not an automatic inverse. □

Principle 9413.303 (Phase compactness and scale ledger)**.** *Unit phase belongs to the compact carrier*

$$S^1 \cong \mathbb{R}/2\pi\mathbb{Z},$$

so phase error is read modulo winding. Positive scale belongs, after logarithm, to the noncompact carrier

$$\mathsf{Real}^\uparrow_{>0} \cong (\mathsf{Real}^\uparrow, +),$$

so scale error is read as directed drift. In a closed BEDC time–frequency packet, phase may close inside the unit carrier, whereas nontrivial scale must appear in a boundary ledger or remain an illegal closure component.

Principle 9413.304 (Compact phase drift is not pointwise convergence)**.** *A phase orbit*

$$q_N = e^{iN\alpha}$$

stays in the compact unit carrier:

$$|q_N| = 1$$

for every N. This is bounded compact drift, not a convergence claim. Depending on the phase step and on additional analytic rows, such an orbit may be periodic, recurrent, equidistributed, averaged by a summability procedure, or used in a cancellation argument. None of these behaviours creates a real positive scale, and none is licensed as pointwise convergence without a separate convergence, averaging, or capture ledger.

Corollary 9413.305 (Scale amplifies while phase stays radial-unit)**.** *Let A be a finite active family with heights $h_a > 0$, and let*

$$U_a(s) = e^{-(s-1/2)h_a}$$

for $s = 1/2 + \delta + i\tau$. Define

$$d_a(s) := \log |U_a(s)|, \qquad E_A(s) := \sum_{a\in A} d_a(s)^2, \qquad W_A := \sum_{a\in A} h_a^2.$$

Then

$$E_A(s) = \delta^2 W_A.$$

Thus a nonzero normal displacement is amplified by any cofinal tower with $W_A \to \infty$, while the phase factors $e^{-i\tau h_a}$ contribute zero logarithmic radial energy.

Proof. The centered channel factors as

$$U_a(s) = e^{-\delta h_a} e^{-i\tau h_a}.$$

Since $|e^{-i\tau h_a}| = 1$,

$$d_a(s) = \log |U_a(s)| = -\delta h_a.$$

Squaring and summing over A gives

$$E_A(s) = \sum_{a\in A} \delta^2 h_a^2 = \delta^2 W_A.$$

The phase term has logarithmic modulus zero in every active channel, so it cannot contribute to the positive radial energy. □

Corollary 9413.306 (Finite resolution does not remove scale drift)**.** *A finite readout may fail to distinguish a small scale residue from the identity scale, but cofinal refinement cannot erase it. If $0 < \eta < 1$, then repeated scale residue satisfies*

$$(1-\eta)^N \to 0$$

as N tends along the natural refinement tower, while the logarithmic residue satisfies

$$N \log(1-\eta) \to -\infty.$$

Proof. Since $0 < 1-\eta < 1$, multiplication by $1-\eta$ is a strict contraction. Its iterates tend to zero. Taking logarithms gives

$$\log\big((1-\eta)^N\big) = N\log(1-\eta),$$

and $\log(1-\eta) < 0$, so the logarithmic residue diverges negatively. Thus finite resolution can hide a nontrivial scale residue only at a bounded window; the cofinal tower reads the drift. □

Principle 9413.307 (Phase time and scale time)**.** *The unitary time law*

$$e^{-itH}$$

is a phase row: when H is read in a unitary carrier, the inverse row is e^{itH}. The dissipative law

$$e^{-tH}, \qquad t \geq 0,$$

is a scale semigroup: reversing it requires the expanding row e^{tH}, which is not licensed by the forward semigroup without extra stability or boundary ledger data. Thus the zeta factor $e^{-i\tau h}$ belongs to phase closure, while $e^{-\delta h}$ belongs to scale drift unless a legal ledger accounts for it.

Theorem 9413.308 (No radial closure anomaly)**.** *The row*

$$\mathsf{NoRadialClosureAnomaly}_\zeta$$

holds for any zero-relevant closed generation certificate whose hidden coordinates are limited to unit phase rows and compact prime-register fibres. More explicitly, let

$$s = \frac{1}{2} + \delta + i\tau, \qquad U_a(s) = e^{-(s-1/2)h_a}, \qquad h_a > 0,$$

be an active centered channel in such a certificate. If the closure is licensed inside the closed time–frequency carrier, then

$$e^{-\delta h_a} = 1.$$

Consequently $\delta = 0$, so the legal closure has unit radial part and s lies on the critical line.

Proof. The centered channel factors as

$$U_a(s) = e^{-\delta h_a} e^{-i\tau h_a}.$$

The second factor is a unit phase row. Compact prime-register fibres, for instance finite faces of

$$\prod_{p\in S} \mathbb{Z}_p,$$

can encode prime-local residue or solenoid data, but they do not supply a nontrivial character into the real positive scale group $\mathsf{Real}^{\uparrow}_{>0}$. Therefore the real positive factor can belong to the closed hidden carrier only when it is trivial, by Definition 9413.557. Thus

$$e^{-\delta h_a} = 1.$$

Since $h_a > 0$, this forces $\delta = 0$. □

Corollary 9413.309 (Projected cancellation is not radial closure)**.** *A completed analytic readout may display a zero by global projection, but if a witness for that readout requires a nontrivial factor*

$$e^{-\delta h_a} \in \mathsf{Real}^{\uparrow}_{>0},$$

then that factor is a radial defect, not a phase closure or a prime-register residue.

Proof. Global zerohood is a projected cancellation row by Definition 9413.295. Legal closed generation uses the unit phase carrier together with compact prime-register fibres. By Definition 9413.308, a nontrivial real positive factor cannot be absorbed by those coordinates. Hence it marks a radial defect in the zero-relevant packet rather than a legal closed phase component. □

Corollary 9413.310 (Off-half zero rows would carry all-prime radial energy)**.** *If a critical-strip zero row had $\delta\#0$, then every displayed prime coordinate would carry nonzero radial defect, and the global prime normal energy would be infinite.*

Proof. For every displayed prime, Definition 9413.301 gives

$$d_p(s) = -\delta \log p.$$

Since $\delta\#0$ and $\log p > 0$, each prime row detects the same off-half normal displacement. Summing the positive square energies over finite prime windows gives the extended global energy of Definition 9413.672. By Definition 9413.675, that energy is infinite. □

Corollary 9413.311 (The no-hair target is zero relevance of radial energy)**.** *The remaining RH-facing target is not the detection of an off-half radial deformation. It is the zero-relevance claim that a completed zeta zero cannot carry the all-prime positive radial energy of Definition 9413.310.*

Proof. Detection is already finite and prime-local: each displayed prime reads $d_p(s) = -\delta \log p$, and every finite prime window reads the same normal displacement after normalization. The completed zero ledger must still be linked to that detected obstruction. This is the no-hair boundary of Definition 9413.678 and the cofinal socket form of Definition 9413.687. □

9413.22 Observation-Classified Symmetry on the Critical Surface

section 9413.20 reads zeta through prime atoms, logarithmic time, functional symmetry, and a zero ledger. section 9413.23 then extracts the minimal ontic core as observation-time, distinction-atom, and symmetry-transport. The critical line is the place where these two views meet: it is not a literal boundary between constructive and classical reasoning, nor a side-by-side separation of discrete and continuous objects. It is the observation-classified fixed surface of the zeta mirror, with prime-local and Laplace readouts giving compatible tests of the same classifier.

Definition 9413.312 (Critical mirror classifier)**.** *For a complex history*

$$s = \sigma + i\tau,$$

write

$$J(s) := 1 - \overline{s}, \qquad \delta(s) := \Re(s) - \frac{1}{2}.$$

The critical mirror classifier is the three-way readout

$$\mathsf{HalfClass}_\zeta(s) := \begin{cases} \mathsf{LeftBias}, & \delta(s) < 0, \\ \mathsf{Fixed}, & \delta(s) = 0, \\ \mathsf{RightBias}, & \delta(s) > 0. \end{cases}$$

It classifies a point by its observed displacement from the mirror fixed surface.

Theorem 9413.313 (The critical line is the mirror fixed surface)**.** *For the mirror $J(s) = 1 - \overline{s}$,*

$$J(s) = s \quad \Longleftrightarrow \quad \delta(s) = 0 \quad \Longleftrightarrow \quad \Re(s) = \frac{1}{2}.$$

Thus the line $\Re(s) = 1/2$ is supplied by symmetry before any zero row is read.

Proof. Writing $s = \sigma + i\tau$ gives

$$J(s) = 1 - \overline{\sigma + i\tau} = 1 - \sigma + i\tau.$$

Hence $J(s) = s$ is equivalent to

$$1 - \sigma + i\tau = \sigma + i\tau,$$

which is equivalent to $\sigma = 1/2$. Since $\delta(s) = \sigma - 1/2$, this is the same as $\delta(s) = 0$. The zero predicate is not used in this calculation. □

Definition 9413.314 (Observation-classified symmetry)**.** *An* observation-classified symmetry *is a packet*

$$(\mathcal{X}, J, \delta)$$

where $J : \mathcal{X} \to \mathcal{X}$ is an involutive symmetry and $\delta : \mathcal{X} \to \mathbb{R}$ is an observation row satisfying

$$\delta(Jx) = -\delta(x).$$

The observation row separates the J-orbits into fixed and split classes:

$$\mathsf{FixedOrbit}_J(x) :\Longleftrightarrow \delta(x) = 0,$$

and

$$\mathsf{SplitOrbit}_J(x) :\Longleftrightarrow \delta(x)\#0.$$

For zeta, this packet is obtained from

$$\mathcal{X} = \mathsf{Complex}^\uparrow, \qquad J(s) = 1 - \overline{s}, \qquad \delta(s) = \Re(s) - \frac{1}{2}.$$

Theorem 9413.315 (Zeta mirror orbits are classified by the half displacement)**.** *The zeta mirror satisfies*

$$\delta(J(s)) = -\delta(s).$$

Consequently the observation row $\delta(s)$ separates mirror orbits into the fixed class $\delta(s) = 0$ and the split class $\delta(s)\#0$.

Proof. By definition,

$$J(s) = 1 - \overline{s}.$$

If $s = \sigma + i\tau$, then $J(s) = 1 - \sigma + i\tau$. Hence

$$\delta(J(s)) = \Re(J(s)) - \frac{1}{2} = 1 - \sigma - \frac{1}{2} = -\left(\sigma - \frac{1}{2}\right) = -\delta(s).$$

The fixed class is the zero fiber of δ, and the split class is its apartness fiber. □

Definition 9413.316 (Critical-surface readout packet)**.** *The critical-surface readout packet of the zeta carrier is*

$$\mathsf{CritRead}_\zeta(s) := (\mathsf{MirrorFix}(s), \mathsf{PrimeUnit}(s), \mathsf{NoLaplaceBias}(s)),$$

where

$$\mathsf{MirrorFix}(s) :\Longleftrightarrow s = J(s),$$
$$\mathsf{PrimeUnit}(s) :\Longleftrightarrow \forall p \in \mathsf{Prime}^{\uparrow},\ |p^{1/2-s}| = 1,$$

and, for logarithmic time $x > 0$,

$$\mathsf{NoLaplaceBias}(s) :\Longleftrightarrow e^{-\delta(s)x} = 1.$$

The three rows are respectively the symmetry readout, the prime-local readout, and the Laplace readout of the same centered surface.

Theorem 9413.317 (Prime and Laplace reads detect the same fixed surface)**.** *For $s = 1/2+\delta+i\tau$, the following rows are equivalent readings of the centered surface:*

$$s = J(s), \qquad \delta = 0, \qquad \forall p \in \mathsf{Prime}^{\uparrow},\ |p^{1/2-s}| = 1, \qquad \forall x > 0,\ e^{-\delta x} = 1.$$

Proof. The equivalence of $s = J(s)$ and $\delta = 0$ is Definition 9413.313. For each displayed prime row,

$$p^{1/2-s} = p^{-\delta} e^{-i\tau \log p},$$

so its modulus is $p^{-\delta}$. This is one for every displayed prime exactly when $\delta = 0$, as in Definition 9413.278. The Laplace row decomposes as

$$e^{-s\log n} = e^{-(1/2+\delta)\log n} e^{-i\tau \log n}.$$

The factor $e^{-\delta x}$ is the additional bias along positive logarithmic time x. It is neutral for every displayed positive logarithmic time exactly on the zero fiber of δ. □

Corollary 9413.318 (The critical line is a balance surface, not a side boundary)**.** *The line $\Re(s) = 1/2$ is not the literal boundary between discrete and continuous projections. The discrete prime readout and the analytic Laplace-continuation readout coexist in the zeta carrier, and the critical line is their centered balance classifier.*

Proof. The prime-local row reads the centered channel

$$p^{1/2-s},$$

while the Laplace row reads

$$n^{-s} = e^{-s\log n}.$$

Both rows are present as projections of the zeta carrier. By Definition 9413.317, their centered classifiers agree exactly on $\delta = 0$. The absolute-convergence boundary of the Dirichlet and Euler product rows is a different ledger, namely the $\Re(s) > 1$ domain of Definition 9243.4. □

Definition 9413.319 (Prime-window observation of the split class)**.** *For a nonempty finite prime window S, the observation of the split class is the defect row*

$$D_S(s) := \sum_{p \in S} \log |p^{1/2-s}|.$$

If $s = 1/2 + \delta + i\tau$, then

$$D_S(s) = -\delta \sum_{p \in S} \log p.$$

Theorem 9413.320 (Prime windows observe split mirror orbits)**.** *If $\mathsf{SplitOrbit}_J(s)$ holds and S is a nonempty finite prime window, then the prime-window observation satisfies*

$$D_S(s) \# 0.$$

Proof. For the zeta mirror, $\mathsf{SplitOrbit}_J(s)$ is $\delta(s)\#0$ by Definition 9413.314. The defect formula of Definition 9413.319 gives

$$D_S(s) = -\delta(s) \sum_{p \in S} \log p.$$

The logarithmic sum is positive for a nonempty displayed prime window. Thus apartness of $\delta(s)$ from zero gives apartness of $D_S(s)$ from zero, matching Definition 9413.286. □

Definition 9413.321 (Zero-fixedness target)**.** *The* zero-fixedness target *is the section*

$$\mathsf{ZeroFixed}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to s = J(s)\right).$$

Equivalently, it asks that every critical-strip zero observation belongs to the fixed mirror class rather than the split mirror class.

Theorem 9413.322 (Zero-fixedness is the orbit form of the RH target)**.** *The zero-fixedness target is the observation-classified orbit form of the BEDC RH target.*

Proof. The BEDC RH target is the fixed-half section sending a row

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)$$

to an $\mathsf{OnCritLine}(s)$ witness, as in Definition 9413.199. By Definition 9413.313, the same conclusion may be read as $s = J(s)$. Thus the fixed-half section is equivalently the assertion that zero rows in the critical strip occupy the fixed mirror class. □

Corollary 9413.323 (Mirror closure alone does not supply zero-fixedness)**.** *Transport of zero rows along the mirror J is weaker than zero-fixedness.*

Proof. Mirror closure supplies a companion zero row at $J(s)$ when the functional-equation and non-escape ledgers are present. It does not identify s with $J(s)$. The remaining row is precisely the passage from a possible split mirror orbit to the fixed mirror orbit, as isolated in Definition 9241.14 and Definition 9413.321. □

Theorem 9413.324 (Observation-classified critical-surface principle)**.** *The zeta critical surface is the common observation classifier of three compatible rows:*

functional mirror fixedness, *prime-local unit amplitude,* *absence of extra Laplace bias.*

The RH-facing obligation is not to construct the surface, but to show that the critical-strip zero ledger factors through its fixed class.

Proof. The three compatible rows are assembled in Definition 9413.317. Prime windows observe off-fixed displacement by Definition 9413.320. The zero-facing target is the fixed-class section of Definition 9413.322. Therefore the critical surface is already determined as a classifier; the remaining boundary is the zero-relevant factorization through that classifier. □

9413.23 Ontic Core and Minimal Closure

section 9413.20 reads zeta as an arithmetic-spectral projection of atom, time, and symmetry. If the object-level examples are bracketed and only the ontic architecture is kept, the triple becomes

$$\mathsf{OnticCore} := (\mathsf{ObsTime}, \mathsf{DistAtom}, \mathsf{SymTransport}).$$

The three entries are observation as time, distinction as atom, and persistence as symmetry transport. The third entry is not shape symmetry alone. It is classifier-stable transport that preserves distinction through observation-time.

Definition 9413.325 (Observation-time row)**.** *An* observation-time row *is a finite readout event carried by a history*

$$h : \mathsf{Hist}$$

together with the continuation relation

$$h \preceq h' :\Longleftrightarrow \mathsf{Cont}(h, h').$$

In this row, time is not an external parameter. It is the readable order of observations under continuation.

Principle 9413.326 (Time is observable continuation)**.** *Inside the BEDC carrier discipline, time is the continuation order of observation histories. Without observed histories there is no internal time readout; without continuation there are only isolated readings.*

Definition 9413.327 (Distinction-atom row)**.** *A* distinction-atom row *is an irreducible stable distinction in a displayed reality. It has the abstract form*

$$x \# y$$

when the current classifier cannot identify the two rows, and the atomic form

$$\mathsf{Atom}(a)$$

when a is a minimal stable distinction under the generation law of that reality. Number-theoretic primes are the multiplicative arithmetic projection of this row, not its only instance.

Definition 9413.328 (Symmetry-transport row)**.** *A* symmetry-transport row *is a transport*

$$g : X \to X$$

that preserves classifier sameness and reflected distinction:

$$x \sim_X y \to g(x) \sim_X g(y),$$

and

$$x \# y \Longleftrightarrow g(x) \# g(y).$$

When g also preserves continuation,

$$h \preceq h' \to g(h) \preceq g(h'),$$

it is an ontic symmetry transport. In BEDC terms this is the role played by hsame*-respect,* Cont*, classifier stability,* StabilityCert*, and* NameCert*.*

Theorem 9413.329 (Symmetry is distinction preserved through observation-time)**.** *The symmetry-transport row is precisely the preservation of distinction-atom data along observation-time.*

Proof. Observation-time supplies histories and continuation rows $h \preceq h'$. Distinction-atom data supplies the classifier boundary $x\#y$. A symmetry transport is admissible only when it sends continuation rows to continuation rows and preserves the classifier boundary:

$$h \preceq h' \to g(h) \preceq g(h'),$$

$$x\#y \iff g(x)\#g(y).$$

Thus the content of symmetry is not visual resemblance. It is stable transport of distinction through observation-time. □

Corollary 9413.330 (Observation, distinction, and persistence form a loop)**.** *The ontic core is the loop*

$$\mathsf{ObsTime} \to \mathsf{DistAtom} \to \mathsf{SymTransport} \to \mathsf{ObsTime}.$$

Observation supplies readable time; distinction supplies observable content; symmetry transport lets that content persist across time.

Proof. Without observation-time, distinction does not enter a generated history. Without distinction, observation has no detectable content. Without symmetry transport, a distinction in one observation cannot be tracked through later observations. Hence the three rows are not independent decorations; they close one carrier loop. □

Definition 9413.331 (Minimal ontic core)**.** *The* minimal ontic core *is*

$$\mathsf{OnticCore} := (\mathsf{Observation}, \mathsf{Distinction}, \mathsf{Persistence})$$

with the readings

$$\mathsf{Observation} = \textit{finite readout producing time},$$

$$\mathsf{Distinction} = \textit{irreducible difference producing atom},$$

and

$$\mathsf{Persistence} = \textit{transport preserving distinction across observation-time.}$$

The persistence row is the ontic reading of symmetry.

Theorem 9413.332 (Stable interfaces require the ontic core)**.** *A stable BEDC interface must display observation-time, distinction-atom, and symmetry-transport ledgers before it can be consumed as a mature named object.*

Proof. The roadmap presents mature objects through a NameCert surface

$$(\mathsf{SourceSpec}_N, \mathsf{PatternSpec}_N, \mathsf{ClassifierSpec}_N, \mathsf{StabilityCert}_N, \mathsf{LedgerPolicy}_N).$$

The source and pattern rows expose how the object is observed or generated. The classifier row exposes sameness and distinction. The stability certificate exposes preservation of the classifier under transport. The ledger policy records what is hidden, scoped, or refused. These are precisely the observation-time, distinction-atom, and symmetry-transport roles of Definition 9413.331. □

Corollary 9413.333 (Kernel reading of the ontic core)**.** *The BEDC kernel reads the ontic core through the spine*

$$\mathsf{Mark} \to \mathsf{Hist} \to \mathsf{Ext}, \mathsf{Cont} \to \mathsf{Ask}, \mathsf{Sig} \to \mathsf{Pkg}, \mathsf{Gap} \to \mathsf{NameCert}.$$

Here histories and continuations read observation-time, marks and classifier gaps read distinction-atom, and hsame*-respect,* Cont*-respect,* StabilityCert*, and* NameCert *read symmetry-transport.*

Proof. The displayed spine is the kernel-layer routing surface of the roadmap. The earlier layers produce readable histories and continuation. The classifier and gap layers keep distinctions from being collapsed. The package and naming layers admit only transports whose stability and ledger rows have been displayed. □

Definition 9413.334 (Ontic collapse of the core)**.** *An* ontic core collapse *is an unaudited step that erases one of the three core rows:*

$$(\exists x,\ P(x)) \to \sum_x P(x),$$

$$x \sim y \to [x] = [y],$$

or

$$(P \leftrightarrow Q) \to (P = Q).$$

These are respectively collapse of observation-time provenance, symmetry-transport fibers, and distinction-atom provenance.

Theorem 9413.335 (The three excluded axioms collapse the ontic core)**.** *Read through the minimal ontic core, the three excluded dependencies collapse the three core rows:*

Classical.choice *collapses observation-time provenance,*

Quot.sound *collapses symmetry-transport fibers,*

and

propext *collapses distinction provenance.*

Proof. This is the ontic-core reading of Definition 9413.283 and Definition 9387.5. Choice supplies a witness without the generating path. Quot.sound turns a classifier relation into quotient equality without retaining the transport fiber. propext turns bidirectional implication into proposition equality without retaining the two directions as distinct provenance. □

Corollary 9413.336 (Axiom-purity protects observation, distinction, and persistence)**.** *The axiom-purity discipline protects the minimal ontic core by refusing unaudited collapse of observation-time, distinction-atom, and symmetry-transport rows.*

Proof. By Definition 9413.335, the excluded dependencies correspond exactly to the three collapse modes. Refusing them preserves the ledgered core rather than compressing it into an oracle value, quotient equality, or proposition equality. □

Theorem 9413.337 (Minimal closure of the ontic core)**.** *Observation, distinction, and persistence form the minimal closure needed for a stable object interface.*

Proof. If observation and distinction are present without persistence, a distinction can be seen but cannot be transported through later observations; the result is not a stable object. If observation and persistence are present without distinction, the continuation has no detectable content. If distinction and persistence are present without observation, there is no history or continuation surface on which the distinction can be generated. Hence all three rows are required. □

Theorem 9413.338 (Ontic-core projection principle)**.** *Mature mathematical objects are projections of the minimal ontic core. Zeta is one dense arithmetic-spectral projection; it is not the core itself.*

Proof. For $\mathsf{Nat}^{\uparrow}$, observation-time is successor history, distinction is the zero/successor split, and persistence is induction stability. For $\mathsf{Real}^{\uparrow}$, observation-time is stream/modulus data, distinction is apartness, and persistence is classifier stability. For the phase and transform ladder, observation-time appears as phase or logarithmic time, distinction as modes or prime-local factors, and persistence as duality, unitary balance, or functional symmetry. The zeta projection compresses these rows into prime factors, log-time Laplace readout, and the mirror $J(s) = 1 - \overline{s}$, as in Definition 9413.272. Thus zeta is a projection of the core, not an exhaustive replacement for it. □

9413.24 Object Induction and the RH Reality Route

The RH route can be organized as an induction over licensed mathematical interfaces rather than as an induction over natural-number indices. The induction variable is a BEDC object admitted through the dependency tower

$$\text{kernel} \to \text{finite data} \to \text{arithmetic} \to \text{algebra} \to \text{analysis} \to \text{spectral and zeta carriers.}$$

The invariant carried by this induction is the ontic core of section 9413.23:

$$\mathsf{OnticCore} := (\mathsf{ObsTime}, \mathsf{DistAtom}, \mathsf{SymTransport}).$$

The point of this organization is twofold. First, it explains why zeta inherits observation-time, distinction-atom, and symmetry-transport rows. Second, it isolates the part that does not follow from inheritance: the zeta-specific incompatibility between zero rows and ontic defect.

Definition 9413.339 (Licensed object tower)**.** *The* licensed object tower *is the directed dependency presentation whose objects are mature interfaces*

$$X^{\uparrow}$$

admitted by a displayed naming certificate

$$\mathsf{NameCert}(X) = (\mathsf{SourceSpec}_X, \mathsf{PatternSpec}_X, \mathsf{ClassifierSpec}_X, \mathsf{StabilityCert}_X, \mathsf{LedgerPolicy}_X),$$

and whose arrows are generalized continuation, projection, transport, or bridge rows between such interfaces. The dependency direction always runs from lower licensed interfaces to the interface that consumes them.

Definition 9413.340 (Ontic readiness predicate)**.** *For a licensed interface $X^{\uparrow}$, the predicate*

$$\mathsf{OnticReady}(X)$$

means that X carries rows

$$\mathsf{ObsTime}_X, \qquad \mathsf{DistAtom}_X, \qquad \mathsf{SymTransport}_X$$

with a ledger showing how they are projected from dependencies, how their classifier is preserved under transport, and how unaudited collapse of observation-time, distinction provenance, or symmetry fibers is refused.

Principle 9413.341 (Object-induction rule)**.** *Let $X^{\uparrow}$ be a licensed interface. If every displayed dependency $Y \in \mathrm{Deps}(X)$ satisfies $\mathsf{OnticReady}(Y)$, and if $\mathsf{NameCert}(X)$ supplies source, pattern, classifier, stability, and ledger rows transporting those ontic rows into X, then*

$$\mathsf{OnticReady}(X)$$

holds. The base case is the kernel spine

$$\mathsf{Mark} \to \mathsf{Hist} \to \mathsf{Ext}, \mathsf{Cont} \to \mathsf{Ask}, \mathsf{Sig} \to \mathsf{Pkg}, \mathsf{Gap} \to \mathsf{NameCert},$$

read as in Definition 9413.333.

Theorem 9413.342 (NameCert transports the ontic core)**.** *Within the licensed object tower, a $\mathsf{NameCert}(X)$ packet transports the ontic core from the dependencies of X into the public interface of X.*

Proof. The source and pattern rows of $\mathsf{NameCert}(X)$ record the generated data and therefore the observation-time surface. The classifier row records sameness, apartness, and generated distinction. The stability row records preservation of the classifier under permitted transports. The ledger policy records the boundary of what is hidden, scoped, refused, or still missing. These are exactly the rows isolated in Definition 9413.332. □

Theorem 9413.343 (Object induction yields an ontic section)**.** *The object-induction rule yields a schematic section*

$$\mathsf{OnticCoreSection} : \mathcal{C}_{\mathrm{BEDC}} \to \mathcal{E}_{\mathrm{Ontic}}$$

from the licensed BEDC dependency presentation to the indexed packet of ontic-core readouts.

Proof. At the kernel base, the rows Hist, Cont, hsame, Gap, Pkg, and NameCert supply observation-time, distinction-atom, and symmetry-transport by Definition 9413.333. For the inductive step, apply Definition 9413.342 to a licensed interface X. The dependency hypothesis supplies the ontic rows on the inputs of X, and $\mathsf{NameCert}(X)$ supplies the transport and ledger rows needed to read them at X. Thus the ontic-core assignment is stable along the dependency direction. □

Corollary 9413.344 (Axiom-purity is part of the induction invariant)**.** *The object-induction invariant is not merely the presence of three rows; it also includes refusal of unaudited collapse of those rows.*

Proof. Definition 9413.335 identifies Classical.choice, Quot.sound, and propext as collapses of observation-time provenance, symmetry-transport fibers, and distinction provenance. Therefore a transport that preserved only the visible outputs but not the collapse ledger would fail to preserve OnticReady. □

Definition 9413.345 (Reality-indexed ontic fibre)**.** *For a licensed object $X^{\uparrow}$, its* reality-indexed ontic fibre *is the packet*

$$\mathcal{E}_X := (\mathsf{Readouts}_X, \mathsf{Classifier}_X, \mathsf{Transport}_X, \mathsf{Ledger}_X, \mathsf{Boundary}_X).$$

Projection maps

$$\pi_i : X^{\uparrow} \to R_i$$

select the reality readouts of X. In this language, $\mathsf{OnticCoreSection}$ *assigns to each licensed object its observation-time, distinction-atom, and symmetry-transport rows inside the fibre $\mathcal{E}_X$.*

Theorem 9413.346 (Zeta is the arithmetic-spectral fibre of the ontic section)**.** *At the zeta object, the ontic section specializes to the arithmetic spectral packet*

$$\mathcal{O}_{\zeta}^{\mathrm{ontic}} = (\mathsf{PrimeAtoms}, \mathsf{LogTime}, \mathsf{LaplaceReadout}, \mathsf{EulerProduct}, \mathsf{FunctionalSymmetry}, \mathsf{ZeroLedger}).$$

Its three core rows are prime atoms, logarithmic time, and functional symmetry.

Proof. This is the specialization of Definition 9413.272. The atom row is the Euler-product face

$$\prod_p (1 - p^{-s})^{-1}.$$

The time row is the logarithmic Laplace readout

$$n^{-s} = e^{-s \log n}.$$

The symmetry row is the mirror

$$J(s) = 1 - \overline{s}.$$

The zero ledger is an additional spectral readout over the same carrier, not a replacement for the three core rows. □

Definition 9413.347 (Reality-induction RH package)**.** *The* reality-induction RH package *is the sequence of rows*

$\mathsf{ObjInd}_{\mathrm{Ontic}}$, $\mathsf{ZetaOnticProjection}$, $\mathsf{OnticBalance}$, $\mathsf{ZeroFibreTarget}$, $\mathsf{DefectVisibility}$, $\mathsf{DefectZeroIncompatibilit}$

The first row is supplied by object induction. The last row is the zeta-specific rigidity obligation.

Theorem 9413.348 (Balance is the zeta fixed-half classifier)**.** *For the zeta fibre, ontic balance is the fixed-half classifier:*

$$\mathsf{OnticBalance}(s) \iff \Re(s) = \frac{1}{2} \iff s = J(s).$$

Proof. The equivalence between $\mathsf{OnticBalance}(s)$ and $\Re(s) = 1/2$ is Definition 9413.278. The equivalence between $\Re(s) = 1/2$ and $s = J(s)$ is Definition 9413.313. Thus the same classifier can be read through prime-local balance or through the functional mirror. □

Definition 9413.349 (Ontic rigidity form of RH)**.** *The* ontic rigidity form *of the RH target is the section*

$$\mathsf{OnticRigidity}_{\zeta} := \prod_{s:\mathsf{Complex}^{\uparrow}} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{OnticBalance}(s)\right).$$

It is the ontic-balance reading of the zero-fibre fixedness target of Definition 9413.280.

Theorem 9413.350 (Ontic rigidity is the RH section target)**.** *The ontic rigidity form is equivalent, as a target, to the BEDC RH fixed-half section.*

Proof. The fixed-half section is the section form of RH by Definition 9413.199. By Definition 9413.348, the conclusion $\mathsf{OnCritLine}(s)$ may be read as $\mathsf{OnticBalance}(s)$. Substituting this target row gives Definition 9413.349. □

Theorem 9413.351 (Defect visibility is the finite-window read of imbalance)**.** *If the zeta fibre carries an ontic defect at s, then every nonempty finite prime window reads a nonzero defect*

$$D_S(s) = \sum_{p \in S} \log |p^{1/2-s}|.$$

Proof. This is the finite-window defect calculation of Definition 9413.286. Writing $s = 1/2 + \delta + i\tau$ gives

$$D_S(s) = -\delta \sum_{p \in S} \log p.$$

If $\delta \# 0$ and S is nonempty, the displayed sum is apart from zero. □

Definition 9413.352 (Reality-induction hard point)**.** *The hard point of the reality-induction RH route is the zeta-specific row*

$$\mathsf{OnticDefectZeroIncompatibility} := \prod_s \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \mathsf{OnticDefect}(s) \to \bot\right).$$

Equivalently, after finite-window extraction, it is the bridge from prime-window defect in the completed zeta carrier to exclusion of a zero row at the same source.

Theorem 9413.353 (The hard point closes the RH route)**.** *Assume ontic defect-zero incompatibility and the located row converting absence of ontic defect into ontic balance. Then the ontic rigidity form of RH is obtained.*

Proof. Given rows

$$\mathsf{ZetaZero}(s), \qquad \mathsf{InCritStrip}(s),$$

the incompatibility row of Definition 9413.352 rules out $\mathsf{OnticDefect}(s)$. The located row converts the absence of that defect into $\mathsf{OnticBalance}(s)$. This is precisely the argument of Definition 9413.288 expressed as the reality-induction route. □

Corollary 9413.354 (Object induction does not itself prove RH)**.** *Object induction supplies the ontic rows that zeta must carry, but it does not supply the zeta-specific zero-defect incompatibility row.*

Proof. Object induction yields the section of Definition 9413.343 and the zeta specialization of Definition 9413.346. It therefore explains the presence of prime atoms, log-time, and mirror symmetry in the zeta carrier. The RH section still needs the incompatibility row of Definition 9413.352. That row is zeta-specific and is not produced by the general object-induction principle. □

Theorem 9413.355 (Reality-induction normal form of the RH route)**.** *The unified-reality RH route has the normal form*

object induction ⇒ zeta ontic projection ⇒ fixed-half balance classifier ⇒ zero-fibre section target,

with finite-window defect visibility as the observable off-balance row and ontic defect-zero incompatibility as the remaining rigidity obligation.

Proof. Object induction is Definition 9413.343. The zeta specialization is Definition 9413.346. The fixed-half balance classifier is Definition 9413.348. The zero-fibre section target is Definition 9413.350. The finite-window read of off-balance data is Definition 9413.351. The unclosed rigidity row is Definition 9413.352. These rows give the proof-chain architecture without claiming the missing analytic bridge. □

Corollary 9413.356 (Categorical reading)**.** *In categorical language, the route says that* OnticCoreSection *is a section over the licensed BEDC object presentation, while RH is the assertion that the zeta-zero fibre admits a section into the fixed-half subfibre.*

Proof. The first statement is Definition 9413.343. The second is the fixed-half section form of Definition 9413.198 and Definition 9413.199. The two statements have different logical roles: the first supplies the ambient ontic rows for licensed objects, while the second is the zeta-specific zero-fibre rigidity target. □

9413.25 Triadic Structural Induction

section 9413.24 organizes licensed objects by their construction history, and section 9413.47 reads the RHRoute invariant through prime ledger, unit boundary, and recursive readback. The present section records the common induction principle behind those two uses. The induction is not over natural-number indices and not over every named object in an ambient universe. It is structural induction over objects generated by BEDC constructors and carrying construction certificates.

Definition 9413.357 (Triadic base packet)**.** *The* triadic base packet *is the triple*

$$\mathfrak{B}_{\triangle} := (\mathsf{P}_0, \mathsf{U}_0, \mathsf{T}_0)$$

with the following roles:

$$\mathsf{P}_0 := \textit{minimal distinction, finite source ledger, and prime register},$$

$$\mathsf{U}_0 := \textit{unit phase boundary and orthogonal positive readout},$$

and

$$\mathsf{T}_0 := \textit{append-only observation generation and finite witness order.}$$

The packet is a role declaration, not an additional primitive carrier. Its concrete rows are supplied by the kernel distinction and history interfaces, the unit-circle and Pythagorean readouts of section 9413.6, and the prime-register routes used by the zeta-facing chapters.

Definition 9413.358 (Triadic construction invariant)**.** *For a licensed BEDC object X, the predicate*

$$\mathcal{I}_{\triangle}(X)$$

means that X carries three compatible certificate rows

$$\mathcal{I}_{\mathsf{P}}(X), \qquad \mathcal{I}_{\mathsf{U}}(X), \qquad \mathcal{I}_{\mathsf{T}}(X).$$

The source row $\mathcal{I}_{\mathsf{P}}(X)$ records generated provenance, irreducible decomposition, and ledger auditability. The unit row $\mathcal{I}_{\mathsf{U}}(X)$ records unit-boundary closure, positive orthogonal readout, or legal gauge. The time row $\mathcal{I}_{\mathsf{T}}(X)$ records recursive generation, append-only transport, and finite visibility of failures. The predicate is the compatibility of the three rows, not their independent presence.

Principle 9413.359 (Certificate-bounded domain of the induction)**.** *The structural induction governed by $\mathcal{I}_\triangle$ ranges only over objects generated by the declared BEDC construction grammar and admitted by a certificate. A mathematical phrase not accompanied by such a construction certificate does not inherit $\mathcal{I}_\triangle$ merely by being named.*

9413.25.1 Circle–Triangle–Register Grammar

Definition 9413.360 (BEDC null surface)**.** *The* BEDC null surface

$$\varnothing_{\mathrm{BEDC}}$$

is the pre-object state in which no distinction row, history row, coordinate row, or ledger row has been displayed. It is not used as a set-theoretic carrier. It is the boundary from which a certified object can begin only when an apartness event is displayed:

$$B_0 \# B_1.$$

The corresponding history rows are

$$\mathsf{Hist}_0 = (B_0), \qquad \mathsf{Hist}_1 = (B_0, B_1).$$

Definition 9413.361 (Initial distinction split)**.** *An initial distinction split over the BEDC null surface is a packet*

$$\mathfrak{D}_1 := (B_0, B_1, \mathsf{Hist}_0, \mathsf{Hist}_1, \mathcal{H}_0, \mathcal{H}_1, E_1, \Lambda_1)$$

such that the ledger row contains the earlier mark,

$$\mathsf{Hist}_0 \subseteq \mathsf{Hist}_1,$$

and the Hilbert readout row splits as

$$\mathcal{H}_1 = \mathcal{H}_0 \oplus E_1, \qquad E_1 \perp \mathcal{H}_0.$$

Thus ledger containment and Hilbert orthogonality are not competing claims. The displayed norm readout is

$$\|B_1\|^2 = \|B_0\|^2 + \|E_1\|^2$$

at the resolution supplied by the packet, and Λ_1 records the residual row E_1.

Definition 9413.362 (Circle–triangle–register grammar)**.** *The* circle–triangle–register grammar *is the least certified construction grammar generated from an initial distinction split by the following three constructor families.*

The circle constructor attaches a unit phase row

$$\mathsf{Circle}(\theta) = e^{i\theta} \in \mathbb{T}$$

with

$$|e^{i\theta}| = 1.$$

It supplies a unit-boundary row and no positive-real radial scale row.

The triangle-readout constructor attaches an orthogonal decomposition row

$$v = Pv + \eta, \qquad \eta \perp \mathrm{im}(P),$$

with readout

$$\|v\|^2 = \|Pv\|^2 + \|\eta\|^2.$$

It supplies the positive residual-square row.

The register constructor sends every displayed residual r that is used by the object to an explicit ledger entry

$$\mathsf{Register}(r) \in \Lambda.$$

Finite arithmetic residuals may be addressed through the Prime–Zeckendorf–Goedel register of Definition 9291.8; the register constructor does not allow a used residual to disappear by being encodable.

Definition 9413.363 (Circle–triangle–register generated class)**.** *Let*

$$\mathcal{C}_{\circ\triangle\Lambda}$$

be the finite generated class obtained from packets satisfying Definition 9413.361 by repeated application of the circle, triangle-readout, and register constructors of Definition 9413.362. A limit point of this class belongs to the same generated domain only after it supplies a limit closure row in the sense of Definition 9413.367.

Theorem 9413.364 (Circle–triangle–register generation induction)**.** *Assume the initial distinction split satisfies*

$$\mathcal{I}_\triangle(\mathfrak{D}_1),$$

and assume that each displayed circle, triangle-readout, and register constructor is triadic-preserving. Then every finitely generated object

$$X \in \mathcal{C}_{\circ\triangle\Lambda}$$

satisfies

$$\mathcal{I}_\triangle(X).$$

Proof. Proceed by structural induction on the construction tree of X. The base case is the displayed initial distinction split Definition 9413.361, which carries the source ledger, unit-boundary refusal of radial scale, and generated witness order required by $\mathcal{I}_\triangle$. For a constructor node, the induction hypotheses give $\mathcal{I}_\triangle$ for all inputs. The constructor hypothesis says that the applied circle, triangle-readout, or register constructor is triadic-preserving in the sense of Definition 9413.365. Therefore the output also satisfies $\mathcal{I}_\triangle$. This covers every finite construction tree in $\mathcal{C}_{\circ\triangle\Lambda}$. □

Definition 9413.365 (Triadic constructor preservation)**.** *Let*

$$F(X_1, \ldots, X_n)$$

be a legal constructor in the BEDC grammar. The constructor is triadic-preserving *when it supplies a transport row*

$$\mathcal{I}_\triangle(X_1), \ldots, \mathcal{I}_\triangle(X_n) \Longrightarrow \mathcal{I}_\triangle(F(X_1, \ldots, X_n)).$$

The transport must display how source ledgers combine or restrict, how unit-boundary or positivity rows are preserved, and how the resulting object remains generated through finite or explicitly convergent witness data.

Theorem 9413.366 (Triadic structural induction)**.** *Let $\mathcal{C}_\triangle$ be the class generated from the triadic base packet by a family of legal constructors. If the base packet satisfies $\mathcal{I}_\triangle$ and every constructor in the family is triadic-preserving, then every finitely generated $X \in \mathcal{C}_\triangle$ satisfies*

$$\mathcal{I}_\triangle(X).$$

Proof. Proceed by structural induction on the construction tree of X. For a base leaf, the claim is the base-packet hypothesis. For a constructor node

$$X = F(X_1, \ldots, X_n),$$

the induction hypotheses give $\mathcal{I}_\triangle(X_i)$ for each input. Since F is triadic-preserving, Definition 9413.365 supplies $\mathcal{I}_\triangle(X)$. This covers every finite construction tree in the generated class. □

Definition 9413.367 (Limit closure row)**.** *A generated tower*

$$X_0 \to X_1 \to X_2 \to \cdots$$

has a triadic limit closure row *when it supplies a limit object X_∞, compatible transports of $\mathcal{I}_\triangle(X_m)$ along the tower, and a closedness certificate*

$$\left(\prod_m \mathcal{I}_\triangle(X_m)\right) \Longrightarrow \mathcal{I}_\triangle(X_\infty)$$

in the declared topology or convergence discipline.

Theorem 9413.368 (Triadic induction with certified limits)**.** *The conclusion of Definition 9413.366 extends to limit objects only when the construction supplies the limit closure row of Definition 9413.367.*

Proof. The finite stages are covered by Definition 9413.366. The displayed limit closure row is precisely the additional rule transporting the invariant from all finite stages to X_∞. Without that row, finite preservation gives no license to infer that an uninspected limit preserves source ledger, unit positivity, or finite witness visibility. □

9413.26 Constructor Risk Surfaces

Principle 9413.369 (Product preservation)**.** *Products are triadic-preserving only when the product certificate displays ledger pairing, positivity of the product or sum norm readout, and a compatible interleaving of the two observation orders. A product that forgets either provenance row or changes the witness order without transport data is not a triadic-preserving constructor.*

Principle 9413.370 (Quotient and projection preservation)**.** *Quotients and projections are high-risk constructors because they hide distinctions. They are triadic-preserving only when the hidden distinction is retained as a legal fibre, gauge, or ledger row. The solenoid projection*

$$\Sigma_S \to \mathbb{T}$$

is legal in this sense because the hidden row is the prime-register fibre of Definition 9289.4. A projection that needs an unrecorded positive-real scale fibre is not a pure unit-phase constructor.

Principle 9413.371 (Limit preservation)**.** *An infinite tower preserves the triadic invariant only by a closedness row, not by the absence of a discovered counterexample. For positive kernels, a typical legal row is finite-window convergence*

$$K_m \to K$$

together with preservation of every finite Gram inequality in the limit. This is a construction certificate; it is stronger than merely having checked many finite levels.

Principle 9413.372 (Analytic continuation preservation)**.** *Analytic continuation is triadic-preserving only when it displays local source agreement, the connected continuation domain, branch choices, and pole exclusion. Local Taylor agreement alone does not preserve $\mathcal{I}_\triangle$, because a missing branch or pole row can hide exactly the information that the source and unit certificates are meant to audit.*

9413.27 Zeta Constructor Preservation Boundary

Definition 9413.373 (ZetaBEDCConstruction)**.** *The obligation*

$$\mathsf{ZetaBEDCConstruction}$$

asserts that the completed zeta carrier, its zero-relevant observations, and its Pick or moment positivity readouts are generated by legal BEDC constructors preserving $\mathcal{I}_\triangle$. Its constructor surface includes Euler product source rows, prime-power ledger rows, Gamma and rational-boundary rows, completed normalization, functional-equation transport, analytic continuation, logarithmic derivative readout, Pick or Stieltjes transform, and finite or convergent positive-kernel towers.

Definition 9413.374 (ConstructorPreservationForXi)**.** *The obligation*

$$\mathsf{ConstructorPreservationForXi}$$

is the preservation half of ZetaBEDCConstruction*. It asks that each constructor used in the completed zeta route be triadic-preserving in the sense of Definition 9413.365. In particular, it must account for the negative sign in the prime side of ζ'/ζ, the archimedean Gamma correction, completed normalization, analytic continuation, and limit passage for finite positive-kernel or moment towers.*

Principle 9413.375 (Zeta constructor preservation is the induction target)**.** *Once* ZetaBEDCConstruction *is established, the general structural induction of Definition 9413.366 supplies the triadic invariant on the completed zeta carrier. What remains zeta-specific is not another restatement of RH, but the constructor preservation proof for Euler product, Gamma completion, continuation, logarithmic derivative, Pick transform, and finite tower convergence.*

Theorem 9413.376 (Zeta BEDC construction feeds the source-positive frontier)**.** *Assume* ZetaBEDCConstruction *and a source-built Pick factorization for the completed zeta kernel. Then the source-positive RH frontier has the positive witness required by Definition 9329.22.*

Proof. The zeta construction row places the completed zeta carrier and its zero-relevant observations inside the certified BEDC construction grammar. By Definition 9413.366, its generated objects carry $\mathcal{I}_\triangle$, including source ledger, legal unit-boundary or positivity row, and finite or convergent witness discipline. The assumed source-built Pick factorization is exactly the positive-kernel witness named in Definition 9271.8. Hence the hypotheses needed for the source-positive frontier are supplied, subject only to the standard zero-exclusion transport stated there. □

Principle 9413.377 (Status of triadic structural induction)**.** *Triadic structural induction explains why BEDC-generated certified objects inherit source ledger, unit-boundary positivity, and generated witness rows. It does not assert that an arbitrary named object is generated, and it does not replace the analytic proof that completed zeta's constructors preserve the invariant. For the RH route, the remaining construction problem is* $\mathsf{ConstructorPreservationForXi}$ *together with coverage of the completed zero ledger by the generated carrier.*

9413.28 Universal Generation Closure

section 9413.25 proves the triadic invariant for certified construction trees. The present section records the larger closure boundary behind that induction. BEDC does not begin from a stock of mature mathematical objects. A mature interface is usable only after it has entered through generated histories, package and gap rows, a naming certificate, and whatever limit ledger its public use requires.

Definition 9413.378 (BEDC generation stages)**.** *The BEDC generation stages are the classes*

$$\mathsf{BEDCGen}_0, \mathsf{BEDCGen}_1, \mathsf{BEDCGen}_2, \ldots$$

defined as follows. The base stage is the raw distinction surface

$$\mathsf{BEDCGen}_0 := \{\mathsf{b0}, \mathsf{b1}\}.$$

The successor stage $\mathsf{BEDCGen}_{n+1}$ *is generated from* $\mathsf{BEDCGen}_n$ *by the displayed kernel and interface constructors: history extension, continuation, asking, signature formation, package-token formation, gap membership, exact globalization, circle phase readout, orthogonal triangle readout, residual registration, NameCert formation, and derived-interface admission. In particular, a proposed public interface* $X^{\uparrow}$ *may enter only through a row*

$$\mathsf{NameCert}(X) = (\mathsf{SourceSpec}_X, \mathsf{PatternSpec}_X, \mathsf{ClassifierSpec}_X, \mathsf{StabilityCert}_X, \mathsf{LedgerPolicy}_X).$$

Definition 9413.379 (BEDC generated closure)**.** *The finite BEDC generated closure is*

$$\mathsf{BEDCGen}_\infty := \bigcup_{n \geq 0} \mathsf{BEDCGen}_n.$$

The completed generated closure

$$\overline{\mathsf{BEDCGen}}$$

contains an additional object only when its completion, limit, analytic continuation, quotient, or projection row supplies a ledger and a stability certificate. Thus a limit point is not admitted by being named as a limit; it is admitted by a closure row in the sense of Definition 9413.367.

Definition 9413.380 (BEDC-licensed mathematics)**.** *For an object or interface* X*, the predicate*

$$\mathsf{BEDCLicensedMath}(X)$$

means that every public use of X *factors through generated dependency rows and a certificate surface. Concretely, either* $X \in \mathsf{BEDCGen}_\infty$*, or* X *is admitted as a derived interface through* $\mathsf{NameCert}(X)$*, or* X *is admitted as a certified limit, projection, quotient, continuation, or bridge over previously licensed rows. Host notation alone is not a license.*

Theorem 9413.381 (Internal BEDC mathematics lies in the generated closure)**.** *For every object or interface X,*

$$\mathsf{BEDCLicensedMath}(X) \Longrightarrow X \in \overline{\mathsf{BEDCGen}}.$$

Proof. Unfold Definition 9413.380. If X is generated at a finite stage, then it belongs to $\mathsf{BEDCGen}_\infty$ and hence to $\overline{\mathsf{BEDCGen}}$. If X is a derived interface, then Definition 9352.17 requires $\mathsf{NameCert}(X)$; the certificate fields are generated dependency, classifier, stability, and ledger rows, so the interface is admitted by the successor-stage constructor of Definition 9413.378. If X is a completion, continuation, projection, quotient, or bridge, the definition requires an explicit closure or ledger row over previously licensed inputs, which is exactly membership in the completed closure. □

Theorem 9413.382 (Generated closure carries the triadic invariant)**.** *Assume that the initial BEDC distinction packet satisfies $\mathcal{I}_\triangle$, that every constructor named in Definition 9413.378 is triadic-preserving, and that every admitted completion row is a triadic limit closure row. Then every object*

$$X \in \overline{\mathsf{BEDCGen}}$$

satisfies

$$\mathcal{I}_\triangle(X).$$

Proof. If X lies in the finite generated closure $\mathsf{BEDCGen}_\infty$, then X belongs to some finite stage and therefore to a finite construction tree. The claim follows from Definition 9413.366. If X is admitted only after a completion, projection, quotient, continuation, or bridge row, the hypothesis says that the row is a triadic limit closure row. The limit transport is exactly the rule used in Definition 9413.368, so the triadic invariant is preserved at the admitted object. □

Definition 9413.383 (External conservative bridge obligation)**.** *The obligation*

$$\mathsf{AllExternalMathBridgeableToBEDC}$$

states that each standard mathematical structure X used by a mature argument has a BEDC interface $X^\uparrow$ such that

$$X^\uparrow \in \overline{\mathsf{BEDCGen}}$$

and every exported theorem consumed from X is transported through a conservative bridge row. This is an obligation family, not a theorem of the kernel. It is discharged layer by layer by arithmetic, algebra, order, set, type, completion, analysis, geometry, category, homology, number-theoretic, and spectral interface spines.

Definition 9413.384 (Zeta zeros in the BEDC closure)**.** *The obligation*

$$\mathsf{ZetaZerosInBEDCClosure}$$

states that every completed non-trivial zeta zero packet consumed by the RH route is an element of $\overline{\mathsf{BEDCGen}}$ *through the licensed* $\mathsf{ZetaZeros}^\uparrow$ *surface, the completed zeta construction rows, the zero classifier, the Li-coordinate readout, and the source-positive Pick or moment witness rows. It is stronger than licensing the predicate* $\mathsf{ZetaZero}$ *alone: the zero-relevant observations must also carry the triadic source, unit, and witness rows.*

Definition 9413.385 (Zeta triangular closure)**.** *The obligation*

$$\mathsf{ZetaTriangularClosure}$$

is the assertion that ZetaZerosInBEDCClosure *is compatible with the circle–triangle–register invariant. For each completed non-trivial zero packet ρ, its Li coordinate, prime-source ledger, scale-phase defect split, projection witnesses, and positive-kernel or moment rows must be transported through one generated certificate family.*

Theorem 9413.386 (Universal closure route is conditionally fixed-half)**.** *Assume* ZetaTriangularClosure *and* NoHiddenRadialRegister *for the completed zeta zero ledger. Then every completed non-trivial zero packet admitted by that closure has fixed-half Li readout.*

Proof. Let ρ be a completed non-trivial zero packet admitted by ZetaTriangularClosure. The closure supplies the Li coordinate row

$$z_\rho = 1 - \frac{1}{\rho} = e^{\ell + i\theta}$$

and transports it through the generated circle–triangle–register certificate. If $\ell \# 0$, then Definition 9331.18 classifies the packet as not generated as a legal pure closure unless the radial scale is recorded as scale-ledgered data. The NoHiddenRadialRegister hypothesis refuses both hidden radial gauge and ledger-free tail absorption for a pure zeta closure. Hence the located radial readback gives $\ell = 0$. Therefore

$$\left|1 - \frac{1}{\rho}\right| = 1,$$

and Definition 9290.16 gives

$$\Re(\rho) = \frac{1}{2}.$$

□

Principle 9413.387 (Status of universal generation closure)**.** *The internal closure theorem says only that BEDC-licensed mathematics is inside the BEDC generated closure. The external bridge obligation and the zeta triangular closure obligation remain mathematical work. For the RH route, the universal closure perspective changes the target from a detached zero-location assertion to a carrier question: completed zeta zero packets must be shown to enter the generated closure with the triadic rows intact.*

9413.29 Zero Recursor and Cover Boundary

The zero-signature route requires a type-level distinction before its faithfulness rows can be read correctly. A single zeta zero source is not a constructor for the whole zero fibre. Even a proof that one zero admits an ontic-core expression does not supply a section over all zero sources. The constructive RH target is a total map out of the zero source, and totality requires a cover or recursor for that source.

Definition 9413.388 (Zero source recursor)**.** *Let*

$$\mathcal{Z}_\zeta := \sum_{s:\mathsf{Complex}^\uparrow} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s))$$

be the critical-strip zero source. A zero source recursor *is a packet*

$$\mathsf{ZeroRecursor}_\zeta := (\mathsf{Seed}, \mathsf{Step}, \mathsf{SymTransport}, \mathsf{Cover}, \mathsf{FarEndUnity})$$

where Seed *supplies a generated zero-source row,* Step *supplies the permitted observation-time or spectral-time continuation rows,* SymTransport *transports generated rows through the mirror* $J(s) = 1 - \overline{s}$*,* Cover *states that every row of* $\mathcal{Z}_\zeta$ *is generated by the recursor, and* FarEndUnity *supplies far-end unity for generated zero rows.*

Definition 9413.389 (Core expression for zero sources)**.** *A zero-source row* $z : \mathcal{Z}_\zeta$ *has a* core expression *when its zero data are read only through the displayed ontic-core rows*

$$(\mathsf{ObsTime}, \mathsf{DistAtom}, \mathsf{SymTransport})$$

of the zeta carrier. The row is written

$$\mathsf{CoreExpr}_\zeta(z).$$

It records expression through the permitted observation-time, distinction-atom, and symmetry-transport ledgers; it is not a claim that the whole zero source has been generated.

Principle 9413.390 (Seed expression is not zero-source construction)**.** *A seed row*

$$z_0 : \mathcal{Z}_\zeta, \qquad \mathsf{CoreExpr}_\zeta(z_0)$$

does not imply

$$\prod_{z:\mathcal{Z}_\zeta} \mathsf{CoreExpr}_\zeta(z).$$

The latter is a dependent section over the zero source. It requires a cover or recursor whose generation rows reach every zero-source row.

Definition 9413.391 (Zero-source cover)**.** *The cover row of a zero source recursor is a displayed surjective generation map*

$$\mathsf{Generate}_\zeta : \mathsf{Param}_\zeta \to \mathcal{Z}_\zeta$$

together with

$$\mathsf{Cover}_\zeta := \prod_{z:\mathcal{Z}_\zeta} \sum_{a:\mathsf{Param}_\zeta} (\mathsf{Generate}_\zeta(a) = z)\,.$$

It is the row that turns a generated family into a construction principle for the whole zero source.

Theorem 9413.392 (Covered recursor transports core expression)**.** *Assume a zero source recursor whose seed, step, and mirror transport rows preserve core expression, and whose cover row reaches every zero source. Then every critical-strip zero source has a core expression:*

$$\prod_{z:\mathcal{Z}_\zeta} \mathsf{CoreExpr}_\zeta(z).$$

Proof. Let $z : \mathcal{Z}_\zeta$. The cover row supplies a parameter $a : \mathsf{Param}_\zeta$ with

$$\mathsf{Generate}_\zeta(a) = z.$$

Starting from the seed row and applying the displayed step and mirror transport rows along the generating path for a, the recursor preserves $\mathsf{CoreExpr}_\zeta$ at each generated zero row. Transporting along the cover equality gives $\mathsf{CoreExpr}_\zeta(z)$. □

Theorem 9413.393 (Covered far-end-unified recursor gives the RH section)**.** *Assume a zero source recursor whose cover reaches every zero-source row and whose far-end unity row holds for every generated zero. Then the RH fixed-half section is obtained.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s. By cover, z is generated by some parameter of the zero source recursor. The far-end-unity row of the recursor supplies

$$\mathsf{FarEndUnity}_\zeta(s).$$

By Definition 9413.170, this is equivalent to $\delta(s) = 0$, hence to $\Re(s) = 1/2$. The fixed-half section equivalence of Definition 9413.199 gives the RH section. □

Theorem 9413.394 (Zero recursor cover isolates the same hard point)**.** *The zero-recursor route reduces the RH-facing task to two zeta-specific rows: cover of the whole zero source and far-end unity for generated zero rows.*

Proof. Definition 9413.390 shows that a single expressed zero cannot supply the dependent RH section. The cover row of Definition 9413.391 upgrades a generated family to a total zero-source construction. The far-end-unity row then converts each generated zero to the fixed-half surface by Definition 9413.393. Thus the missing content is not the shared vocabulary of the zero type, but the total cover and the refusal of hidden far-end defect absorption. The latter is the same analytic rigidity already isolated as Definition 9413.202 and Definition 9413.187. □

Corollary 9413.395 (Zero type sameness is weaker than zero recursor totality)**.** *The statement that zero rows have the same type, or that one zero row is core-expressible, is strictly weaker than a covered zero recursor.*

Proof. Type sameness supplies a common codomain for rows of $\mathcal{Z}_\zeta$. It does not supply a generating path to an arbitrary element of that type. A covered zero recursor supplies that path through $\mathsf{Generate}_\zeta$ and Cover_ζ. Only the latter can produce the dependent section required by the constructive RH target. □

9413.30 Zero-Fibre Normal Sheet Geometry

Concretized in §9043: finite normal-sheet support certificate

The geometric reading of the RH route must distinguish ordinary holomorphic regularity from zero-fibre rigidity. An off-fixed zero does not, by itself, say that the completed zeta readout is nonsmooth or nonconformal at that point. It says that the zero fibre has a normal sheet away from the fixed line. The RH-facing statement is therefore a zero-fibre support claim, not a failure of local complex analyticity.

Definition 9413.396 (Completed zeta body)**.** *Write*

$$s = \frac{1}{2} + \delta + i\tau$$

and set

$$F(\delta, \tau) := \xi\left(\frac{1}{2} + \delta + i\tau\right).$$

The completed zeta body *is the graph packet*

$$\mathcal{B}_\zeta := \{(\delta, \tau, z) : z = F(\delta, \tau)\}.$$

Its zero fibre *is*

$$\mathcal{Z}_\zeta^{\mathrm{geom}} := \{(\delta,\tau) : F(\delta,\tau) = 0\},$$

and the fixed line is

$$\mathcal{C}_\zeta := \{(\delta,\tau) : \delta = 0\}.$$

The RH section asks for $\mathcal{Z}_\zeta^{\mathrm{geom}}$ *to be supported on* $\mathcal{C}_\zeta$ *inside the critical strip.*

Definition 9413.397 (Mirror coordinates)**.** *The functional-equation mirror*

$$J(s) = 1 - \overline{s}$$

acts in (δ,τ) *coordinates by*

$$J(\delta,\tau) = (-\delta,\tau).$$

For the completed readout, the mirror row has the form

$$F(-\delta,\tau) = \overline{F(\delta,\tau)}.$$

If $F = A + iB$*, then* A *is mirror-even and* B *is mirror-odd:*

$$A(-\delta,\tau) = A(\delta,\tau), \qquad B(-\delta,\tau) = -B(\delta,\tau).$$

Theorem 9413.398 (Mirror symmetry gives paired zeros, not RH)**.** *If* $F(\delta_0,\tau_0) = 0$*, then* $F(-\delta_0,\tau_0) = 0$*. This mirror closure does not imply* $\delta_0 = 0$*.*

Proof. By the mirror row of Definition 9413.397,

$$F(-\delta_0,\tau_0) = \overline{F(\delta_0,\tau_0)}.$$

If the right side is $\overline{0}$, it is zero. The conclusion gives a mirror companion, not equality of the two coordinates. The missing statement is exactly the zero-fixedness target of Definition 9413.321. □

Definition 9413.399 (Normal zero sheet)**.** *A* normal zero sheet *for the completed zeta body is a zero-fibre row with nonzero normal coordinate:*

$$\mathsf{NormalZeroSheet}_\zeta := \sum_{\delta,\tau} \left(\delta\#0 \times F(\delta,\tau) = 0\right).$$

The no-extra-zero-sheet *row is*

$$\mathsf{NoExtraZeroSheet}_\zeta := \neg\mathsf{NormalZeroSheet}_\zeta.$$

Theorem 9413.400 (No extra zero sheet is the RH support form)**.** *The no-extra-zero-sheet row is the geometric support form of the RH fixed-half section.*

Proof. In (δ,τ) coordinates, the RH conclusion for a zero row is

$$F(\delta,\tau) = 0 \to \delta = 0.$$

This is precisely the exclusion of a zero row with $\delta\#0$, together with the located fixed-half collapse that converts absence of normal apartness into the fixed-half row. The section form is Definition 9413.199. □

Principle 9413.401 (Local conformality is not zero-fibre rigidity)**.** *Holomorphic smoothness, mirror symmetry, and local conformality at a simple zero do not imply no-extra-zero-sheet.*

Proof. Let $w = s - 1/2$ and take

$$G(w) = w^2 - a^2$$

with a real and $a\#0$. Then

$$G(-\overline{w}) = \overline{G(w)},$$

so the same mirror symmetry is present. The zeros $w = a$ and $w = -a$ are off the fixed line, and

$$G'(w) = 2w$$

is nonzero at both zeros. Thus the local readout is conformal at those zeros while the zero fibre still has off-fixed normal sheets. Therefore the RH-facing task is not ordinary conformality but exclusion of those normal sheets for the completed zeta carrier. □

Definition 9413.402 (Zero-fibre faithfulness)**.** *The completed zeta zero fibre is* faithful *when a zero row cannot coexist with a normal prime-window defect:*

$$\mathsf{ZeroFibreFaithful}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \sum_{S:\mathsf{FinitePrimeWindow}_{\neq\varnothing}} (D_S(s)\#0) \to \bot \right).$$

This is the zero-fibre geometric form of defect-zero incompatibility.

Theorem 9413.403 (Zero-fibre faithfulness gives the RH section)**.** *Assume zero-fibre faithfulness and located fixed-half collapse. Then the RH fixed-half section is obtained.*

Proof. Let s carry critical-strip and zeta-zero rows. If $\delta(s)\#0$, then Definition 9413.201 gives $D_S(s)\#0$ for every nonempty finite prime window S. This supplies the existential defect row excluded by Definition 9413.402. Hence $\neg(\delta(s)\#0)$. Located fixed-half collapse gives $\delta(s) = 0$, and Definition 9413.199 gives the RH section. □

Theorem 9413.404 (Zero-fibre faithfulness is the normal-sheet reading of defect rigidity)**.** *Zero-fibre faithfulness, no-extra-zero-sheet, and defect-zero incompatibility are three readings of the same RH-facing rigidity boundary.*

Proof. An off-fixed zero sheet has $\delta(s)\#0$. By the prime-window defect calculation of Definition 9413.201, it therefore carries a finite prime-window defect. Excluding coexistence of that defect with a zero row is Definition 9413.402. The same exclusion is named as defect-zero incompatibility in Definition 9413.202 and as no far-end absorption in Definition 9413.143. Thus the geometric normal-sheet language identifies the same unclosed analytic boundary; it does not replace it with a local conformality claim. □

9413.31 Time-Fibre Mirror Atomicity

The mirror row in the completed zeta carrier is not a reversal of observation time. It is a normal reflection inside one time fibre. This distinction sharpens the zero-fibre geometry of section 9413.30: an off-fixed zero would not be a zero at another time; it would be a second normal read in the same time slot.

Definition 9413.405 (Directed zeta time)**.** *The* directed zeta time *object is the observation-frequency row*

$$\mathbb{T}_\zeta := \{\tau : \mathsf{Real}^{\uparrow}_{\geq 0}\}.$$

In critical-strip coordinates

$$s = \frac{1}{2} + \delta + i\tau,$$

write

$$\pi_T(\delta, \tau) := \tau, \qquad \pi_N(\delta, \tau) := \delta.$$

The order row $\tau_1 \leq \tau_2$ records continuation or observation order. It does not supply a default reverse morphism $\tau_2 \to \tau_1$.

Definition 9413.406 (Deterministic observation update)**.** *A directed observation carrier has deterministic update when every displayed state admits at most one authorized successor row. Writing X_t for the state fibre at time t, t^+ for the displayed successor time, and $\mathsf{Step}_t(x, y)$ for the update relation, this row is*

$$\mathsf{DetStep} := \prod_t \prod_{x:X_t} \prod_{y_1,y_2:X_{t^+}} (\mathsf{Step}_t(x, y_1) \times \mathsf{Step}_t(x, y_2) \to y_1 = y_2)\,.$$

Thus one time slot carries at most one generation step or observation update.

Principle 9413.407 (Deterministic update is weaker than zero-fibre atomicity)**.** *Deterministic update is a generation-side property. It does not imply that every readout inside the generated object is singleton-valued:*

$$\mathsf{DetStep} \not\Rightarrow \mathsf{TimeFibreAtom}_\zeta.$$

A deterministic stage may produce one polynomial, spectral packet, or zero carrier whose internal zero ledger has several rows. In the quartic spectral carrier, for example, one recurrence stage generates one displayed polynomial while the fixed endpoint window may carry an indexed zero family. Hence the RH-facing mirror argument requires a separate zero-reality condition: the normal zero read in each directed zeta time fibre must itself be single-valued.

Definition 9413.408 (Time-fibre mirror)**.** *The zeta mirror*

$$J(s) = 1 - \overline{s}$$

acts on (δ, τ) coordinates by

$$J(\delta, \tau) = (-\delta, \tau).$$

Thus it preserves the time projection and reverses only the normal projection:

$$\pi_T(J(\delta, \tau)) = \pi_T(\delta, \tau), \qquad \pi_N(J(\delta, \tau)) = -\pi_N(\delta, \tau).$$

Theorem 9413.409 (The zeta mirror is fibrewise in time)**.** *The functional-equation mirror is a time-fibre symmetry, not a time reversal.*

Proof. By Definition 9413.408, the mirror sends (δ, τ) to $(-\delta, \tau)$. The time coordinate is unchanged, while the normal coordinate changes sign. Hence the companion row supplied by mirror closure lies in the same time fibre. □

Definition 9413.410 (Zero time fibre)**.** *For a directed time row $\tau : \mathbb{T}_\zeta$, the* zero time fibre *is*

$$Z_{\zeta,\tau} := \{\delta : (\delta, \tau) \in \mathcal{Z}_\zeta^{\mathrm{geom}}\},$$

where $\mathcal{Z}_\zeta^{\mathrm{geom}}$ is the completed zeta zero fibre of Definition 9413.396. In this notation, the RH support form says

$$\prod_{\tau:\mathbb{T}_\zeta} \prod_{\delta \in Z_{\zeta,\tau}} (\delta = 0).$$

Definition 9413.411 (Time-fibre atomicity)**.** *The zero fibre satisfies* time-fibre atomicity *when each directed time fibre carries at most one normal zero read:*

$$\mathsf{TimeFibreAtom}_\zeta := \prod_{\tau:\mathbb{T}_\zeta} \prod_{\delta_1,\delta_2} (\delta_1 \in Z_{\zeta,\tau} \times \delta_2 \in Z_{\zeta,\tau} \to \delta_1 = \delta_2)\,.$$

Theorem 9413.412 (Mirror closure plus time-fibre atomicity gives no extra zero sheet)**.** *Assume mirror closure for the completed zeta zero fibre and time-fibre atomicity. Then the no-extra-zero-sheet row holds.*

Proof. Suppose a normal zero sheet were present. Then for some δ, τ there are rows

$$\delta \# 0, \qquad (\delta, \tau) \in \mathcal{Z}_\zeta^{\mathrm{geom}}.$$

Mirror closure and Definition 9413.409 put $(-\delta, \tau)$ in the same zero time fibre. Time-fibre atomicity gives

$$\delta = -\delta.$$

In the characteristic-zero real readout this implies $\delta = 0$, contradicting $\delta \# 0$. Hence no normal zero sheet is present. □

Corollary 9413.413 (Time-fibre atomicity gives the RH section)**.** *Under mirror closure and located fixed-half collapse, time-fibre atomicity gives the RH fixed-half section.*

Proof. By Definition 9413.412, there is no off-fixed normal zero sheet. By Definition 9413.400, this is the geometric support form of the RH section. □

Definition 9413.414 (Zero graph form)**.** *The zero fibre has* zero graph form *when there is a normal readout function*

$$\delta_Z : \mathbb{T}_\zeta \to \mathsf{Real}^\uparrow$$

such that every zero in a time fibre has that normal coordinate:

$$\mathsf{ZeroGraph}_\zeta := \sum_{\delta_Z:\mathbb{T}_\zeta \to \mathsf{Real}^\uparrow} \prod_{\tau:\mathbb{T}_\zeta} \prod_{\delta \in Z_{\zeta,\tau}} (\delta = \delta_Z(\tau))\,.$$

Theorem 9413.415 (Zero graph form implies time-fibre atomicity)**.** *Zero graph form implies time-fibre atomicity.*

Proof. Let δ_1 and δ_2 be two zero reads in the same time fibre $Z_{\zeta,\tau}$. By zero graph form, both are equal to the displayed value $\delta_Z(\tau)$. Therefore $\delta_1 = \delta_2$. □

Corollary 9413.416 (Zero graph form gives the fixed surface under mirror closure)**.** *If the zero fibre has zero graph form and is mirror-closed, then every zero-source row lies on the fixed surface.*

Proof. Zero graph form gives time-fibre atomicity by Definition 9413.415. The fixed-surface conclusion then follows from Definition 9413.413. □

Corollary 9413.417 (Off-fixed zeros are double normal reads)**.** *An off-fixed zero, together with mirror closure, produces two distinct normal reads in one time fibre.*

Proof. If (δ, τ) is a zero and $\delta \# 0$, mirror closure gives $(-\delta, \tau)$ as another zero in the same time fibre. Since $\delta \# 0$, the two normal coordinates are distinct. Thus off-fixed zerohood, under mirror closure, witnesses failure of time-fibre atomicity. □

Theorem 9413.418 (Time-fibre atomicity is the slot form of defect rigidity)**.** *Time-fibre atomicity, zero graph form, zero-fibre faithfulness, and defect-zero incompatibility are equivalent readings of the same zero-source rigidity boundary.*

Proof. The time-fibre reading says that mirror companions must occupy one normal slot at fixed τ. The zero graph reading expresses the same condition as a single-valued normal coordinate over directed time. If that condition fails, then by Definition 9413.417 there is an off-fixed zero, and by Definition 9413.201 every nonempty finite prime window detects a nonzero defect. Excluding that defect from a zero row is Definition 9413.402, which is the normal-sheet reading of Definition 9413.202. The four formulations therefore place the same unclosed analytic load in different coordinates. □

9413.32 Zero Signature Faithfulness and the Mirror Slot Principle

section 9413.24 isolates the remaining RH-facing hard point as zeta-specific rigidity of the zero fibre. The same hard point can be expressed as a signature faithfulness principle. A critical-strip zero has a mirror companion under the functional equation. If the zero carrier has no hidden observable beyond its ontic signature, then a zero and its mirror companion occupy the same signature slot. Faithfulness of that slot forces them to be the same zero, hence to lie on the fixed surface.

Definition 9413.419 (Zero source and mirror companion)**.** *The critical-strip zero source is*

$$\mathcal{Z}_\zeta := \sum_{s:\mathsf{Complex}^\uparrow} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)) .$$

For $s = \frac{1}{2} + \delta + i\gamma$*, the mirror is*

$$J(s) := 1 - \overline{s} = \frac{1}{2} - \delta + i\gamma.$$

The mirror companion row is the transport, supplied by the functional-equation and non-escape ledgers, from a zero-source row at s *to a zero-source row at* $J(s)$*.*

Definition 9413.420 (Zero ontic signature)**.** *The* zero ontic signature *is the packet*

$$\Sigma_Z(s) := (\mathsf{AtomType}_Z(s), \mathsf{SpecTime}_Z(s), \mathsf{MirrorSlot}_Z(s)),$$

where $\mathsf{AtomType}_Z(s)$ *records the zero as an irreducible spectral atom row,* $\mathsf{SpecTime}_Z(s)$ *records the spectral time coordinate* $\Im(s)$*, and* $\mathsf{MirrorSlot}_Z(s)$ *records the unordered mirror orbit generated by* s *and* $J(s)$*.*

Definition 9413.421 (Mirror-even signature)**.** *A zero signature is* mirror-even *when the mirror companion has the same signature:*

$$\Sigma_Z(J(s)) = \Sigma_Z(s).$$

For the signature of Definition 9413.420, this means that the mirror companion has the same zero-atom type, the same imaginary spectral time, and the same mirror slot.

Definition 9413.422 (Zero signature faithfulness)**.** *The zero source has* signature faithfulness *when the signature slot is faithful to zero identity:*

$$\mathsf{ZeroSignatureFaithful}_\zeta := \prod_{s,t:\mathcal{Z}_\zeta} (\Sigma_Z(s) = \Sigma_Z(t) \to s = t)\,.$$

Equivalently, the zero carrier has no hidden fourth observable that can separate two zero-source rows at the same carrier layer after their atom type, spectral time, and mirror slot agree. A higher-layer object is not excluded by this definition when it is carried by an explicit extension ledger; it is excluded only when it is used as an unledgered same-layer coordinate.

Theorem 9413.423 (Signature faithfulness implies zero-fixedness)**.** *Assume mirror closure for critical-strip zero rows, mirror-even zero signature, and zero signature faithfulness. Then the zero-fixedness target holds:*

$$\prod_{s:\mathsf{Complex}^\uparrow} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to s = J(s))\,.$$

Proof. Let s carry rows $\mathsf{ZetaZero}(s)$ and $\mathsf{InCritStrip}(s)$. Mirror closure supplies the companion zero-source row at $J(s)$. Mirror-evenness gives

$$\Sigma_Z(J(s)) = \Sigma_Z(s).$$

Signature faithfulness applied to the two zero-source rows gives

$$J(s) = s.$$

This is exactly the zero-fixedness conclusion of Definition 9413.321. □

Corollary 9413.424 (Signature faithfulness gives the RH section)**.** *Under the hypotheses of Definition 9413.423, the BEDC RH fixed-half section is obtained.*

Proof. By Definition 9413.423, every critical-strip zero row satisfies $s = J(s)$. By Definition 9413.313, this is equivalent to $\Re(s) = 1/2$, hence to the critical-line output row. The fixed-half section equivalence of Definition 9413.199 gives the RH section target. □

Definition 9413.425 (Mirror-odd observable)**.** *Let R be an additive characteristic-zero readout carrier. A zero observable*

$$F : \mathcal{Z}_\zeta \to R$$

is mirror-odd *when*

$$F(J(s)) = -F(s).$$

The normal displacement

$$\delta(s) := \Re(s) - \frac{1}{2}$$

is the basic mirror-odd observable for the zeta mirror.

Definition 9413.426 (Zero observable factorization)**.** *The zero source has* observable factorization through the zero signature *when every zero observable F in the displayed observable class factors through Σ_Z:*

$$F(s) = f(\Sigma_Z(s))$$

for some signature-level readout f.

Theorem 9413.427 (Mirror-odd observables vanish under signature factorization)**.** *Assume mirror-even zero signature and zero observable factorization through that signature. Then every mirror-odd zero observable in the factorizing class is zero.*

Proof. Let F be mirror-odd and suppose

$$F(s) = f(\Sigma_Z(s)).$$

Mirror-evenness gives

$$\Sigma_Z(J(s)) = \Sigma_Z(s).$$

Therefore

$$F(J(s)) = f(\Sigma_Z(J(s))) = f(\Sigma_Z(s)) = F(s).$$

Since F is mirror-odd, also $F(J(s)) = -F(s)$. Hence

$$F(s) = -F(s).$$

In characteristic zero this forces $F(s) = 0$. □

Corollary 9413.428 (Normal displacement vanishes under zero signature closure)**.** *If the normal displacement*

$$\delta(s) = \Re(s) - \frac{1}{2}$$

is a zero observable that factors through a mirror-even faithful zero signature, then $\delta(s) = 0$ for every critical-strip zero-source row.

Proof. By Definition 9413.425, δ is mirror-odd. Applying Definition 9413.427 to $F = \delta$ gives $\delta(s) = 0$. This is the fixed-half condition. □

Definition 9413.429 (No atomic mirror splitting)**.** *The* no atomic mirror splitting *row is*

$$\mathsf{NoAtomicMirrorSplitting}_\zeta := \prod_s \left(\mathsf{ZeroAtom}(s) \times s\#J(s) \to \bot\right).$$

It says that a zeta zero atom is symmetry-absolute rather than a paired atom separated by a hidden mirror-odd observable.

Theorem 9413.430 (Signature faithfulness rules out atomic mirror splitting)**.** *Mirror-even zero signature and zero signature faithfulness rule out atomic mirror splitting.*

Proof. Suppose a zero atom at s carried $s\#J(s)$. Mirror closure places the mirror companion in the same zero source. Mirror-evenness gives equal zero signatures for s and $J(s)$, and signature faithfulness gives $s = J(s)$. This contradicts $s\#J(s)$. □

Theorem 9413.431 (Split mirror zeros create prime-window defects)**.** *If a critical-strip zero source has $s\#J(s)$, then it carries the normal defect $\delta(s)\#0$ and every nonempty finite prime window reads a nonzero prime-window defect.*

Proof. For the mirror $J(s) = 1 - \overline{s}$, the equality $s = J(s)$ is equivalent to $\delta(s) = 0$ by Definition 9413.313. Thus apartness $s\#J(s)$ gives the off-fixed defect row $\delta(s)\#0$ in the located comparison. The finite-window defect calculation is Definition 9413.320. □

Corollary 9413.432 (Signature faithfulness is a zero-relevance form of defect rigidity)**.** *Zero signature faithfulness turns prime-visible mirror splitting into a zero-relevant contradiction. In that sense it is a signature form of ontic defect-zero incompatibility.*

Proof. By Definition 9413.431, a split mirror zero produces a prime-window defect. By Definition 9413.430, the same split row contradicts mirror-even signature faithfulness. This is the same logical role played by Definition 9413.352: a visible off-balance defect cannot coexist with a zero row in the completed zeta carrier. □

Theorem 9413.433 (Mirror slot principle)**.** *The mirror slot principle is the implication*

$$\textit{mirror closure} + \textit{mirror-even zero signature} + \textit{zero signature faithfulness} \Rightarrow \textit{zero-fixedness}.$$

It is a generalized slot-uniqueness principle for the zero carrier, not a finite counting argument.

Proof. The implication is exactly Definition 9413.423. The word slot refers to the signature fibre of Σ_Z, not to a finite pigeonhole set. The principle says that one signature fibre cannot contain two mirror-separated zero atoms when the zero signature is faithful. □

Corollary 9413.434 (The signature hard point)**.** *The unclosed content of the signature route is*

$$\mathsf{ZeroSignatureFaithful}_\zeta$$

or, equivalently for the normal displacement route, factorization of zero observables through a mirror-even zero signature.

Proof. Mirror closure and the algebraic identity $\delta(J(s)) = -\delta(s)$ are structural rows already displayed by the functional-equation mirror. What remains is the assertion that the zero signature has no hidden coordinate capable of separating s from $J(s)$. That assertion is exactly Definition 9413.422 or the factorization row of Definition 9413.426. Without it, a mirror companion may be a paired zero rather than the same zero. □

Principle 9413.435 (Expression is not construction)**.** *Expressing the RH target in the language of observation-time, distinction-atom, and symmetry-transport does not by itself construct an RH witness. The constructive target remains a total section*

$$\Phi : \mathcal{Z}_\zeta \to \mathcal{H}_\zeta,$$

or equivalently a function sending each row

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)$$

to an explicit $\mathsf{OnCritLine}(s)$ *witness. A vocabulary for the target is therefore weaker than an inhabitant of the target.*

Definition 9413.436 (Zero ontic completeness)**.** *The zero source has* zero ontic completeness *when the displayed ontic signature is not only mirror-even but observable-complete for the zero carrier:*

$$\mathsf{ZeroOnticComplete}_\zeta := \prod_F \sum_f \prod_{s:\mathcal{Z}_\zeta} F(s) = f(\Sigma_Z(s)),$$

where F ranges over the zero observables admitted by the displayed zero carrier. This is the factorization form of the claim that no additional zero-observable coordinate is available beyond the zero ontic signature.

Definition 9413.437 (No-fourth-ledger row)**.** *The* no-fourth-ledger row *for the zeta zero carrier is the refusal of an off-critical observable ledger independent of*

$$\Sigma_Z(s) = (\mathsf{AtomType}_Z(s), \mathsf{SpecTime}_Z(s), \mathsf{MirrorSlot}_Z(s)).$$

Equivalently, any displayed normal displacement row

$$\delta(s) = \Re(s) - \frac{1}{2}$$

must factor through the zero signature if it is admitted as a zero observable at the same zero-source layer. If it does not factor through that signature, then it must instead be carried as an explicit higher-layer normal-extension ledger of Definition 9413.438; the no-fourth-ledger row refuses precisely the unledgered same-layer use.

Definition 9413.438 (Off-critical normal-extension ledger)**.** *An* off-critical normal-extension ledger *for a zero-source row*

$$s = \frac{1}{2} + \delta + i\tau$$

is a higher-layer extension ledger that licenses

$$\delta \# 0$$

as a normal axis of the zero reality. Such a ledger must display the zero source, the mirror orbit, the normal apartness row, the finite prime-window defect rows generated by the apartness, and the zero-compatibility row explaining why those defect rows may coexist with the completed zero ledger. In notation this is written

$$\mathsf{NormalExtLedger}_\zeta(s, \delta).$$

Theorem 9413.439 (Zero ontic completeness implies zero-fixedness)**.** *Assume mirror closure, mirror-even zero signature, zero ontic completeness, and that the normal displacement $\delta(s)$ is a displayed zero observable. Then every critical-strip zero source is fixed by the mirror:*

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to s = J(s).$$

Proof. By zero ontic completeness, the normal displacement factors through the zero signature:

$$\delta(s) = f(\Sigma_Z(s)).$$

For the mirror companion,

$$\delta(J(s)) = f(\Sigma_Z(J(s))).$$

Mirror-evenness gives

$$\Sigma_Z(J(s)) = \Sigma_Z(s),$$

hence

$$\delta(J(s)) = \delta(s).$$

The mirror calculation of Definition 9413.425 also gives

$$\delta(J(s)) = -\delta(s).$$

Therefore $\delta(s) = -\delta(s)$, and the characteristic-zero real readout gives $\delta(s) = 0$. By Definition 9413.313, this is equivalent to $s = J(s)$. □

Corollary 9413.440 (Zero ontic completeness gives the RH target)**.** *Under the hypotheses of Definition 9413.439, the BEDC RH fixed-half section is obtained.*

Proof. The theorem gives zero-fixedness for every critical-strip zero source. The fixed-surface calculation converts zero-fixedness into $\mathsf{OnCritLine}(s)$, and Definition 9413.199 identifies this with the RH section target. □

Definition 9413.441 (Ontic-expression package)**.** *The* ontic-expression package *for RH is the data*

$$(\mathsf{OnticCore}, \mathsf{ZetaOnticProjection}, \mathsf{OnticBalance}, \mathsf{ZeroFibreTarget}).$$

It presents the RH target as a statement about zero rows landing in the atom-time-symmetry balance surface. It does not include $\mathsf{ZeroOnticComplete}_\zeta$*, signature faithfulness, or the defect-zero incompatibility bridge.*

Theorem 9413.442 (Ontic expression is weaker than RH construction)**.** *The ontic-expression package is a correct presentation of the RH target but not an RH proof object.*

Proof. The package contains the target row

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{OnticBalance}(s),$$

as in Definition 9413.349. To be a proof object it would need to produce this output for every zero-source input. That production is exactly the section Φ of Definition 9413.435. The ontic-expression package names the codomain and explains the balance surface; it does not supply the total function. □

Theorem 9413.443 (No-fourth-ledger is a signature form of defect-zero incompatibility)**.** *For the zeta zero carrier, the no-fourth-ledger row is the signature form of the same missing bridge isolated as ontic defect-zero incompatibility.*

Proof. If a critical-strip zero carried an off-critical displacement $\delta(s)\#0$, then Definition 9413.431 gives a finite prime-window defect. Such a defect is an additional observable row unless it is excluded by the zero carrier. The no-fourth-ledger row expresses this exclusion as signature completeness: the zero signature has no independent coordinate capable of recording the off-critical displacement. The defect-zero route of Definition 9413.352 expresses the same exclusion as incompatibility between a zero row and an ontic defect. Both formulations assign the remaining analytic load to the same zero-relevant rigidity claim. □

Corollary 9413.444 (Exact boundary of the signature route)**.** *The signature route proves RH exactly when the zeta zero carrier is shown to be complete and faithful for the displayed ontic signature.*

Proof. If completeness and faithfulness hold, then Definition 9413.439 and Definition 9413.440 give the RH section. Conversely, without completeness or faithfulness, the mirror may preserve the zero set while allowing paired zero atoms in one mirror orbit. Such a paired orbit uses the same three formal roles but does not collapse to the fixed surface. Thus the boundary is not the availability of the three ontic words, but the completeness and faithfulness of their zero-source signature. □

Concretized in §8973: $\mathsf{ZeroSignatureFaithfulness}^{\uparrow}$ realizes the mirror-slot faithfulness packet as finite NameCert data.

9413.33 Core Commonality and Completion Boundaries

The unified-reality programme is a theory of commonality, but the word "common" has two distinct roles. The first role is ontic: every licensed BEDC object must expose observation-time, distinction-atom, and symmetry-persistence rows. The second role is object-specific: one may ask whether those rows are complete and faithful for all public observables of a given carrier. The first role is the unifying language of the theory. The second role is a proof obligation, and in the zeta-zero case it is strong enough to imply the RH section.

Definition 9413.445 (Core commonality basis)**.** *The* core commonality basis *is*

$$\mathsf{Core} := (\mathsf{ObsTime}, \mathsf{DistAtom}, \mathsf{SymPersist}),$$

where $\mathsf{ObsTime}$ *records observation, history, and continuation;* $\mathsf{DistAtom}$ *records irreducible distinction and atom data; and* $\mathsf{SymPersist}$ *records classifier-stable transport preserving distinction through observation-time.*

Definition 9413.446 (Core signature of a licensed object)**.** *For a licensed object* $X^{\uparrow}$*, a* core signature *is a displayed readout*

$$\Sigma_X : X^{\uparrow} \to \mathsf{ObsTime}_X \times \mathsf{DistAtom}_X \times \mathsf{SymPersist}_X.$$

It records that X *can be observed through histories, has stable distinctions, and carries those distinctions through permitted transports.*

Definition 9413.447 (Core completeness)**.** *A licensed object* $X^{\uparrow}$ *is* core-complete *when every displayed public observable*

$$F : X^{\uparrow} \to R$$

in the public carrier class factors through the core signature:

$$F = \overline{F} \circ \Sigma_X$$

for some readout

$$\overline{F} : \mathsf{ObsTime}_X \times \mathsf{DistAtom}_X \times \mathsf{SymPersist}_X \to R.$$

This does not deny the existence of derived observables such as order, area, derivative, spectrum, zero, or defect. It says that no such observable is admitted as an independent fourth ontic primitive.

Definition 9413.448 (Independent fourth observable)**.** *An* independent fourth observable *for* $X^{\uparrow}$ *is a public observable* $Q : X^{\uparrow} \to R_Q$ *for which no factorization through* Σ_X *is supplied and which is not explicitly carried by a higher-layer extension ledger, boundary row, bridge row, or refused external operation.*

Definition 9413.449 (Layered generation license)**.** *A displayed row Y over a carrier layer L has a* layered generation license *when it is licensed in one of two ways. Either it is an ordinary core readout, meaning that it factors through the displayed core signature of L, or it is a higher-layer extension row, meaning that the source, gap or NonCollapse witness, classifier, transport, and boundary ledger for Y are explicitly displayed over L:*

$$\mathsf{Licensed}_L(Y) := \mathsf{CoreRead}_L(Y) \ \vee \ \mathsf{ExtensionLedger}_L(Y).$$

The second case creates an object in a derived layer. It does not add a fourth primitive to the source layer.

Principle 9413.450 (No same-layer fourth primitive)**.** *The anti-primitive discipline forbids an unledgered fourth role at the same carrier layer. It does not forbid derived objects. Algebraic generators, circle constraints, branch rows, spectral factors, and zero resonances are admissible only when their generation and extension ledgers are displayed; without such ledgers they are primitive intrusions rather than BEDC objects.*

Theorem 9413.451 (Core completeness excludes independent fourth observables)**.** *If $X^{\uparrow}$ is core-complete, then every displayed public observable of X is either a core-signature readout, a licensed higher-layer extension, or is outside the core surface as an explicit bridge, boundary, or refusal. In particular, no independent fourth observable is admitted inside the same-layer core interface.*

Proof. Core completeness gives a factorization

$$F = \overline{F} \circ \Sigma_X$$

for every public observable F in the core class. Therefore such an F is a readout of the core signature rather than an independent primitive. If a displayed row does not factor through the core signature, the licensed alternatives are exactly those of Definition 9413.449: carry it by a higher-layer extension ledger, place it in a bridge or boundary ledger, or refuse it at the public core surface. This is the anti-primitive discipline of Definition 9413.332 and Definition 9413.344. □

Corollary 9413.452 (Fourth commonality is a theory-extension signal)**.** *If a genuinely independent public observable Q is required for a carrier, then either Q is a derived core readout, a bridge or boundary row, or the three-row core is not complete for that carrier.*

Proof. By Definition 9413.451, a core-complete carrier leaves no place for an independent fourth observable inside its public core interface. Thus a proposed Q must be reclassified as a derived core readout, carried by a higher-layer extension ledger, placed in a bridge or boundary ledger, refused as an unaudited primitive, or treated as evidence that the core-completeness claim for the carrier has failed. □

Definition 9413.453 (Zeta zero core-completeness target)**.** *The* zeta zero core-completeness target *is*

$$\mathsf{CoreComplete}(\mathcal{Z}_\zeta),$$

where the source carrier $\mathcal{Z}_\zeta$ is the critical-strip zero source and Σ_Z is the zero ontic signature of Definition 9413.420. It asserts that every public zero observable factors through the atom-type, spectral time, and symmetry-persistence signature of the zero source.

Definition 9413.454 (Normal displacement as a candidate fourth observable)**.** *For the zeta mirror, the normal displacement is*

$$\delta(s) := \Re(s) - \frac{1}{2}.$$

It is a candidate fourth observable for the zero source because it separates the mirror companions

$$s = \frac{1}{2} + \delta + i\gamma, \qquad J(s) = \frac{1}{2} - \delta + i\gamma$$

by the sign rule

$$\delta(J(s)) = -\delta(s),$$

while their zero atom type, spectral time, and mirror orbit signature are the same.

Theorem 9413.455 (Zeta zero core completeness forces the fixed surface)**.** *Assume mirror closure, mirror-even zero signature, core completeness of the zeta zero source, and that δ is a public zero observable. Then every critical-strip zero lies on the fixed surface*

$$\Re(s) = \frac{1}{2}.$$

Proof. Core completeness of $\mathcal{Z}_\zeta$ gives a factorization

$$\delta(s) = f(\Sigma_Z(s)).$$

Mirror-evenness gives

$$\Sigma_Z(J(s)) = \Sigma_Z(s),$$

so

$$\delta(J(s)) = f(\Sigma_Z(J(s))) = f(\Sigma_Z(s)) = \delta(s).$$

But the direct mirror calculation in Definition 9413.454 gives

$$\delta(J(s)) = -\delta(s).$$

Hence $\delta(s) = 0$ in the characteristic-zero real readout. This is the fixed surface $\Re(s) = 1/2$. □

Corollary 9413.456 (Core completeness gives the RH witness shape)**.** *Under the hypotheses of Definition 9413.455, the zeta zero source admits the RH fixed-half section.*

Proof. The theorem assigns the fixed-half conclusion to every critical-strip zero source row. By Definition 9413.199, this is exactly the RH fixed-half section, i.e. the constructive witness shape needed for the BEDC RH target. □

Definition 9413.457 (Layered normal-coordinate discipline)**.** *The zeta zero source satisfies* layered normal-coordinate discipline *when every displayed normal coordinate of a critical-strip zero is licensed in exactly the sense of Definition 9413.449: it either factors through the zero ontic signature Σ_Z, or it is carried by an off-critical normal-extension ledger.*

Theorem 9413.458 (Excluding off-critical normal extensions gives the fixed surface)**.** *Assume mirror closure, mirror-even zero signature, layered normal-coordinate discipline, and located fixed-half collapse. If no off-critical normal-extension ledger exists for a zeta zero source, then every critical-strip zero lies on the fixed surface.*

Proof. Let $s = \frac{1}{2} + \delta + i\tau$ be a critical-strip zero source. By layered normal-coordinate discipline, the normal coordinate is either a signature readout or an off-critical normal extension. In the first case, the proof of Definition 9413.455 applies: mirror-evenness makes the signature value the same at s and $J(s)$, while the normal coordinate is mirror-odd, so $\delta = 0$.

In the second case, the normal coordinate is licensed by $\mathsf{NormalExtLedger}_\zeta(s, \delta)$. The hypothesis excluding off-critical normal-extension ledgers rules out $\delta \# 0$. Located fixed-half collapse then gives $\delta = 0$. Hence in all licensed cases the zero source lies on $\Re(s) = 1/2$. □

Theorem 9413.459 (Core expression is distinct from core completeness)**.** *The claim that every licensed object carries the core commonality basis is weaker than the claim that a specific object is core-complete.*

Proof. Definition 9413.343 supplies the core rows to licensed objects by object induction. This only gives the existence of observation-time, distinction-atom, and symmetry-persistence ledgers. Core completeness additionally asserts that every public observable factors through those ledgers. A symmetric two-point carrier can have observation, distinction, and symmetry while still carrying a non-fixed mirror orbit. Thus core expression does not collapse all symmetry orbits to fixed orbits; completeness and faithfulness are the additional claims. □

Theorem 9413.460 (No-fourth-ledger is the zeta core-completeness boundary)**.** *For the zeta zero source, the no-fourth-ledger row is the boundary form of core completeness with respect to the normal displacement.*

Proof. If $\delta(s) \# 0$ occurred on a zero source row, then Definition 9413.431 supplies a finite prime-window defect. This defect is a public witness of off-fixed displacement unless the zero carrier excludes it. The no-fourth-ledger row of Definition 9413.437 expresses precisely that exclusion: δ cannot stand as an independent observable outside the zero signature. Therefore the no-fourth-ledger row is the normal-displacement instance of core completeness. □

Corollary 9413.461 (Defect-zero incompatibility is the analytic form)**.** *The analytic form of the zeta core-completeness boundary is defect-zero incompatibility.*

Proof. The visible off-fixed displacement is read by finite prime-window defects. To prove that the zero source is core-complete with respect to this displacement, one must show that such a defect cannot coexist with the completed zeta zero ledger. This is exactly the role of Definition 9413.202 and Definition 9413.352. □

Theorem 9413.462 (Core commonality completion principle)**.** *The unified-reality programme supplies the common ontic basis for licensed objects. RH requires the stronger zeta-zero statement that the zero source is complete and faithful for that basis.*

Proof. The common basis is Definition 9413.445. Its object-level transport is Definition 9413.343. The zeta zero completion target is Definition 9413.453. If that target holds for the normal displacement, then Definition 9413.455 and Definition 9413.456 give the RH section. If it fails, the failure is an independent observable in the zero carrier, which is exactly the fourth-ledger boundary identified by Definition 9413.460. □

Concretized in §9100: Common-carrier completion boundaries are realized as finite source, observable-ledger, dyadic tolerance, stream-window, regular-readback, real-seal, transport, replay, provenance, and local NameCert rows.

9413.34 Prime-Sieve Odd Exactness

The fixed-half surface admits several equivalent readouts: mirror fixedness, unit centered prime amplitude, absence of real Laplace bias, and vanishing normal displacement. These equivalences identify the classifier surface. They do not, by themselves, prove that the zeta zero ledger lands on that surface. The RH-facing bridge is the exactness claim that a prime-visible mirror-odd defect cannot survive as a zero row inside the completed zeta carrier.

Definition 9413.463 (Fixed-surface readout cycle)**.** *For the zeta mirror*

$$J(s) := 1 - \overline{s}$$

and the normal displacement

$$\delta(s) := \Re(s) - \frac{1}{2},$$

the fixed-surface readout cycle *is the package of equivalent surface predicates*

$$\Re(s) = \frac{1}{2}, \qquad |p^{1/2-s}| = 1 \text{ for every displayed prime } p,$$

$$e^{-\delta(s)x} = 1 \text{ for logarithmic time } x > 0, \qquad J(s) = s.$$

It is a classifier package for the half surface, not a zero-exclusion principle.

Theorem 9413.464 (The fixed-surface cycle is a readout equivalence)**.** *The fixed-surface readout cycle expresses the same centered surface read in prime, Laplace, and mirror coordinates. It does not imply*

$$\mathsf{ZetaZero}(s) \to \Re(s) = \frac{1}{2}.$$

Proof. Definition 9413.313 identifies $\Re(s) = 1/2$ with $J(s) = s$. Definition 9413.317 identifies the same surface with the prime-unit and no-Laplace-bias readouts. None of these equivalences contains the hypothesis $\mathsf{ZetaZero}(s)$ or a bridge from the zero ledger to the fixed surface. That bridge is the defect-zero incompatibility obligation of Definition 9413.202. □

Definition 9413.465 (Mirror-odd prime-defect vector)**.** *The* mirror-odd prime-defect vector *is the prime-indexed readout*

$$\mathcal{D}(s) := \big(d_p(s)\big)_{p \in \mathsf{Prime}^{\uparrow}}, \qquad d_p(s) := \log |p^{1/2-s}|.$$

For a finite prime window S, its finite shadow is

$$D_S(s) := \sum_{p \in S} d_p(s).$$

Thus D_S is the window defect row of Definition 9413.200.

Definition 9413.466 (Time-fibre even and odd normal reads)**.** *For a fixed directed time coordinate τ, the mirror pair of normal reads is*

$$\delta, \qquad -\delta.$$

Its even and odd normal components are

$$\delta_{\text{even}} := \frac{\delta + (-\delta)}{2} = 0,$$

and

$$\delta_{\mathrm{odd}} := \frac{\delta - (-\delta)}{2} = \delta.$$

Thus the mirror-even component of a two-read time fibre is already on the fixed surface; the RH-facing issue is whether the mirror-odd component can remain nonzero on a zero row.

Definition 9413.467 (Odd zero defect)**.** *An* odd zero defect *for the completed zeta carrier is the coexistence of a critical-strip zero row with a nonzero finite prime-window mirror-odd defect:*

$$\mathsf{OddZeroDefect}_\zeta := \sum_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \sum_{S:\mathsf{FinitePrimeWindow}} (D_S(s)\#0) \right).$$

The corresponding refusal row is

$$\mathsf{NoOddZeroDefect}_\zeta := \neg\mathsf{OddZeroDefect}_\zeta.$$

Definition 9413.468 (Even defect energy)**.** *For a nonempty finite prime window S, the* defect energy *and normalized defect energy are*

$$E_S(s) := D_S(s)^2, \qquad \overline{E}_S(s) := \left(\overline{D}_S(s)\right)^2.$$

The corresponding refusal row is

$$\mathsf{NoEvenDefectEnergy}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \sum_{S:\mathsf{FinitePrimeWindow}_{\neq\varnothing}} (\overline{E}_S(s)\#0) \to \bot \right).$$

Theorem 9413.469 (Prime-defect is mirror-odd)**.** *For $s = 1/2 + \delta + i\tau$ and $J(s) = 1 - \overline{s}$,*

$$d_p(s) = -\delta \log p, \qquad d_p(J(s)) = -d_p(s).$$

Consequently

$$\mathcal{D}(J(s)) = -\mathcal{D}(s).$$

Proof. The centered prime amplitude is

$$p^{1/2-s} = p^{-\delta} p^{-i\tau},$$

so

$$d_p(s) = \log |p^{1/2-s}| = -\delta \log p.$$

Since

$$J(s) = \frac{1}{2} - \delta + i\tau,$$

the normal displacement of $J(s)$ is $-\delta$. Substituting this into the same formula gives

$$d_p(J(s)) = \delta \log p = -d_p(s).$$

The vector statement is obtained componentwise. □

Theorem 9413.470 (Defect energy is mirror-even)**.** *For every nonempty finite prime window S,*

$$E_S(J(s)) = E_S(s), \qquad \overline{E}_S(J(s)) = \overline{E}_S(s).$$

Proof. By Definition 9413.469,

$$D_S(J(s)) = -D_S(s).$$

Squaring gives

$$E_S(J(s)) = D_S(J(s))^2 = D_S(s)^2 = E_S(s).$$

The normalized statement follows in the same way from

$$\overline{D}_S(J(s)) = -\overline{D}_S(s),$$

which is the normalized form of the same computation. □

Theorem 9413.471 (Prime-window defect measures the odd normal read)**.** *For $s = 1/2 + \delta + i\tau$ and every nonempty finite prime window S, the normalized prime-window defect is the negative odd normal component:*

$$\overline{D}_S(s) = -\delta_{\mathrm{odd}}.$$

Proof. By Definition 9413.466, the odd normal component is $\delta_{\mathrm{odd}} = \delta$. The normalized defect computation of Definition 9413.167 gives

$$\overline{D}_S(s) = -\delta.$$

Therefore $\overline{D}_S(s) = -\delta_{\mathrm{odd}}$. □

Corollary 9413.472 (Normalized defect energy measures squared odd normal read)**.** *For $s = 1/2 + \delta + i\tau$ and every nonempty finite prime window S,*

$$\overline{E}_S(s) = \delta_{\mathrm{odd}}^2.$$

Proof. By Definition 9413.471,

$$\overline{D}_S(s) = -\delta_{\mathrm{odd}}.$$

Squaring gives $\overline{E}_S(s) = \delta_{\mathrm{odd}}^2$. □

Corollary 9413.473 (Finite windows separate nonfixed mirror orbits)**.** *If $\delta(s)\#0$ and S is a nonempty finite prime window, then*

$$D_S(s)\#0.$$

Proof. Summing the formula of Definition 9413.469 over S gives

$$D_S(s) = -\delta(s) \sum_{p \in S} \log p.$$

The displayed prime rows have positive logarithm, and S is nonempty. Thus the finite sum is positive, so apartness of $\delta(s)$ from zero gives apartness of $D_S(s)$ from zero. This is the same visibility row as Definition 9413.201 and Definition 9413.320. □

Definition 9413.474 (Parity row as a finite prime sieve)**.** *The parity split of the ordinary Dirichlet series is the finite prime-window sieve associated with the prime 2:*

$$\sum_{n \geq 1} n^{-s} = \sum_{\substack{n \geq 1 \\ 2 \nmid n}} n^{-s} + \sum_{\substack{n \geq 1 \\ 2 | n}} n^{-s}.$$

The even part is $2^{-s}\zeta(s)$, and the alternating row is

$$\eta(s) = \sum_{n \geq 1} (-1)^{n-1} n^{-s} = (1 - 2^{1-s})\zeta(s).$$

Thus parity is the v_2 face of the prime-factorization ledger.

Definition 9413.475 (Finite prime-sieve tower)**.** *For a finite prime window S, the S-sieved* zeta readout *is*

$$\zeta_S(s) := \zeta(s) \prod_{p \in S} (1 - p^{-s}).$$

On the half-plane where the Euler and Dirichlet expansions are absolutely convergent, this readout is

$$\zeta_S(s) = \sum_{\gcd(n, \prod_{p \in S} p) = 1} n^{-s}.$$

The finite prime-sieve tower is the family of these readouts as S ranges over finite prime windows.

Theorem 9413.476 (Parity is the first finite sieve shadow)**.** *The parity construction of Definition 9413.474 is the $S = \{2\}$ instance of the finite prime-sieve tower.*

Proof. For $S = \{2\}$,

$$\zeta_S(s) = \zeta(s)(1 - 2^{-s})$$

removes the terms divisible by 2 in the absolutely convergent Dirichlet region. The alternating eta row instead applies the signed parity combination

$$(1 - 2^{1-s})\zeta(s).$$

Both rows are finite manipulations of the same v_2 coordinate. Hence parity is not separate from prime sieving; it is the lowest finite prime-window face of the same distinction ledger. □

Definition 9413.477 (Prime-sieve odd exactness)**.** *The* prime-sieve odd exactness *target for the completed zeta carrier is the row*

$$\mathsf{PrimeSieveOddExactness}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \sum_{S:\mathsf{FinitePrimeWindow}} (D_S(s) \# 0) \to \bot \right).$$

It says that a mirror-odd prime-window defect visible at a finite sieve level cannot coexist with the completed zero ledger.

Theorem 9413.478 (No odd zero defect is prime-sieve odd exactness)**.** *For the completed zeta carrier,*

$$\mathsf{NoOddZeroDefect}_\zeta$$

is the same refusal row as prime-sieve odd exactness.

Proof. Unfold Definition 9413.467. Its positive data are a zero row, a critical-strip row, and an existential finite prime-window defect $D_S(s)\#0$. This is exactly the antecedent excluded by Definition 9413.477. The two names therefore describe the same carrier refusal: no completed zeta zero may carry a nonzero mirror-odd finite prime-window defect. □

Theorem 9413.479 (Odd defect refusal is even energy refusal)**.** *For the completed zeta carrier,*

$$\mathsf{NoOddZeroDefect}_\zeta \iff \mathsf{NoEvenDefectEnergy}_\zeta.$$

Proof. For every nonempty finite prime window S, the normalization row $L_S\#0$ of Definition 9413.165 identifies nonzero $D_S(s)$ with nonzero $\overline{D}_S(s)$. Squaring over the located real readout identifies nonzero $\overline{D}_S(s)$ with nonzero

$$\overline{E}_S(s) = \overline{D}_S(s)^2.$$

Therefore the positive data excluded by Definition 9413.467 are equivalent to the positive data excluded by Definition 9413.468. The two refusal rows are the same obstruction, written once as signed odd defect and once as mirror-even energy. □

Corollary 9413.480 (Mirror pairs do not cancel defect energy)**.** *If s and $J(s)$ are mirror-paired zero-source rows in one time fibre and $\delta(s)\#0$, then every nonempty finite prime window carries nonzero mirror-even defect energy.*

Proof. The signed defects cancel:

$$D_S(s) + D_S(J(s)) = 0,$$

by Definition 9413.469. However, Definition 9413.470 gives

$$E_S(s) + E_S(J(s)) = 2E_S(s).$$

By Definition 9413.472, the normalized energy is $\delta(s)^2$, hence nonzero when $\delta(s)\#0$. Thus a mirror pair can cancel the sign of the odd defect but not its even energy. □

Theorem 9413.481 (Prime-sieve odd exactness is defect-zero incompatibility)**.** *Prime-sieve odd exactness is the finite-sieve, mirror-odd form of the defect-zero incompatibility route.*

Proof. By Definition 9413.478, prime-sieve odd exactness may be read as $\mathsf{NoOddZeroDefect}_\zeta$. The existential finite-window component in Definition 9413.477 is precisely the prime-defect row of Definition 9413.200. The remaining hypotheses place that defect in the same completed source as a critical-strip zero row. Excluding this coexistence is exactly the content of Definition 9413.202, also identified as the hard point in Definition 9413.352 and as the analytic form of core completion in Definition 9413.461. □

Definition 9413.482 (Odd-exactness proof packet)**.** *An* odd-exactness proof packet *for the zeta route consists of the rows*

MirrorOddDecomposition, FiniteWindowSeparation, SieveContinuationExactness, ZeroIncompatibility.

The first row records $\mathcal{D}(J(s)) = -\mathcal{D}(s)$. The second row records that nonzero normal displacement is visible in a finite prime window. The third row records that a finite sieve defect remains a source-compatible defect after passage through the completed zeta carrier. The fourth row records that such a defect is incompatible with a zero ledger.

Theorem 9413.483 (Odd-exactness packets close the RH section route)**.** *Assume an odd-exactness proof packet, zero-ledger soundness, and the located fixed-half collapse row. Then the RH fixed-half section exists.*

Proof. Let s carry a critical-strip zero row. If $\delta(s)\#0$, finite-window separation supplies a nonempty finite prime window S with $D_S(s)\#0$. Sieve-continuation exactness keeps this finite defect source-compatible with the completed zeta carrier. Zero incompatibility then contradicts the zero ledger. Hence the off-half apartness row is excluded. The located fixed-half collapse row turns this exclusion into $\mathsf{OnCritLine}(s)$, and Definition 9413.199 reads the result as the RH section. □

Corollary 9413.484 (The obstruction is analytic exactness)**.** *Within the prime-sieve route, the obstruction is not the equivalence of the fixed-surface readouts and not the finite-window defect formula. It is the exactness of finite prime-sieve defect through the completed zeta carrier.*

Proof. The readout equivalences are supplied by Definition 9413.464. The finite-window visibility row is supplied by Definition 9413.473. What remains is the passage from a visible finite prime-window defect to zero-ledger exclusion in the completed zeta carrier. This is the SieveContinuationExactness and ZeroIncompatibility part of Definition 9413.482. □

Theorem 9413.485 (The quartic laboratory marks the zero-relevance boundary)**.** *The quartic spectral carrier shows why visibility of a defect must be strengthened to zero relevance before it can serve as an RH bridge.*

Proof. In the quartic carrier, branch data alone do not yield the endpoint zero law. The zero law also uses the dominance and local-interference ledgers, as isolated in Definition 9413.99 and scoped by Definition 9413.209. The zeta analogue is that finite prime-window defect is visible but not yet zero-relevant. Prime-sieve odd exactness is the missing zero-relevance row for the completed zeta carrier. □

Corollary 9413.486 (Prime-sieve exactness is the no-fourth-ledger test)**.** *For the zeta zero source, prime-sieve odd exactness is the analytic test that the normal displacement is not an independent fourth observable.*

Proof. Definition 9413.462 identifies the RH-facing completion problem as the claim that the zeta zero source is complete and faithful for the core basis. The normal displacement is the candidate fourth observable of Definition 9413.454. By Definition 9413.484, the only remaining prime-sieve obstruction is whether finite odd defect can coexist with a zero ledger. Therefore prime-sieve odd exactness is the analytic no-fourth-ledger test for this observable. □

9413.35 Recursive Parity Tower

Prime-sieve odd exactness separates the signed mirror-odd defect from its mirror-even energy. The same separation persists after the Euler local factor is resolved by repeated parity splitting. A prime supplies the dimension; the exponent-depth inside that prime dimension supplies a binary recursion tree. The normalized radial defect read by every finite part of this tree is the same normal displacement from the fixed-half surface.

Definition 9413.487 (Local parity recursion)**.** *For a formal variable x, the finite parity recursion packet is*

$$P_m(x) := \prod_{j=0}^{m} (1 + x^{2^j}).$$

It satisfies

$$(1 - x)P_m(x) = 1 - x^{2^{m+1}},$$

and hence

$$P_m(x) = \frac{1 - x^{2^{m+1}}}{1 - x}$$

whenever $1 - x$ is invertible. On a convergent analytic readout with $|x| < 1$, the limiting row is

$$\frac{1}{1 - x} = \prod_{j \geq 0} (1 + x^{2^j}).$$

Proof. The identity follows by the telescoping chain

$$(1-x)(1+x) = 1-x^2, \qquad (1-x^2)(1+x^2) = 1-x^4,$$

and so on through the factor $1+x^{2^m}$. Multiplying these rows gives $(1-x)P_m(x) = 1-x^{2^{m+1}}$. If $|x|<1$, the terminal term $x^{2^{m+1}}$ tends to zero in the displayed analytic readout. □

Theorem 9413.488 (Euler local factors are recursive parity trees)**.** *On the local convergence region $\Re(s)>0$, each Euler local factor admits the recursive parity expansion*

$$(1-p^{-s})^{-1} = \prod_{j\geq 0}\left(1+p^{-2^j s}\right).$$

On the Euler-product convergence region $\Re(s)>1$ this gives the two-indexed readout

$$\zeta(s) = \prod_{p\in\mathsf{Prime}^{\uparrow}}\prod_{j\geq 0}\left(1+p^{-2^j s}\right).$$

Proof. Apply Definition 9413.487 with $x = p^{-s}$. The local condition $\Re(s)>0$ gives $|p^{-s}|<1$. The global statement is the same local identity inserted into the ordinary Euler-product row on $\Re(s)>1$. □

Definition 9413.489 (Recursive parity tower)**.** *The recursive parity tower of the zeta Euler face is the two-indexed node family*

$$\mathsf{ParityTower}_{\zeta} := \mathsf{Prime}^{\uparrow}\times\mathsf{Nat}^{\uparrow},$$

where (p,j) records the prime dimension p and the binary depth j inside that dimension. Its centered node channel is

$$U_{p,j}(s) := p^{2^j(1/2-s)}.$$

For a nonempty finite node family $A\subset\mathsf{ParityTower}_{\zeta}$, define

$$D_A^{\mathrm{rec}}(s) := \sum_{(p,j)\in A}\log|U_{p,j}(s)|,$$

and its positive weight

$$W_A := \sum_{(p,j)\in A} 2^j\log p.$$

The normalized recursive defect and recursive defect energy are

$$\overline{D}_A^{\mathrm{rec}}(s) := \frac{D_A^{\mathrm{rec}}(s)}{W_A}, \qquad \overline{E}_A^{\mathrm{rec}}(s) := \left(\overline{D}_A^{\mathrm{rec}}(s)\right)^2.$$

Theorem 9413.490 (Recursive normalized defects are depth-invariant)**.** *If*

$$s = \frac{1}{2}+\delta+i\tau,$$

then for every nonempty finite node family $A\subset\mathsf{ParityTower}_{\zeta}$,

$$\overline{D}_A^{\mathrm{rec}}(s) = -\delta.$$

Proof. For a node (p, j),

$$U_{p,j}(s) = p^{2^j(1/2-s)} = p^{-2^j\delta} e^{-i2^j\tau \log p}.$$

Thus

$$\log |U_{p,j}(s)| = -2^j \delta \log p.$$

Summing over A gives

$$D_A^{\mathrm{rec}}(s) = -\delta \sum_{(p,j)\in A} 2^j \log p = -\delta W_A.$$

Since A is nonempty and every displayed prime logarithm is positive, W_A is a positive normalization row. Dividing by W_A gives the claim. □

Corollary 9413.491 (Recursive defect energy is depth-invariant)**.** *For $s = 1/2 + \delta + i\tau$ and every nonempty finite node family $A \subset \mathsf{ParityTower}_\zeta$,*

$$\overline{E}_A^{\mathrm{rec}}(s) = \delta^2.$$

Consequently the signed recursive defect is mirror-odd, while the recursive defect energy is mirror-even.

Proof. The first statement is the square of Definition 9413.490. Under the mirror $J(s) = 1 - \overline{s}$, the normal displacement changes from δ to $-\delta$. Hence $\overline{D}_A^{\mathrm{rec}}$ changes sign, while $\overline{E}_A^{\mathrm{rec}}$ is unchanged. □

Definition 9413.492 (Recursive odd energy refusal)**.** *The recursive odd energy refusal row is*

$$\mathsf{NoRecursiveOddEnergyZero}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \sum_{A:\mathsf{FiniteParitySubtree}_{\neq\varnothing}} (\overline{E}_A^{\mathrm{rec}}(s)\#0) \to \bot \right).$$

Here $\mathsf{FiniteParitySubtree}_{\neq\varnothing}$ denotes a nonempty finite node family in $\mathsf{ParityTower}_\zeta$. The row says that no completed zeta zero may carry nonzero mirror-even energy anywhere in the recursive parity tower.

Theorem 9413.493 (Recursive odd energy refusal is conditionally sufficient)**.** *Together with the located fixed-half collapse row, the recursive odd energy refusal row is sufficient for the RH fixed-half section.*

Proof. Let s carry a critical-strip zero row and write

$$s = \frac{1}{2} + \delta + i\tau.$$

Suppose $\delta\#0$. Choose any nonempty finite node family $A \subset \mathsf{ParityTower}_\zeta$. By Definition 9413.491,

$$\overline{E}_A^{\mathrm{rec}}(s) = \delta^2,$$

which is nonzero in the located real readout when $\delta\#0$. This supplies the positive data excluded by Definition 9413.492. Therefore $\neg(\delta\#0)$. The located fixed-half collapse row converts this into $\delta = 0$, hence $\Re(s) = 1/2$ by the fixed-surface calculation of Definition 9413.313. □

Corollary 9413.494 (Recursive parity does not hide an off-half defect)**.** *Within the recursive parity tower, an off-half normal displacement is not a defect of one depth layer only. Every nonempty finite subtree reads the same normalized odd defect and the same mirror-even defect energy.*

Proof. The normalized odd defect is depth-invariant by Definition 9413.490, and the energy is depth-invariant by Definition 9413.491. Thus recursion through parity depth cannot cancel, dilute, or relocate the normal displacement. Any remaining obstruction is the same zero-relevance obstruction isolated in Definition 9413.484, now read across the full recursive parity tower. □

9413.36 Parity Closure Tower Certificate

The recursive parity tower displays the normal defect at every finite prime-adic depth, but that visibility is not yet a zero-exclusion theorem. The missing statement can be sharpened by separating two notions that the functional equation tends to blur. Mirror symmetry gives paired zero packets; it does not by itself identify a packet with its mirror inside the same routing closure. A parity closure tower is the stronger object: the mirror packet lies in the same recursive routing closure, while the normal defect is routing-invariant and parity-odd.

Definition 9413.495 (Abstract parity-routing packet)**.** *An* abstract parity-routing packet *consists of a topological space X, a homeomorphism*

$$\mathcal{R} : X \to X,$$

an involution

$$P : X \to X, \qquad P^2 = \mathrm{id},$$

and a continuous real readout

$$\Delta : X \to \mathsf{Real}^{\uparrow}$$

such that

$$P\mathcal{R}P = \mathcal{R}^{-1},$$

$$\Delta(\mathcal{R}x) = \Delta(x),$$

and

$$\Delta(Px) = -\Delta(x).$$

The map $\mathcal{R}$ is the packet-routing step, P is parity reflection, and Δ is the signed normal defect read by the packet.

Theorem 9413.496 (Parity closure kills odd defect)**.** *Let $(X, \mathcal{R}, P, \Delta)$ be an abstract parity-routing packet. If*

$$Px \in \overline{\{\mathcal{R}^m x : m \in \mathbb{Z}\}},$$

then

$$\Delta(x) = 0.$$

Proof. The closure hypothesis gives a sequence of integers m_j such that

$$\mathcal{R}^{m_j} x \to Px.$$

By continuity of Δ,

$$\Delta(Px) = \lim_j \Delta(\mathcal{R}^{m_j} x).$$

Routing invariance gives

$$\Delta(\mathcal{R}^{m_j} x) = \Delta(x)$$

for every j, hence

$$\Delta(Px) = \Delta(x).$$

Parity oddness gives

$$\Delta(Px) = -\Delta(x).$$

Thus $\Delta(x) = -\Delta(x)$, and the located real readout gives $\Delta(x) = 0$. □

Definition 9413.497 (Eta return loop and cut coordinate)**.** *For*

$$\eta(s) = \sum_{n\geq 1}(-1)^{n-1}n^{-s},$$

write

$$v_N(s) := (-1)^{N-1}N^{-s}, \qquad P_N(s) := \sum_{n\leq N} v_n(s), \qquad R_N(s) := \sum_{n>N} v_n(s).$$

On a zero row $\eta(s) = 0$,

$$P_N(s) + R_N(s) = 0.$$

The local cut coordinate at the Nth segment is the row

$$P_{N-1}(s) + \theta_N(s)v_N(s) = 0.$$

Theorem 9413.498 (Eta cut coordinates satisfy exact routing recursion)**.** *On an eta zero row, the cut coordinates satisfy*

$$\theta_N(s) = 1 - \left(\frac{N}{N+1}\right)^s \theta_{N+1}(s).$$

Proof. By Definition 9413.497,

$$\theta_N(s) = -\frac{P_{N-1}(s)}{v_N(s)}.$$

Since $P_{N-1} + v_N + R_N = 0$,

$$P_{N-1} = -v_N - R_N,$$

so

$$\theta_N(s) = 1 + \frac{R_N(s)}{v_N(s)}.$$

Also $R_N = v_{N+1} + R_{N+1}$, and the definition of θ_{N+1} gives

$$R_N = v_{N+1}\theta_{N+1}.$$

Finally

$$\frac{v_{N+1}}{v_N} = -\left(\frac{N}{N+1}\right)^s.$$

Substitution gives the displayed recursion. □

Definition 9413.499 (Parity closure tower certificate)**.** *For a critical-strip zeta zero $s = 1/2 + \delta + i\tau$, a* zeta parity closure tower certificate *consists of a canonical zero-relevant packet x_s in an abstract parity-routing packet $(X, \mathcal{R}, P, \Delta)$, together with rows:*

$$\mathsf{ActiveCapture}(x_s, s), \qquad \Delta(x_s) = \delta,$$

$$Px_s \in \overline{\{\mathcal{R}^m x_s : m \in \mathbb{Z}\}},$$

and a zero-relevance ledger saying that x_s is the packet whose dominance, endpoint, tail, or solenoid rows control the completed zero. The equality $\Delta(x_s) = \delta$ is the defect-invariance row; the closure row is stronger than the statement that s and $1 - \overline{s}$ are both zeros.

Theorem 9413.500 (Parity closure tower certificates are conditionally sufficient)**.** *If every critical-strip zeta zero carries a zeta parity closure tower certificate, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

The certificate supplies x_s with

$$\Delta(x_s) = \delta$$

and

$$Px_s \in \overline{\{\mathcal{R}^m x_s : m \in \mathbb{Z}\}}.$$

By Definition 9413.496,

$$\Delta(x_s) = 0.$$

Hence $\delta = 0$, so $\Re(s) = 1/2$. Since z was arbitrary, Definition 9413.199 supplies the RH fixed-half section. □

Corollary 9413.501 (Functional equation pairing is not packet closure)**.** *The completed zeta functional equation supplies mirror pairing of zero coordinates, but the parity closure tower certificate requires a stronger packet-level identification.*

Proof. The mirror

$$J(s) := 1 - \overline{s}$$

sends

$$\frac{1}{2} + \delta + i\tau \quad \text{to} \quad \frac{1}{2} - \delta + i\tau.$$

The completed functional equation and conjugation symmetry place zeros in mirror-related positions. This gives a paired-zero row

$$s \longmapsto J(s).$$

It does not by itself give

$$Px_s \in \overline{\{\mathcal{R}^m x_s : m \in \mathbb{Z}\}},$$

nor does it identify the active endpoint, Rouché, solenoid, or dominance packet for s with its mirror inside one recursive closure. Thus the parity closure certificate isolates the noncircular bridge left after ordinary functional-equation symmetry has been accounted for. □

Corollary 9413.502 (Relation to endpoint and solenoid certificates)**.** *Endpoint bisection and solenoid Lee–Yang rows are candidate mechanisms for producing the active capture and zero-compatible routing closure required by a parity closure tower certificate.*

Proof. The endpoint bisection certificate of Definition 9413.762 identifies a finite endpoint window, a distinguished segment, and a Rouché ledger. These are possible sources for $\mathsf{ActiveCapture}(x_s, s)$. The solenoid-compatible resonance lift of Definition 9413.780 identifies a compact phase carrier and forbids hidden noncompact real scale. This is a possible source for the zero-compatible routing closure. The parity closure tower certificate records the abstract consequence common to these mechanisms: once the signed defect is both routing-invariant and parity-odd inside the same closure, it must vanish. □

Definition 9413.503 (Parity closure bridge obligations)**.** *The parity closure route leaves four bridge obligations:*

$$\mathsf{ActiveCapture}, \qquad \mathsf{DefectInvariant}, \qquad \mathsf{ParityClosure}, \qquad \mathsf{ZeroCompatibleBound}.$$

Active capture constructs the zero-relevant packet from the completed zero ledger. Defect invariance proves that its signed readout is $\Re(s) - 1/2$. Parity closure places the mirror packet in the same routing closure. Zero-compatible bound or compactness prevents the closure from using a hidden noncompact real scale.

Corollary 9413.504 (The bridge obligations are the proof load)**.** *The parity closure route proves a conditional RH theorem, but the zeta-specific proof load is the construction of the four bridge obligations in Definition 9413.503.*

Proof. Definition 9413.496 is an abstract topological theorem, and Definition 9413.500 is its zeta-facing conditional use. Neither theorem constructs the canonical packet space, its routing, its dominance ledger, or its compact zero-compatible carrier from the completed zeta row. Those tasks are exactly the four bridge obligations. Consequently the remaining work is not another restatement of the fixed-half surface, but the construction of a zero-relevant recursive packet tower satisfying those obligations. □

9413.37 Prime Charge, Parity, and Phase Dictionary

The parity closure route benefits from a sharper projection dictionary. The three primary reads are not parity, energy, and an unspecified third observable. The more stable triad is prime charge, parity, and phase. Energy is a derived second-order observable: it is the square readout of a failure of these three rows to close.

Definition 9413.505 (Prime charge, parity, and phase projections)**.** *The* prime charge–parity–phase dictionary *assigns the three ontic roles to their zeta-facing projections as follows:*

Ontic role	***Primary projection***	***Zeta read***
Distinction or primality	*prime charge, label, fibre*	p, v_p, S, (p, j), $\prod_{p\in S} \mathbb{Z}_p$
Symmetry or unit boundary	*parity, mirror, unit circle*	$J(s) = 1 - \overline{s}$ *and* $\delta \mapsto -\delta$
Time or recursion	*phase, action, routing*	$e^{-i\tau h_a}$ *and* $\mathcal{R} : X \to X$

For a node $a = (p, j)$, the prime charge determines the positive height

$$h_a := 2^j \log p.$$

For $s = 1/2 + \delta + i\tau$, the local channel is

$$U_a(s) := e^{-(s-1/2)h_a} = e^{-\delta h_a} e^{-i\tau h_a}.$$

Definition 9413.506 (Prime charge)**.** *The* prime charge *of a displayed resonance node is its discrete prime-register row. In a finite prime family S, this register is read through the compact fibre*

$$\prod_{p\in S} \mathbb{Z}_p$$

behind the solenoid projection

$$\Sigma_S \twoheadrightarrow \mathbb{T}.$$

It records which prime slice, valuation depth, or parity depth a node belongs to. It is therefore a distinction read, not a real positive scale.

Theorem 9413.507 (Prime charge determines the height ledger)**.** *For every displayed node $a = (p, j)$, the prime charge determines the Hamiltonian height*

$$h_a = 2^j \log p,$$

and hence determines the normal defect and phase rows

$$\log |U_a(s)| = -\delta h_a, \qquad \arg U_a(s) \equiv -\tau h_a \pmod{2\pi}.$$

Proof. The node label $a = (p, j)$ records both the prime slice p and the parity depth j. The height row is therefore $h_a = 2^j \log p$. Substituting this into

$$U_a(s) = e^{-\delta h_a} e^{-i\tau h_a}$$

gives the modulus and argument readouts. □

Definition 9413.508 (Energy as derived closure-defect observable)**.** *For a finite active packet A, the first-order normal defect of a node is*

$$d_a(s) := \log |U_a(s)| = -\delta h_a.$$

The associated energy is the second-order read

$$\mathcal{E}_A(s) := \sum_{a \in A} d_a(s)^2.$$

It is not a primary ontic projection. It forgets the parity orientation of the defect and records only its magnitude.

Theorem 9413.509 (Energy is the square of triadic closure failure)**.** *For $s = 1/2 + \delta + i\tau$ and a finite active packet A,*

$$\mathcal{E}_A(s) = \delta^2 \sum_{a \in A} h_a^2.$$

Under the mirror $J(s) = 1 - \overline{s}$, the first-order defect changes sign, while the energy is unchanged.

Proof. The defect formula gives $d_a(s) = -\delta h_a$, so

$$\mathcal{E}_A(s) = \sum_{a \in A} \delta^2 h_a^2 = \delta^2 \sum_{a \in A} h_a^2.$$

The mirror sends δ to $-\delta$, so d_a changes sign. Squaring removes the sign, hence the energy is mirror-even. □

Definition 9413.510 (Triadic closure defect)**.** *A* triadic closure defect *for a zero-relevant packet is the failure of the prime-charge ledger, parity/unit-boundary row, and phase-routing row to close in one packet. In the local zeta channel the defect has first-order read*

$$\Omega_a(s) := \log |U_a(s)| = -\delta h_a.$$

The unit-boundary row is

$$\Omega_a(s) = 0,$$

or equivalently

$$|U_a(s)| = 1.$$

Theorem 9413.511 (Unit triadic closure forces the fixed-half row)**.** *Let a be a displayed node with $h_a > 0$. If*

$$|U_a(s)| = 1$$

for $s = 1/2 + \delta + i\tau$, then

$$\delta = 0.$$

Proof. The modulus read is

$$|U_a(s)| = e^{-\delta h_a}.$$

If this equals 1, then

$$-\delta h_a = 0.$$

Since $h_a > 0$, the located real readout gives $\delta = 0$. □

Definition 9413.512 (Oriented triadic closure tower)**.** *An* oriented triadic closure tower *for a critical-strip zero $s = 1/2 + \delta + i\tau$ is a zero-relevant recursive packet tower carrying:*

$$\mathsf{PrimeChargeLedger}, \qquad \mathsf{ParityOddDefect}, \qquad \mathsf{PhaseRouting},$$

$$\mathsf{WindingCapture}, \qquad \mathsf{SolenoidGaugeDiscipline}, \qquad \mathsf{EnergyOrUnitBound}.$$

The winding row records Rouché or local-degree capture of the zero. The solenoid row permits phase and prime-register fibre information, but not a hidden real positive scale. The energy or unit-bound row prevents the triadic closure defect from remaining nonzero along the tower.

Corollary 9413.513 (Oriented triadic closure is a proof-role refinement)**.** *The oriented triadic closure tower refines the parity closure tower by separating the three primary projections from the derived energy observable.*

Proof. The parity closure tower of Definition 9413.499 uses a signed defect Δ, routing invariance, and parity oddness. The present dictionary identifies where these rows come from. Prime charge supplies h_a, phase routing supplies $e^{-i\tau h_a}$ and the successor relation, and parity supplies the sign change $\delta \mapsto -\delta$. Energy appears only after the first-order defect is squared. Thus the oriented triadic tower keeps the primary projection data visible instead of treating energy as a primitive row. □

Corollary 9413.514 (Solenoid fibres carry charge but not real scale)**.** *The solenoid fibre is the natural carrier for prime charge, while the factor $e^{-\delta h_a}$ is a noncompact scale defect rather than a legal hidden charge.*

Proof. By Definition 9413.506, the hidden fibre behind a finite solenoid phase projection is $\prod_{p \in S} \mathbb{Z}_p$. This records prime-register information. By Definition 9413.781, a compact solenoid phase carrier has no nontrivial continuous positive real character. Therefore the real factor $e^{-\delta h_a}$ cannot be absorbed into the prime-register fibre. It is precisely the closure defect measured by Definition 9413.510. □

Corollary 9413.515 (RH-facing use of the projection dictionary)**.** *In the zeta route, the proof-relevant projections are prime charge, parity, phase routing, winding capture, and the derived energy bound.*

Proof. Prime charge determines the heights h_a. Parity records the sign of δ. Phase routing records the unitary part $e^{-i\tau h_a}$ and the recursive successor structure. Winding capture is required to make the packet zero-relevant rather than merely visible. Energy detects whether a nonzero triadic closure defect is being carried along a cofinal tower. These are exactly the proof-role components named in Definition 9413.512. □

Concretized in §8995: PrimeParityPhaseUp realizes the prime-charge, parity, phase, height-ledger, and closure-defect rows as one finite NameCert packet.

9413.38 Triadic Closure Tower Program

The projection dictionary can be organized as a constructive tower. The tower does not claim an unconditional proof of the Riemann hypothesis. Its role is to state the certificate whose construction would discharge the zero-rigidity problem. Each layer records four rows:

$$\Omega_n := (O_n, G_n, I_n, F_n),$$

where O_n is the layer object, G_n is the generation rule from the preceding layer, I_n is the invariant retained by the layer, and F_n is the information lost in the projection fibre. The discipline is that no later layer may introduce an unledgered object; every carrier must be generated from previous rows and the triadic roles of distinction, symmetry, and time.

Definition 9413.516 (Triadic construction layer)**.** *A* triadic construction layer *is a packet*

$$\Omega_n = (O_n, G_n, I_n, F_n).$$

The generation row

$$G_n : O_n \rightsquigarrow O_{n+1}$$

is legal only when it is a displayed operation on the current carrier and the triadic roles. The invariant I_n is the datum preserved by the layer, and the fibre F_n records which data are no longer visible after projection to the next readout.

Principle 9413.517 (No unledgered later object)**.** *In a triadic construction tower, an object at layer $n+1$ is licensed only by the preceding packet and the displayed generation rule. A zero-relevant endpoint packet, solenoid carrier, selector, routing space, or energy bound cannot be introduced as an external primitive.*

Definition 9413.518 (Zeta triadic construction spine)**.** *The* zeta triadic construction spine *is the following schematic sequence of construction layers.*

Layer	***Object***	***Retained invariant***
Ontic roles	$(\mathsf{D}, \mathsf{S}, \mathsf{T})$	*triadic closure of distinction, symmetry, and time*
Projection dictionary	*prime charge, parity, phase*	*charge ledger, mirror sign, phase routing*
Euler unit core	e^{-itH}	*unitary flow when* $H = H^*$
Prime ledger	$\bigoplus_p \mathbb{Z}e_p$	$\log n = \sum_p v_p(n) \log p$
Selector and dynamics	*FRACTRAN and Zeckendorf–Godel rows*	*auditable prime-register routing and legal prime-family selection*
Solenoid carrier	$\Sigma_S = \widehat{\mathbb{Z}[S^{-1}]}$	*visible unit circle with prime-register fibre*

Energy bound	$\mathcal{E}_n = \delta^2 W_n$	*off-half growth contradicts a zero-compatible bound*

Definition 9413.519 (Zeta triadic closure tower certificate)**.** *For a critical-strip zero coordinate*

$$s = \frac{1}{2} + \delta + i\tau,$$

a zeta triadic closure tower certificate *consists of a point* x_s *in a recursive packet space* X_∞ *together with the following rows:*

$$\mathsf{ActiveCapture}(x_s, s), \qquad \mathsf{DefectExtraction}(\Delta(x_s) = \delta),$$

$$\mathsf{PrimeRouting}(X_\infty, \mathcal{R}), \qquad \mathsf{TriadicClosure}(\mathsf{PrimeCharge}, \mathsf{Parity}, \mathsf{Phase}),$$

$$\mathsf{ParityClosure}\left(Jx_s \in \overline{\{\mathcal{R}^m x_s : m \in \mathbb{Z}\}}\right),$$

and a bound-versus-growth row

$$W_n \to \infty, \qquad \mathcal{E}_n(s) \le B_s < \infty.$$

Active capture means Rouché or local-degree capture of the completed zero. Defect extraction identifies the packet defect with $\Re(s) - 1/2$*. Prime routing supplies the inverse-limit successor structure. Triadic closure permits only unit phase and prime-register gauge, not a hidden positive real scale.*

Theorem 9413.520 (Triadic closure tower certificates are conditionally sufficient)**.** *If every critical-strip zeta zero carries a zeta triadic closure tower certificate, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

The certificate supplies a packet x_s with

$$\Delta(x_s) = \delta.$$

By the parity-closure row,

$$Jx_s \in \overline{\{\mathcal{R}^m x_s : m \in \mathbb{Z}\}}.$$

The abstract parity-routing theorem Definition 9413.496 gives

$$\Delta(x_s) = 0.$$

Therefore $\delta = 0$ and $\Re(s) = 1/2$. Since the zero row was arbitrary, Definition 9413.199 gives the RH fixed-half section. □

Corollary 9413.521 (Energy gives the same contradiction)**.** *In a zeta triadic closure tower certificate, the bound-versus-growth row also excludes $\delta\#0$.*

Proof. For a finite active packet A_n, Definition 9413.509 gives

$$\mathcal{E}_n(s) = \delta^2 W_n, \qquad W_n := \sum_{a \in A_n} h_a^2.$$

If $\delta\#0$ and $W_n \to \infty$, then

$$\mathcal{E}_n(s) \to \infty.$$

This contradicts the zero-compatible bound

$$\mathcal{E}_n(s) \le B_s < \infty.$$

Hence $\neg(\delta\#0)$, and located fixed-half collapse gives $\delta = 0$. □

Definition 9413.522 (Triadic closure source obligations)**.** *The triadic closure route leaves three source obligations:*

$$\mathsf{CanonicalEndpointCapture}, \qquad \mathsf{LeeYangUnitBoundary}, \qquad \mathsf{PrimeRoutingParityClosure}.$$

The first constructs, for each completed zero, a dominant endpoint packet with Rouché or winding capture. The second proves a unit-boundary or bounded-energy theorem for that packet. The third constructs the recursive routing closure and the parity relation inside one packet space.

Corollary 9413.523 (The source obligations are not fixed-half aliases)**.** *The source obligations in Definition 9413.522 are zeta-specific construction problems, not restatements of $\Re(s) = 1/2$.*

Proof. Canonical endpoint capture asks for a packet built from the completed zero ledger, as in Definition 9413.762. Lee–Yang unit boundary asks for an independent stability or compactness row, as in Definition 9413.783. Prime routing parity closure asks for the mirror packet to lie inside the same recursive closure, as in Definition 9413.499. None of these rows is the statement $\delta = 0$ written in another coordinate. Each row supplies a missing source mechanism consumed by the conditional theorem. □

Corollary 9413.524 (Selector, solenoid, and endpoint rows form one program)**.** *The Zeckendorf selector, solenoid Lee–Yang, endpoint bisection, parity closure, and energy-bound rows are components of one triadic closure program.*

Proof. The Zeckendorf selector supplies a legal prime-charge family, as in Definition 9413.834. The solenoid carrier supplies compact phase and prime-register fibre discipline. The endpoint bisection row supplies a candidate zero-relevant finite packet. The parity closure row supplies the topological odd-defect cancellation mechanism. The energy row supplies the cofinal contradiction when the normal displacement is nonzero. Together these rows instantiate the spine of Definition 9413.518. □

9413.39 Oriented Triadic Closure Tower Construction

The triadic closure program can be sharpened from a route statement into an object-construction problem. The object to construct is an oriented triadic closure tower over a completed zeta zero. Its layers are not a proof by themselves; they are the certificate rows which make the conditional RH implication noncircular.

Definition 9413.525 (Oriented triadic closure tower object)**.** *For a critical-strip zero coordinate*

$$s = \frac{1}{2} + \delta + i\tau,$$

a zeta oriented triadic closure tower *is a packet*

$$\mathfrak{T}_s := (X_\infty, \mathcal{R}_\infty, J, x_s, A_n, h_a, \Omega_n, \mathcal{B}_s)$$

with the following rows:

$$X_\infty = \varprojlim X_n, \qquad \mathcal{R}_\infty : X_\infty \to X_\infty,$$
$$J^2 = \mathrm{id}, \qquad J\mathcal{R}_\infty J = \mathcal{R}_\infty^{-1},$$

and a distinguished zero packet $x_s \in X_\infty$. Each finite level has active nodes A_n, positive heights $h_a > 0$, and normal-defect vector

$$\Omega_n(s) := (\log |e^{-(s-1/2)h_a}|)_{a \in A_n}.$$

The row $\mathcal{B}_s$ denotes the zero-compatible boundary or energy bound attached to the same packet.

Definition 9413.526 (Finite routing tower)**.** *A* finite routing tower *is a system*

$$X_1 \leftarrow X_2 \leftarrow X_3 \leftarrow \cdots$$

with projections

$$\pi_{n+1,n} : X_{n+1} \to X_n$$

and bijective routing maps

$$\mathcal{R}_n : X_n \to X_n$$

such that

$$\pi_{n+1,n} \circ \mathcal{R}_{n+1} = \mathcal{R}_n \circ \pi_{n+1,n}.$$

The inverse limit carries the induced homeomorphism

$$\mathcal{R}_\infty : X_\infty \to X_\infty.$$

Thus the routing row is not a hidden oracle; it is the inverse limit of finite auditable successor tables.

Definition 9413.527 (Euler-log solenoid bridge)**.** *For a finite or selected prime family S, an* Euler-log solenoid bridge *is a common phase carrier containing the Euler-log phase orbit*

$$\Lambda_S(\tau) := \overline{\{(e^{-it\log p})_{p\in S} : t \in \mathbb{R}\}} \subseteq \mathbb{T}^S$$

and the solenoid phase carrier

$$\Sigma_S = \widehat{\mathbb{Z}[S^{-1}]},$$

with a displayed comparison row between the visible unit-circle phase and the prime-register fibre

$$\prod_{p\in S}\mathbb{Z}_p.$$

The bridge is a source obligation: the multiplicative Euler-log phase does not automatically equal the additive localization phase of the solenoid carrier.

Definition 9413.528 (Construction rows for the oriented tower)**.** *An oriented triadic closure tower is constructed by six rows:*

$$\mathsf{ActiveCapture},\quad \mathsf{EulerLogSolenoidBridge},\quad \mathsf{TriadicClosure},$$

$$\mathsf{DefectExtraction},\quad \mathsf{CofinalGrowth},\quad \mathsf{BoundaryStability}.$$

They mean respectively: the packet captures the completed zero by Rouché or winding; the Euler-log phase and solenoid prime-register fibre sit in one phase container; prime charge, unit boundary, and time routing close modulo legal prime-adic gauge; the normal defect is extracted as $-\delta h_a$; the square weight

$$W_n := \sum_{a\in A_n} h_a^2$$

is cofinal; and the same zero-compatible packet carries a bound

$$|\Omega_n(s)|^2 \le B_s < \infty$$

or a stronger unit-boundary row.

Theorem 9413.529 (Defect extraction for oriented towers)**.** *For $s = 1/2+\delta+i\tau$ and every active node a,*

$$\log|e^{-(s-1/2)h_a}| = -\delta h_a.$$

Consequently

$$|\Omega_n(s)|^2 = \delta^2 \sum_{a\in A_n} h_a^2.$$

Proof. Since $s - 1/2 = \delta + i\tau$,

$$e^{-(s-1/2)h_a} = e^{-\delta h_a} e^{-i\tau h_a}.$$

Taking the logarithm of the modulus gives $-\delta h_a$. Squaring and summing over A_n gives the energy identity. □

Theorem 9413.530 (Oriented triadic closure towers are conditionally sufficient)**.** *If every critical-strip zeta zero carries a zeta oriented triadic closure tower whose construction rows hold, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

Let $\mathfrak{T}_s$ be the associated oriented tower. By Definition 9413.529,

$$|\Omega_n(s)|^2 = \delta^2 W_n.$$

If $\delta\#0$, then cofinal growth $W_n \to \infty$ gives

$$|\Omega_n(s)|^2 \to \infty.$$

This contradicts boundary stability

$$|\Omega_n(s)|^2 \le B_s < \infty.$$

Hence $\neg(\delta\#0)$. Located fixed-half collapse gives $\delta = 0$, so $\Re(s) = 1/2$. The fixed-half section follows from Definition 9413.199. □

Corollary 9413.531 (Parity closure gives the same fixed-half conclusion)**.** *If the oriented tower also satisfies*

$$Jx_s \in \overline{\{\mathcal{R}_\infty^m x_s : m \in \mathbb{Z}\}},$$

and its defect readout is routing-invariant and parity-odd, then $\delta = 0$.

Proof. This is exactly the abstract argument of Definition 9413.496 applied to the routing space X_∞ and to the defect readout $\Delta(x_s) = \delta$. □

Definition 9413.532 (Construction frontier)**.** *The* construction frontier *for the oriented triadic closure tower is the pair*

$$\mathsf{ActiveCapture} \quad \textit{and} \quad \mathsf{BoundaryStability}.$$

Active capture asks for a canonical dominant endpoint packet associated to each completed zero. Boundary stability asks for a Lee–Yang, unitary, solenoid-compactness, or equivalent bound for that same packet. The Euler-log solenoid bridge and routing closure are additional source obligations, but the analytic difficulty concentrates in these two rows.

Corollary 9413.533 (The construction target is not the zero statement)**.** *Constructing* $\mathfrak{T}_s$ *is stronger data than naming the fixed-half surface and weaker than an unconditional RH theorem.*

Proof. The tower includes source data: finite routing tables, phase containers, prime-register fibres, active endpoint capture, and a stability bound. None of these is implied by writing $\Re(s) = 1/2$. Conversely, the tower is introduced as a conditional certificate: until the construction rows are supplied for every completed zero, it remains a proof target rather than an unconditional theorem. □

9413.40 Harmonic Triadic Closure Map

The frequency, chord, solenoid, winding, Rouché, Lee–Yang, and dominance routes are not separate replacements for the RH-facing boundary problem. They occupy different rows of one harmonic triadic closure map. Prime logarithms supply the frequency ledger, phase evolution supplies resonance closure, winding supplies integer local degree, active capture ties a finite packet to an actual zero, and a unit-boundary row forbids an additional real positive scale.

Definition 9413.534 (Harmonic triadic closure packet)**.** *For a critical-strip coordinate*

$$s = \frac{1}{2} + \delta + i\tau,$$

a harmonic triadic closure packet *is a zero-relevant packet*

$$\mathfrak{H}_s := (A_n, h_a, U_a, \mathsf{F}, \mathsf{W}, \mathsf{C}, \mathsf{B})$$

with finite active windows A_n*, positive Hamiltonian heights* $h_a > 0$*, local channels*

$$U_a(s) := e^{-(s-1/2)h_a},$$

and four certificate rows:

$$\mathsf{F} = \mathsf{FrequencyUniqueness}, \qquad \mathsf{W} = \mathsf{IntegerWinding},$$

$$\mathsf{C} = \mathsf{ActiveCapture}, \qquad \mathsf{B} = \mathsf{UnitBoundaryStability}.$$

The rows mean respectively that the displayed frequencies have an auditable prime ledger, the local zero count is an integer winding or local degree, the packet captures the completed zero rather than a spurious finite silence, and the same packet carries a unitary, Lee–Yang, compact-solenoid, or equivalent normal-scale bound.

Definition 9413.535 (Harmonic off-boundary defect)**.** *For a finite active window A_n, the* harmonic off-boundary defect *is*

$$\Omega_{A_n}(s) := (\log |U_a(s)|)_{a \in A_n}.$$

The square weight of the same window is

$$W_{A_n} := \sum_{a \in A_n} h_a^2.$$

Theorem 9413.536 (Harmonic defect reads the normal coordinate)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

every harmonic active window satisfies

$$\Omega_{A_n}(s) = (-\delta h_a)_{a \in A_n},$$

and hence

$$|\Omega_{A_n}(s)|^2 = \delta^2 W_{A_n}.$$

Proof. Since

$$e^{-(s-1/2)h_a} = e^{-\delta h_a} e^{-i\tau h_a},$$

the logarithmic modulus of the local channel is $-\delta h_a$. Squaring and summing over A_n gives the displayed energy identity. □

Definition 9413.537 (Three integer rows)**.** *The harmonic packet separates three integer rows:*

$$\mathsf{PrimeExponentInteger}, \qquad \mathsf{LocalWindingInteger}, \qquad \mathsf{HalfPeriodInteger}.$$

The first is the unique prime-exponent ledger in an integer factorization. The second is the zero multiplicity or local mapping degree read by the argument principle. The third is the half-period index in a two-arm interference packet, where a local cancellation row has phase

$$\arg(A/B) = (2k-1)\pi.$$

These integer rows certify discrete closure data. They do not by themselves certify the unit boundary for the real positive factor $e^{-\delta h_a}$.

Lemma 9413.538 (Integer winding does not remove real scale)**.** *The existence of an integer winding row for a packet does not imply*

$$|U_a(s)| = 1$$

for its active channels.

Proof. The winding row is a statement about the local degree of the projected complex map. For a zero of order m, the argument of the projected function changes by $2\pi m$ around a small boundary loop. The local channel, however, still factors as

$$U_a(s) = e^{-\delta h_a} e^{-i\tau h_a}.$$

The integer m constrains the projected phase ledger. It does not force the real positive factor $e^{-\delta h_a}$ to equal 1. That constraint belongs to the unit-boundary row. □

Theorem 9413.539 (Prime harmonic levels are ledger-separated)**.** *For prime-adic parity nodes*

$$a = (p, j), \qquad b = (q, k),$$

with heights

$$h_a = 2^j \log p, \qquad h_b = 2^k \log q,$$

equality $h_a = h_b$ implies $a = b$.

Proof. This is exactly Definition 9413.737. The case $p = q$ reduces to $2^j = 2^k$. The case $p \neq q$ would give a nontrivial rational linear relation among $\log p$ and $\log q$, contradicting the unique-factorization consequence recorded in Definition 9413.677. □

Definition 9413.540 (Proof roles in the harmonic map)**.** *The harmonic closure map assigns the standard analytic and arithmetic tools to the following proof roles:*

Fourier and spectral decomposition $\rightsquigarrow$ frequency expansion,
unique factorization $\rightsquigarrow$ prime ledger separation,
Kronecker–Weyl and Dirichlet approximation $\rightsquigarrow$ finite phase recurrence,
pigeonhole $\rightsquigarrow$ finite projection collision,
argument principle $\rightsquigarrow$ integer winding,
Rouché $\rightsquigarrow$ active zero capture,
Lee–Yang, BKW, and dominance $\rightsquigarrow$ unit-boundary stability,
Pontryagin duality and solenoids $\rightsquigarrow$ compact phase and prime-register fibre,
Chebotarev and split-prime towers $\rightsquigarrow$ cofinal active growth.

No single row substitutes for the others. In particular, winding and Rouché certify capture, while Lee–Yang or dominance supplies the normal-scale obstruction.

Theorem 9413.541 (Harmonic triadic closure is conditionally sufficient)**.** *Suppose every completed critical-strip zero carries a harmonic triadic closure packet whose active windows satisfy cofinal growth*

$$W_{A_n} \to \infty$$

and whose unit-boundary stability row gives a finite normal-energy bound

$$|\Omega_{A_n}(s)|^2 \leq B_s$$

for all displayed windows. Then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

The harmonic packet attached to z satisfies

$$|\Omega_{A_n}(s)|^2 = \delta^2 W_{A_n}$$

by Definition 9413.536. If $\delta \# 0$, cofinal growth gives

$$|\Omega_{A_n}(s)|^2 \to \infty,$$

contradicting the finite bound supplied by the unit-boundary stability row. Hence $\neg(\delta \# 0)$. Located fixed-half collapse gives $\delta = 0$, and the RH fixed-half section follows through Definition 9413.199. □

Corollary 9413.542 (Capture rows and boundary rows have distinct jobs)**.** *Argument-principle and Rouché rows can certify that a local packet counts the completed zero, but they do not by themselves exclude the factor $e^{-\delta h_a}$. Lee–Yang, BKW, compact solenoid, unitary, or dominance rows are the candidates for excluding that real positive scale.*

Proof. Definition 9413.538 separates integer winding from the modulus condition. Rouché stability preserves zero counts under a boundary inequality; it is an active-capture row. The contradiction in Definition 9413.541 uses the separate finite-energy or unit-boundary bound. Thus capture and boundary stability are independent proof roles. □

Corollary 9413.543 (Solenoid fibres do not carry the real scale row)**.** *A solenoid row can carry visible phase and hidden prime-register data, but a nontrivial real positive scale*

$$e^{-\delta h_a}$$

is not a solenoid fibre coordinate.

Proof. The solenoid row is compact and phase-like. By Definition 9413.781, a compact phase carrier has no nontrivial continuous character into $\mathsf{Real}^{\uparrow}_{>0}$. Therefore the factor $e^{-\delta h_a}$ must be killed by the boundary row, not stored as hidden solenoid data. □

9413.41 Zero-Knowledge Triadic Certificate Layer

The zero-knowledge proof idea enters this route only as a certificate wrapper. It is not an RH proof and it is not a substitute for the zeta-specific source theorems. Its role is to separate public verification from full disclosure of the prime-routing table, zero ordering, solenoid fibre data, and resonance selector choices. The public surface checks finite consistency, active capture, defect extraction, cofinal growth, and unit-boundary stability; the hidden witness contains the detailed tower data.

Definition 9413.544 (Triadic witness for a completed zero)**.** *For a critical-strip coordinate*

$$s = \frac{1}{2} + \delta + i\tau,$$

a triadic witness *for s is a packet*

$$\mathcal{W}_s := (D_n, F_n, T_n, X_n, \mathcal{R}_n, \pi_{n+1,n}, S_n, \Sigma_{S_n}, A_n, h_a, \Omega_n, W_n, B_s)_n$$

equipped with the following rows:

$$\mathsf{ActiveCapture}, \qquad \mathsf{RoutingCompatibility}, \qquad \mathsf{SolenoidCompatibility},$$

$$\mathsf{TriadicClosure}, \qquad \mathsf{DefectExtraction}, \qquad \mathsf{CofinalGrowth}, \qquad \mathsf{BoundaryStability}.$$

The packet is allowed to contain detailed finite routing tables and selector data. The public verifier consumes only the displayed rows and does not require the full inverse-limit routing table as public data.

Definition 9413.545 (Public triadic verifier)**.** *The* public triadic verifier *is the relation*

$$\mathsf{VerifyTriadic}(s, \mathcal{W}_s) = 1$$

which checks the following finite-layer obligations:

$$\mathsf{RoucheCapture}(D_n, F_n, T_n), \qquad \mathsf{Permutation}(\mathcal{R}_n),$$

$$\pi_{n+1,n} \circ \mathcal{R}_{n+1} = \mathcal{R}_n \circ \pi_{n+1,n},$$

$$\mathsf{SolenoidPhaseCarrier}(\Sigma_{S_n}), \qquad \mathsf{TriadicTwoOutOfThree},$$

$$\Omega_n(s) = (-\delta h_a)_{a \in A_n}, \qquad W_n = \sum_{a \in A_n} h_a^2,$$

and the paired growth and bound rows

$$W_n \to \infty, \qquad |\Omega_n(s)|^2 \le B_s < \infty.$$

Here RoucheCapture *may be replaced by any equivalent local-degree or winding capture row that proves the finite packet counts the completed zero.*

Definition 9413.546 (Completeness, soundness, and opacity readings)**.** *The certificate layer has three proof-system readings.* Completeness *means that a genuine zero-relevant source packet can be presented as a witness accepted by* VerifyTriadic*.* Soundness *means that acceptance implies the fixed-half row.* Opacity *means that the verifier need not receive the full routing table, the full zero ordering, or the full selector ledger as public data. No cryptographic commitment scheme is asserted here; the point is the mathematical separation between hidden witness data and public finite checks.*

Theorem 9413.547 (Public triadic verification is sound for the fixed-half row)**.** *If*

$$\mathsf{VerifyTriadic}(s, \mathcal{W}_s) = 1$$

for

$$s = \frac{1}{2} + \delta + i\tau,$$

then

$$\delta = 0.$$

Proof. The verifier accepts only when the defect extraction row gives

$$\Omega_n(s) = (-\delta h_a)_{a \in A_n}$$

and hence

$$|\Omega_n(s)|^2 = \delta^2 W_n.$$

It also accepts only when $W_n \to \infty$ and

$$|\Omega_n(s)|^2 \leq B_s < \infty$$

for the same displayed windows. If $\delta \# 0$, then $\delta^2 W_n \to \infty$, contradicting the finite bound. Hence $\neg(\delta \# 0)$. Located fixed-half collapse gives $\delta = 0$. □

Corollary 9413.548 (Verified triadic witnesses are conditionally sufficient)**.** *If every completed critical-strip zero has a triadic witness accepted by the public triadic verifier, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have coordinate s. By hypothesis, there is a witness $\mathcal{W}_s$ with

$$\mathsf{VerifyTriadic}(s, \mathcal{W}_s) = 1.$$

By Definition 9413.547, the coordinate has $\delta = 0$, hence $\Re(s) = 1/2$. The fixed-half section is therefore obtained through Definition 9413.199. □

Definition 9413.549 (Hidden prime-collision row)**.** *For a finite prime ledger $L_n \subset \mathbb{Z}^{(S_n)}$, a* hidden prime-collision row *consists of hidden rows*

$$x_n, y_n \in L_n, \qquad x_n \neq y_n, \qquad \pi_n(x_n) = \pi_n(y_n),$$

together with the frequency functional

$$H(x) := \sum_{p \in S_n} x_p \log p.$$

The row is valid only when the gap

$$g_n := x_n - y_n$$

satisfies

$$H(g_n) \neq 0.$$

The verifier may consume the equality and non-equality obligations as committed finite rows without exposing the full ledger pair as public data.

Lemma 9413.550 (Prime collisions expose a nonzero frequency gap)**.** *In a hidden prime-collision row, the condition $x_n \neq y_n$ forces*

$$H(x_n - y_n) \neq 0.$$

Proof. If $H(x_n - y_n) = 0$, then

$$\sum_{p \in S_n} (x_{n,p} - y_{n,p}) \log p = 0.$$

This is a rational, indeed integral, linear relation among the displayed prime logarithms. By Definition 9413.677, all coefficients vanish, so $x_n = y_n$, contradicting the collision apartness row. □

Theorem 9413.551 (Hidden collision plus unit boundary kills real scale)**.** *Let a hidden prime-collision row provide a gap g_n with $H(g_n) \neq 0$. For*

$$s = \frac{1}{2} + \delta + i\tau,$$

the channel ratio

$$R_{g_n}(s) := e^{-(s-1/2)H(g_n)}$$

satisfies

$$|R_{g_n}(s)| = e^{-\delta H(g_n)}.$$

If the unit-boundary row gives $|R_{g_n}(s)| = 1$, then $\delta = 0$.

Proof. The displayed factorization gives

$$R_{g_n}(s) = e^{-\delta H(g_n)} e^{-i\tau H(g_n)}.$$

Taking moduli yields the first formula. If the unit-boundary row gives $|R_{g_n}(s)| = 1$, then

$$e^{-\delta H(g_n)} = 1.$$

Taking logarithms in the positive real readout gives

$$-\delta H(g_n) = 0.$$

Since $H(g_n) \neq 0$, it follows that $\delta = 0$. □

Corollary 9413.552 (The zero-knowledge layer does not create the witness)**.** *The certificate layer packages the route; it does not discharge* ActiveCapture *or* BoundaryStability*.*

Proof. Definition 9413.547 uses the rows accepted by the verifier. It does not construct the Rouché island, the dominant resonance family, the solenoid-compatible phase carrier, or the Lee–Yang-type bound. Those remain source rows in the sense of Definition 9413.801. Thus the zero-knowledge layer is a certificate wrapper around source data, not a source theorem. □

9413.42 Analytic Projection and Closed Generability Boundary

The analytic continuation row must be separated from the closed generation row. Analytic continuation recovers a projected analytic object; it does not, by itself, certify that every analytic feature of that projection is generated by the closed triadic dynamics used in the RH-facing route. The distinction is between projected analytic existence and closed-system realizability.

Definition 9413.553 (Analytic projection carrier)**.** *The* analytic projection carrier *for zeta is the carrier*

$$\mathcal{A}_\zeta$$

whose rows are the analytic readouts produced by the Dirichlet-series domain, Euler-product readout on its convergence side, Mellin or contour representations, analytic continuation, pole ledger, functional equation, and completed value projection. A row in $\mathcal{A}_\zeta$ is therefore a projection-side analytic datum. It is licensed as an analytic object, not automatically as a closed dynamical state.

Definition 9413.554 (Closed generability carrier)**.** *The* closed generability carrier *is the subcarrier*

$$\mathcal{G}_\zeta \subseteq \mathcal{A}_\zeta$$

consisting of analytic projection rows which also carry a closed triadic generation certificate. Such a certificate displays:

$$\mathsf{ActiveCapture}, \qquad \mathsf{CompactPhaseOrSolenoidFibre}, \qquad \mathsf{RoutingCompatibility},$$

$$\mathsf{TriadicClosure}, \qquad \mathsf{DefectExtraction}, \qquad \mathsf{BoundaryStability}.$$

Thus $\mathcal{G}_\zeta$ records the analytic rows which are not merely visible in the completed projection, but are generated through finite packets, compatible routing, legal hidden fibres, and unit-boundary stability.

Principle 9413.555 (Analytic continuation is not generability)**.** *Membership in $\mathcal{A}_\zeta$ does not imply membership in $\mathcal{G}_\zeta$. Analytic continuation supplies the projected analytic object and its uniqueness in the analytic category. Closed generability requires additional source rows: zero-relevant packet capture, compatible finite routing, compact phase or solenoid fibre placement, and a unit-boundary or energy-stability certificate.*

Definition 9413.556 (Non-generable analytic residue)**.** *A row $x \in \mathcal{A}_\zeta$ has a* non-generable analytic residue *when it requires at least one of the following data without a closed certificate:*

a nontrivial real positive scale $e^{-\delta h}$,

a hidden coordinate outside compact phase or prime-register fibre,

a projected zero with no active Rouché or local-degree capture,

a finite routing table with no inverse-limit compatibility,

or

a zero-relevant packet with no unit-boundary stability row.

Such a row may still belong to the analytic projection carrier. The point is only that it has not been shown to belong to the closed generability carrier.

Theorem 9413.557 (Real positive scale is not a closed compact residue)**.** *Let a closed generability certificate for a local channel use only unitary phase and compact solenoid prime-register fibres for its hidden coordinates. For*

$$s = \frac{1}{2} + \delta + i\tau, \qquad U_a(s) = e^{-(s-1/2)h_a}, \qquad h_a > 0,$$

the factor

$$e^{-\delta h_a}$$

can be supplied by that compact hidden carrier only when $\delta = 0$.

Proof. The local channel factors as

$$U_a(s) = e^{-\delta h_a} e^{-i\tau h_a}.$$

The phase factor belongs to the unit-circle readout. A compact solenoid fibre can record compact prime-register data, but by Definition 9413.781 it has no nontrivial continuous character into $\mathsf{Real}^{\uparrow}_{>0}$. Hence the real positive factor must be trivial:

$$e^{-\delta h_a} = 1.$$

Since $h_a > 0$, this gives $\delta = 0$. □

Definition 9413.558 (Zeta zero generability row)**.** *The* zeta zero generability row *is the source assertion*

$$\mathsf{ZetaZeroGenerability}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to s \in \mathcal{G}_\zeta)\,.$$

It says that every critical-strip zero of the completed zeta projection has a closed triadic generation certificate. It is not supplied by analytic continuation alone.

Definition 9413.559 (Closed triadic no-real-scale row)**.** *The* closed triadic no-real-scale row *is the assertion*

$$\prod_{s:\mathsf{Complex}^\uparrow} \left(s \in \mathcal{G}_\zeta \to \Re(s) = \frac{1}{2}\right),$$

with the implication witnessed by defect extraction, cofinal growth, and unit-boundary or compact-solenoid stability for the same zero-relevant packet.

Theorem 9413.560 (Generability and no-real-scale rows are conditionally sufficient)**.** *If*

$$\mathsf{ZetaZeroGenerability}_\zeta$$

and the closed triadic no-real-scale row both hold, then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have coordinate s. The zero generability row gives

$$s \in \mathcal{G}_\zeta.$$

The no-real-scale row then gives

$$\Re(s) = \frac{1}{2}.$$

Varying z gives the fixed-half section, equivalently the RH section identified by Definition 9413.199. □

Corollary 9413.561 (The hard source row is generability)**.** *For the analytic-projection route, the hard source row is not the exclusion of real scale inside an already closed packet. It is the construction of a closed packet for each completed zero:*

$$\mathsf{ZetaZeroGenerability}_\zeta.$$

Proof. Once a zero row is in $\mathcal{G}_\zeta$, the compact hidden-fibre argument of Definition 9413.557 or the energy-bound argument of Definition 9413.547 excludes an off-half real scale. What those arguments do not supply is membership in $\mathcal{G}_\zeta$. That membership requires active capture, dominance or tail control, compatible routing, solenoid placement, and boundary stability. This is the same source load isolated in Definition 9413.803. □

Corollary 9413.562 (Projection existence and generability remain separate)**.** *The existence of the analytic continuation of zeta, including its completed functional-equation projection, does not discharge the generability row.*

Proof. The analytic continuation theorem places the completed zeta readout in $\mathcal{A}_\zeta$. By Definition 9413.555, membership in $\mathcal{A}_\zeta$ does not provide the finite packet, routing, solenoid, capture, and boundary rows required for $\mathcal{G}_\zeta$. Therefore the generability row is an additional source theorem, not a consequence of analytic continuation as such. □

9413.43 Oriented Triadic Certificate System

The oriented tower construction can be read as a certificate system. It does not assert the unconditional RH statement. It records the precise conditional form: a completed critical-strip zero placed inside a closed oriented triadic tower has no admissible real positive scale direction. The mathematical burden is therefore the construction of the certificate for every completed zero, not the downstream energy contradiction.

Definition 9413.563 (Ontic triadic rows)**.** *The* ontic triadic rows *are*

$$\Omega_{\mathrm{tri}} := (\mathsf{P}, \mathsf{U}, \mathsf{T}),$$

where P *is the prime-register or discrete-label row,* U *is the unit-boundary, parity, compactness, or Lee–Yang row, and* T *is the phase-time or recursive-routing row. A closed triadic packet carries a closure relation*

$$\mathcal{C}(\mathsf{P}, \mathsf{U}, \mathsf{T}) = 0$$

up to legal gauge. Legal gauge may come from the unit phase circle or from prime-adic register fibres. A nontrivial real positive scale is not a legal gauge row.

Definition 9413.564 (Prime ledger and logarithmic height)**.** *The* prime ledger *is the free finite-support integer register*

$$\mathcal{L}_{\mathsf{Prime}^{\uparrow}} := \bigoplus_{p \in \mathsf{Prime}^{\uparrow}} \mathbb{Z} e_p.$$

For a positive integer

$$n = \prod_p p^{v_p(n)},$$

the ledger row is

$$\nu(n) := \sum_p v_p(n) e_p,$$

and the logarithmic height row is

$$H(n) := \log n = \sum_p v_p(n) \log p.$$

More generally a finite ledger vector

$$x = \sum_p x_p e_p$$

has height

$$H(x) := \sum_p x_p \log p.$$

Lemma 9413.565 (Prime ledger height is separated)**.** *For a finite ledger vector* $x \in \mathcal{L}_{\mathsf{Prime}^{\uparrow}}$*,*

$$H(x) = 0 \quad \Longrightarrow \quad x = 0.$$

Proof. Write

$$x = \sum_{i=1}^{m} x_{p_i} e_{p_i}.$$

If $H(x) = 0$, then

$$\sum_{i=1}^{m} x_{p_i} \log p_i = 0.$$

Exponentiating gives

$$\prod_{i=1}^{m} p_i^{x_{p_i}} = 1.$$

By unique factorization, every exponent x_{p_i} is zero. Hence $x = 0$. □

Definition 9413.566 (Ontic logarithmic Hamiltonian)**.** *The* ontic logarithmic Hamiltonian *on the integer basis is the diagonal readout*

$$H_{\mathrm{ont}}|n\rangle = (\log n)|n\rangle$$

with domain

$$\mathrm{Dom}(H_{\mathrm{ont}}) := \left\{ \psi = (\psi_n) \in \ell^2(\mathsf{Nat}^{\uparrow}_{\geq 1}) : \sum_{n\geq 1} (\log n)^2 |\psi_n|^2 < \infty \right\}.$$

Its unitary phase evolution row is

$$U(\gamma) = e^{-i\gamma H_{\mathrm{ont}}}.$$

This Hamiltonian row is a spectral readout for the logarithmic height, not a primitive physical postulate.

Definition 9413.567 (Oriented triadic certificate)**.** *For a critical-strip coordinate*

$$s_0 = \frac{1}{2} + \delta + i\tau,$$

an oriented triadic certificate *over s_0 is a finite-window tower*

$$\mathcal{W}_{s_0} := (F_n, T_n, D_n, A_n, S_n, \Sigma_{S_n}, X_n, \mathcal{R}_n, \pi_{n+1,n}, \Omega_n, W_n, B_{s_0})_n$$

whose rows are:

$$\mathsf{ActiveCapture}, \quad \mathsf{EulerLogSolenoidBridge}, \quad \mathsf{FiniteTriadicClosure},$$

$$\mathsf{DefectExtraction}, \quad \mathsf{CofinalGrowth}, \quad \mathsf{IndependentBoundaryStability}.$$

The certificate is the fully displayed form of Definition 9413.528. It keeps source data, compatibility data, and boundary data in the same packet.

Definition 9413.568 (Certificate row meanings)**.** *The six certificate rows mean the following. The active-capture row supplies a zero island D_n with*

$$\Xi = F_n + T_n, \qquad |T_n| < |F_n| \quad \text{on } \partial D_n,$$

or an equivalent local-degree capture row. The Euler-log solenoid bridge places the visible Euler-log phase and the prime-register fibre in one phase carrier. The finite triadic closure row closes $(\mathsf{P}, \mathsf{U}, \mathsf{T})$ *modulo legal prime-adic gauge. The defect-extraction row gives*

$$\Omega_n(s_0) = (-\delta h_a)_{a\in A_n}$$

for positive heights $h_a > 0$. The cofinal-growth row gives

$$W_n := \sum_{a \in A_n} h_a^2 \to \infty.$$

The independent-boundary-stability row gives a finite constant

$$B_{s_0} < \infty$$

with

$$|\Omega_n(s_0)|^2 \le B_{s_0}$$

for the same zero-relevant tower.

Proposition 9413.569 (Defect extraction gives square energy)**.** *For an oriented triadic certificate and*

$$s_0 = \frac{1}{2} + \delta + i\tau,$$

the defect row gives

$$|\Omega_n(s_0)|^2 = \delta^2 W_n.$$

Proof. For every active node $a \in A_n$, the local channel is

$$U_a(s_0) = e^{-(s_0 - 1/2)h_a} = e^{-\delta h_a} e^{-i\tau h_a}.$$

Thus

$$\log |U_a(s_0)| = -\delta h_a.$$

By definition,

$$|\Omega_n(s_0)|^2 = \sum_{a \in A_n} (-\delta h_a)^2 = \delta^2 \sum_{a \in A_n} h_a^2 = \delta^2 W_n.$$

□

Proposition 9413.570 (Parity oddness of the normal defect)**.** *For the mirror involution*

$$J(s) = 1 - \overline{s},$$

if $s = 1/2 + \delta + i\tau$, then $J(s) = 1/2 - \delta + i\tau$ and every active node satisfies

$$d_a(Js) = -d_a(s).$$

Proof. The mirror computation gives

$$J\left(\frac{1}{2} + \delta + i\tau\right) = 1 - \left(\frac{1}{2} + \delta - i\tau\right) = \frac{1}{2} - \delta + i\tau.$$

Since $d_a(s) = -\delta h_a$, replacing δ by $-\delta$ gives $d_a(Js) = \delta h_a = -d_a(s)$. □

Proposition 9413.571 (Active capture preserves the zero count)**.** *If the active-capture row holds on a zero island D_n, then F_n and Ξ have the same number of zeros in D_n, counted with multiplicity.*

Proof. The capture row gives

$$\Xi = F_n + T_n$$

and

$$|T_n| < |F_n| \quad \text{on } \partial D_n.$$

By Rouché's theorem, F_n and $F_n + T_n = \Xi$ have the same zero count inside D_n, counted with multiplicity. □

Proposition 9413.572 (A split-prime tower is a cofinal-growth template)**.** *Let q be a rational prime and let (K_n) be a family of number fields with*

$$[K_n : \mathbb{Q}] \to \infty.$$

If q splits completely in K_n as

$$q\mathcal{O}_{K_n} = \mathfrak{q}_{n,1} \cdots \mathfrak{q}_{n,d_n}, \qquad d_n = [K_n : \mathbb{Q}],$$

and each split-prime node has height $\log q$, then the associated square weight satisfies

$$W_n = d_n(\log q)^2 \to \infty.$$

Proof. There are d_n displayed split-prime nodes, each with height $\log q$. Therefore

$$W_n = \sum_{i=1}^{d_n} (\log q)^2 = d_n(\log q)^2.$$

Since $d_n \to \infty$ and $\log q > 0$, the weights are cofinal. □

Theorem 9413.573 (An oriented triadic certificate forces the fixed-half row)**.** *If a critical-strip zero coordinate*

$$s_0 = \frac{1}{2} + \delta + i\tau$$

has an oriented triadic certificate, then

$$\delta = 0.$$

Proof. By Definition 9413.569, the certificate gives

$$|\Omega_n(s_0)|^2 = \delta^2 W_n.$$

Assume $\delta \# 0$. Then $\delta^2 > 0$, and the cofinal-growth row $W_n \to \infty$ gives

$$|\Omega_n(s_0)|^2 \to \infty.$$

This contradicts independent boundary stability,

$$|\Omega_n(s_0)|^2 \leq B_{s_0} < \infty.$$

Hence $\neg(\delta \# 0)$. Located fixed-half collapse gives $\delta = 0$. □

Corollary 9413.574 (Certificate existence is conditionally sufficient)**.** *If every completed critical-strip zeta zero has an oriented triadic certificate, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

By hypothesis, s has an oriented triadic certificate. By Definition 9413.573, we have $\delta = 0$, so $\Re(s) = 1/2$. Varying z gives the fixed-half section, equivalently the RH section of Definition 9413.199. □

Corollary 9413.575 (Off-half zeros are not closed-triadic generated)**.** *If*

$$s = \frac{1}{2} + \delta + i\tau$$

is a critical-strip zero coordinate with $\delta\#0$, then s cannot carry an oriented triadic certificate satisfying cofinal growth and independent boundary stability.

Proof. If such a certificate existed, then Definition 9413.573 would give $\delta = 0$, contradicting $\delta\#0$. □

Definition 9413.576 (Source obligations for the certificate route)**.** *The remaining source obligations for the oriented certificate route are:*

CanonicalActiveCapture, EulerLogSolenoidBridge, FiniteTriadicClosure,

DefectExtraction, ActiveCofinalGrowth, IndependentBoundaryStability.

The defect-extraction row is the direct calculation of Definition 9413.569. The other rows are source theorems: they must be proved for the same zero-relevant tower and may not be inferred merely from the zero predicate.

Theorem 9413.577 (The source obligations are the noncircular content)**.** *The conditional implication from an oriented triadic certificate to the fixed-half row does not discharge the source obligations of Definition 9413.576.*

Proof. The implication uses the certificate rows after they have been supplied. It consumes active capture to ensure zero relevance, cofinal growth to make an off-half defect unbounded, and independent boundary stability to bound the same defect. It does not construct the active endpoint packet, the Euler-log solenoid bridge, the finite triadic closure law, the active growth tower, or the Lee–Yang, unitary, cosine, or dominance stability input. Therefore the proof is noncircular exactly when these rows are proved independently as source data, as also isolated in Definition 9413.561. □

9413.44 Triadic Route Taxonomy

The preceding certificate systems can be compressed into three conditional routes. Each route is a sufficient row for the RH fixed-half section, and none is an unconditional proof until its source predicate has been constructed from the completed zeta zero ledger. The taxonomy prevents the route from oscillating between equivalent surface names: ghost exclusion, stable packet capture, and triadic closure are distinct ways of naming the missing source theorem.

Definition 9413.578 (Closed-generatable zero)**.** *A critical-strip zero coordinate s is* closed-generatable *when it belongs to the closed generability carrier*

$$s \in \mathcal{G}_\zeta$$

of Definition 9413.554. Equivalently, it has a zero-relevant packet with active capture, legal solenoid or prime-register hidden fibre, finite routing compatibility, unit-boundary stability, and no noncompact real positive gauge. Write this row as

$$\mathsf{ClosedGeneratable}_\zeta(s).$$

Definition 9413.579 (No ghost zeta zero row)**.** *The* no ghost zeta zero row *is*

$$\mathsf{NoGhostZetaZero}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{ClosedGeneratable}_\zeta(s)\right).$$

A ghost zero would be a completed analytic zero row in $\mathcal{A}_\zeta$ which has no closed triadic generation certificate in $\mathcal{G}_\zeta$.

Corollary 9413.580 (No ghost zeros are conditionally sufficient)**.** *If*

$$\mathsf{NoGhostZetaZero}_\zeta$$

holds, then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have coordinate s. The no-ghost row gives $\mathsf{ClosedGeneratable}_\zeta(s)$, hence $s \in \mathcal{G}_\zeta$. By Definition 9413.559 and the compact-scale obstruction of Definition 9413.557, closed generability supplies the fixed-half row. Varying z gives the RH section. □

Definition 9413.581 (Stable packet capture row)**.** *The* stable packet capture row *is the assertion that every critical-strip zero coordinate s has a canonical packet P_s with:*

$$\mathsf{RoucheCapture}(P_s, s), \qquad \mathsf{LeeYangStable}(P_s),$$

$$\mathsf{SolenoidCompatible}(P_s, s), \qquad \mathsf{NondegenerateActiveHeight}(P_s).$$

Write this source predicate as

$$\mathsf{ZetaStablePacketCapture}_\zeta.$$

It is stronger than merely displaying a finite model: the packet must be zero-relevant for the completed zeta row.

Theorem 9413.582 (Stable packet capture is conditionally sufficient)**.** *If*

$$\mathsf{ZetaStablePacketCapture}_\zeta$$

holds, then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

The stable packet capture row supplies a packet P_s which captures the completed zero and is Lee–Yang stable. The local channel has the form

$$u_a(s) = e^{-(s-1/2)h_a} = e^{-\delta h_a} e^{-i\tau h_a}$$

with some active height $h_a > 0$. If $\delta > 0$, then all nearby active channels lie inside the unit boundary; if $\delta < 0$, they lie outside it. Lee–Yang stability excludes packet zeros in those regions, while Rouché capture forces the packet to have the same local zero count as the completed zeta readout. Thus $\delta \# 0$ is impossible. Located fixed-half collapse gives $\delta = 0$, and the RH section follows from Definition 9413.199. □

Definition 9413.583 (Zeta triadic closure tower row)**.** *The* zeta triadic closure tower row *is the assertion that every critical-strip zero coordinate* $s = 1/2 + \delta + i\tau$ *has a packet*

$$x_s \in X_\infty$$

inside an inverse-limit routing carrier such that:

$$\mathsf{ActiveCapture}(x_s, s), \qquad \Delta(x_s) = \delta,$$
$$Px_s \in \overline{\{\mathcal{R}_\infty^m x_s : m \in \mathbb{Z}\}},$$

and the same packet carries solenoid compatibility, finite triadic closure, and either the parity-closure defect row or the cofinal energy-bound row of the oriented certificate system. Write this source predicate as

$$\mathsf{ZetaTriadicClosureTower}_\zeta.$$

Theorem 9413.584 (Triadic closure tower is conditionally sufficient)**.** *If*

$$\mathsf{ZetaTriadicClosureTower}_\zeta$$

holds, then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have coordinate $s = 1/2 + \delta + i\tau$. The triadic closure tower row supplies a packet x_s with

$$\Delta(x_s) = \delta$$

and parity closure

$$Px_s \in \overline{\{\mathcal{R}_\infty^m x_s : m \in \mathbb{Z}\}}.$$

By Definition 9413.496,

$$\Delta(x_s) = 0.$$

Thus $\delta = 0$. The fixed-half section follows through Definition 9413.199. □

Corollary 9413.585 (The three source rows form one proof target)**.** *The following rows are conditionally sufficient for the same fixed-half section:*

$$\mathsf{NoGhostZetaZero}_\zeta, \qquad \mathsf{ZetaStablePacketCapture}_\zeta, \qquad \mathsf{ZetaTriadicClosureTower}_\zeta.$$

They differ in presentation, not in the downstream obstruction: each must construct zero-relevant source data that excludes noncompact real scale.

Proof. The first row places every completed zero in the closed generability carrier. The second supplies the strongest local version: canonical Rouché capture plus Lee–Yang stability and solenoid compatibility. The third supplies the routing version: a parity-closed inverse-limit packet or an energy-bounded oriented certificate. The conditional implications are the preceding two theorems and Definition 9413.580. In each case, the unproved content is source construction, not the fixed-half algebra performed after the source data are available. □

Corollary 9413.586 (Stable packet capture is the sharpest local target)**.** *Among the three rows,* $\mathsf{ZetaStablePacketCapture}_\zeta$ *is the sharpest local analytic target.*

Proof. No-ghost exclusion is a global generability statement. The triadic closure tower is a routing and parity statement over an inverse-limit carrier. Stable packet capture names the local analytic object whose construction would feed both: a canonical zero island, Rouché capture, Lee–Yang stability, solenoid compatibility, and nondegenerate active height. Thus it is the local source theorem at which the route should concentrate before the global closure language is invoked. □

9413.45 BEDC RHRoute Formal Bridge

The preceding taxonomy identifies the analytic source theorem that would feed the RH fixed-half section. The Lean-side RHRoute layer should be read in the same way: it supplies a finite formal route discipline and several checked algebraic carriers, but it does not by itself construct the zeta-specific source family for every completed critical-strip zero. The bridge point is therefore not the fixed-half conclusion itself, but the map from completed zero rows to zero-relevant finite certificates.

Definition 9413.587 (RHRoute formal layer)**.** *The* RHRoute formal layer *is the collection of finite BEDC carriers that record:*

$$\mathsf{ConstructiveZetaEval}, \quad \mathsf{MirrorFixedAlgebra}, \quad \mathsf{FinitePrimeWindow},$$

$$\mathsf{PrimeSkewDefect}, \quad \mathsf{LocalGlobalExclusion}, \quad \mathsf{RouteClosureSeparation}.$$

The first row gives rational-complex evaluation packets for the eta-to-zeta readout. The mirror row proves the finite algebraic equivalence between J-fixedness and the critical-line readout. The prime-window rows record finite prime supports, unitary-balance packets, and skew-defect certificates. The route-separation row records that a finite route closure certificate is not uniformly the same thing as an arbitrary fixed statement.

Definition 9413.588 (Formal bridge packet)**.** *For a critical-strip zero coordinate s, an* RHRoute formal bridge packet *consists of:*

$$\mathsf{CritZero}(s), \quad \mathsf{EvalPacket}(s), \quad \mathsf{MirrorOrbit}(s),$$

$$\mathsf{PrimeWindowSource}(s), \quad \mathsf{SkewOrUnitaryBoundary}(s), \quad \mathsf{RouteSeparationAudit}(s).$$

The packet is a formal carrier for the downstream proof route. It is not yet a source theorem unless the prime-window source is produced from the completed zero ledger by active capture, dominance, tail control, and solenoid or Lee–Yang stability.

Definition 9413.589 (RHRoute source bridge)**.** *The* RHRoute source bridge *is the zeta-specific row*

$$\mathsf{RHRouteSourceBridge}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{CritZero}(s) \to \sum_{P:\mathsf{RHRouteFormalBridgePacket}(s)} \mathsf{ZeroRelevant}(P, s) \right).$$

Here $\mathsf{ZeroRelevant}(P, s)$ *means that the finite prime-window or resonance data in P controls a local zero island of the completed zeta readout, rather than merely displaying a visible defect or a compatible finite route.*

Theorem 9413.590 (The formal layer is not the source bridge)**.** *The RHRoute formal layer does not by itself imply*

$$\mathsf{RHRouteSourceBridge}_\zeta.$$

Proof. The formal layer contains finite algebraic and route-theoretic carriers: evaluation packets, mirror-fixed readbacks, prime-window supports, unitary-balance surfaces, skew-defect certificates, and finite route closure decisions. Each of these is a legal finite BEDC object. However, none of them asserts that every completed critical-strip zero has a zero-relevant dominant source packet. In particular, route closure and fixed-statement transport are separated by the route separation row: a closed finite route is not a uniform proof of an arbitrary fixed statement, and a fixed statement is not uniformly a finite route closure certificate. Therefore the missing row is still the source bridge from the zero ledger to zero-relevant finite data. □

Definition 9413.591 (BEDC RHRoute certificate)**.** *A* BEDC RHRoute certificate *for s is an RHRoute formal bridge packet P together with the following additional rows:*

$$\mathsf{ActiveCapture}(P,s), \qquad \mathsf{DominantSource}(P,s), \qquad \mathsf{BoundaryStability}(P,s),$$

$$\mathsf{DefectExtraction}(P,s), \qquad \mathsf{FixedHalfReadback}(P,s).$$

Active capture and dominance make P zero-relevant for the completed zeta readout. Boundary stability prevents the packet from carrying a noncompact real scale. Defect extraction identifies the normal coordinate read by the prime-window or resonance channel. Fixed-half readback transports the resulting J-fixed row to $\mathsf{OnCritLine}(s)$.

Theorem 9413.592 (BEDC RHRoute certificates are sufficient)**.** *If every completed critical-strip zero carries a BEDC RHRoute certificate, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have coordinate s. By hypothesis, s carries a BEDC RHRoute certificate P. The active-capture and dominance rows say that P is zero-relevant for the completed zeta readout. The defect-extraction row reads the normal coordinate

$$\delta(s) = \Re(s) - \frac{1}{2}$$

through the finite prime-window or resonance channel. The boundary stability row excludes a nonzero value of that normal coordinate on a zero-relevant packet; otherwise the same packet would carry a visible prime skew or an unbounded normal energy incompatible with the boundary row. Hence $\delta(s) = 0$. The mirror-fixed algebra then reads this as J-fixedness, and the fixed-half readback gives

$$\mathsf{OnCritLine}(s).$$

Varying z gives the fixed-half section. □

Corollary 9413.593 (The remaining theorem is source construction)**.** *The unclosed content of the RHRoute route is the implication*

$$\mathsf{CritZero}(s) \to \sum_{P:\mathsf{RHRouteFormalBridgePacket}(s)} \left(\mathsf{ActiveCapture}(P,s) \times \mathsf{DominantSource}(P,s) \times \mathsf{BoundaryStability}(P,s)\right).$$

Proof. All rows after source construction are structural. Mirror-fixed readback is the algebraic equivalence between J-fixedness and the critical-line coordinate. Prime-window skew and normal-energy rows detect nonzero off-half displacement once a zero-relevant packet has been supplied. Route separation prevents these finite certificates from being confused with the target statement itself. Thus the proof load is the zeta-specific construction of P: active capture, dominance, tail control, and boundary stability for the completed zero ledger. □

Corollary 9413.594 (Compatibility with the triadic route taxonomy)**.** *The RHRoute formal bridge is a finite certificate interface for the same proof target named by the no-ghost, stable-packet, and triadic-closure rows of section 9413.44.*

Proof. The no-ghost row asks that every completed zero enter the closed generability carrier. The stable-packet row asks for a canonical local zero island with Rouché capture and Lee–Yang stability. The triadic-closure row asks for an inverse-limit packet whose parity or energy certificate kills the normal coordinate. An RHRoute certificate is the finite formal interface through which these rows can be audited: it displays the evaluation packet, the mirror algebra, the finite prime-window source, the skew or unitary boundary, and the route separation audit. It therefore refines the taxonomy without replacing the remaining source theorem. □

9413.46 Generation Invariant Exclusion Route

The RHRoute formal bridge may also be read as an invariant argument in the style of a formal word system. The target is not to guess a direct analytic implication from a zero row to the critical line. The target is to display a generation system, identify an invariant subcarrier, prove that every legal rule preserves that subcarrier, and then prove that every completed zero enters the generated carrier through an independent source theorem.

Definition 9413.595 (Invariant generation system)**.** *An* invariant generation system *for a zero carrier is a tuple*

$$\mathfrak{G} := (\Sigma, \mathcal{W}, \mathcal{A}, \mathcal{R}, \mathcal{T}, \mathcal{I})$$

where Σ is a signature, $\mathcal{W}$ is the ambient carrier of legal packets, $\mathcal{A} \subseteq \mathcal{W}$ is the source family, $\mathcal{R}$ is the family of generation rules, $\mathcal{T}$ is the closed carrier generated from $\mathcal{A}$ by $\mathcal{R}$, and

$$\mathcal{I} : \mathcal{W} \to M$$

is an invariant readout. The system is invariant-closed *when every rule in $\mathcal{R}$ preserves $\mathcal{I}$ on its legal input rows.*

Theorem 9413.596 (Invariant exclusion)**.** *Let $\mathfrak{G}$ be invariant-closed. If a target packet w_* has an invariant value not attained by any source packet in $\mathcal{A}$, then*

$$w_* \notin \mathcal{T}.$$

Proof. Every element of $\mathcal{T}$ is obtained from a source packet by a finite chain of generation rules. Since each rule preserves $\mathcal{I}$, the invariant value of a generated packet agrees with the value of some source packet. The stated separation of invariant values therefore prevents w_* from lying in $\mathcal{T}$. □

Definition 9413.597 (Fixed-half invariant for RHRoute packets)**.** *For an RHRoute formal bridge packet P over a critical-strip coordinate s, the* fixed-half invariant *is the normal readout*

$$\mathcal{I}_{\text{half}}(P) := \delta(s) := \Re(s) - \frac{1}{2}.$$

The fixed subcarrier is

$$\mathcal{W}^J := \{P \in \mathcal{W} : \mathcal{I}_{\text{half}}(P) = 0\}.$$

Equivalently, $\mathcal{W}^J$ is the subcarrier on which the mirror readback gives J-fixedness and hence the critical-line row.

Definition 9413.598 (RH-free generation discipline)**.** *A generation discipline for RHRoute packets is* RH-free *when its rules are allowed to use finite prime-window data, mirror transport, classifier transport, analytic gluing, compatible finite-window closure, and route replay, but are not allowed to use $\mathsf{OnCritLine}(s)$ or $\delta(s) = 0$ as an input rule. The purpose of the discipline is to separate a genuine invariant-preservation proof from a hidden insertion of the desired fixed-half output.*

Definition 9413.599 (Fixed-half closed generation)**.** *An RH-free generation discipline is* fixed-half closed *when*

$$P \in \mathcal{W}^J \quad \Longrightarrow \quad R(P) \in \mathcal{W}^J$$

for every legal rule R and every legal input packet P of that rule. For multi-input rules, the condition is that all inputs lie in $\mathcal{W}^J$ and the output lies in $\mathcal{W}^J$. This is the formal invariant row corresponding to fixed-half closure.

Theorem 9413.600 (Fixed-half generation excludes off-half outputs)**.** *Let an RH-free generation discipline be fixed-half closed, and suppose its source packets lie in $\mathcal{W}^J$. Then every generated packet has $\delta = 0$. In particular, no packet with*

$$s = \frac{1}{2} + r + i\gamma, \qquad r\#0,$$

is generated by that discipline.

Proof. Apply Definition 9413.596 with $\mathcal{I} = \mathcal{I}_{\text{half}}$. The source packets have invariant value 0, and every legal rule preserves the fixed subcarrier. Hence every generated packet has normal readout 0. A packet with $r\#0$ has $\mathcal{I}_{\text{half}} = r\#0$, so it cannot be in the generated carrier. □

Definition 9413.601 (Generated-zero coverage row)**.** *The* generated-zero coverage row *for the completed zeta carrier is*

$$\mathsf{GeneratedZeroCoverage}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{CritZero}(s) \to \sum_{P:\mathcal{T}_\zeta} \mathsf{SameZeroReadout}(P, s) \right),$$

where $\mathcal{T}_\zeta$ is the generated RHRoute packet carrier. The row says that every completed critical-strip zero is covered by a generated packet with the same zero readout. It is the invariant-system form of active capture and zero presentation completeness.

Theorem 9413.602 (Generation coverage and fixed-half closure are sufficient)**.** *Assume:*

$$\mathsf{GeneratedZeroCoverage}_\zeta,$$

and assume the RHRoute generation discipline is RH-free and fixed-half closed with fixed-half source packets. Then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have coordinate s. Generated-zero coverage supplies a generated packet P with the same zero readout as s. By Definition 9413.600, P has $\delta = 0$. Transporting this row along the same-zero readout gives

$$\delta(s) = 0.$$

The mirror-fixed algebra reads this as J-fixedness, hence as $\mathsf{OnCritLine}(s)$. Varying z gives the fixed-half section. □

Definition 9413.603 (Energy form of the invariant)**.** *Let a generated packet tower over $s = 1/2 + r + i\gamma$ have active nodes $a \in A_n$ with heights $h_a > 0$ and local channels*

$$U_a(s) := e^{-(s-1/2)h_a}.$$

Define

$$d_a(s) := \log |U_a(s)| = -rh_a,$$
$$\Omega_n(s) := (d_a(s))_{a \in A_n}, \qquad W_n := \sum_{a \in A_n} h_a^2.$$

The energy invariant is the square norm

$$|\Omega_n(s)|^2 := \sum_{a \in A_n} d_a(s)^2.$$

Lemma 9413.604 (Energy reads the normal coordinate)**.** *For every finite active window A_n,*

$$|\Omega_n(s)|^2 = r^2 W_n.$$

Proof. By definition, $d_a(s) = -rh_a$. Therefore

$$|\Omega_n(s)|^2 = \sum_{a \in A_n} (-rh_a)^2 = r^2 \sum_{a \in A_n} h_a^2 = r^2 W_n.$$

□

Theorem 9413.605 (Energy-bounded generation excludes off-half towers)**.** *Suppose a generated packet tower over $s = 1/2 + r + i\gamma$ satisfies cofinal growth*

$$W_n \to \infty$$

and a boundary-stability bound

$$|\Omega_n(s)|^2 \leq B_s$$

for a finite bound B_s independent of n. Then $r = 0$.

Proof. If $r\#0$, then $r^2 > 0$. By Definition 9413.604,

$$|\Omega_n(s)|^2 = r^2 W_n.$$

The cofinal growth row forces the right side to be unbounded, while the boundary-stability row gives a uniform finite bound. This contradiction excludes $r\#0$, and located fixed-half collapse gives $r = 0$. □

Corollary 9413.606 (The invariant proof load is two bridge rows)**.** *The invariant route closes after two zeta-specific bridge rows are supplied:*

$$\mathsf{ActiveCapture}_\zeta \quad \textit{and} \quad \mathsf{BoundaryStability}_\zeta.$$

Proof. Active capture supplies generated-zero coverage by constructing a zero-relevant generated packet for each completed zero. Boundary stability supplies fixed-half closure, or in the tower reading a uniform energy bound on the same zero-relevant packet family. The invariant argument itself is then formal: generated packets preserve the fixed-half invariant, and off-half packets have a different invariant value or unbounded positive energy. Thus the remaining proof load is source construction and independent boundary stability, not another restatement of the critical-line surface. □

9413.47 Triadic Ontic Invariant Readback

The fixed-half invariant of section 9413.46 is the zeta-facing readout of a higher BEDC invariant. It should not be taken as the primitive invariant itself. The primitive row is the closure preservation of the ontic triad: distinction is not lost, boundary transport remains legal, and recursive generation keeps a unique auditable interpretation.

Definition 9413.607 (Triadic ontic invariant)**.** *The* triadic ontic invariant *is the packet*

$$\mathcal{I}_{\mathrm{BEDC}} := (\mathcal{I}_{\mathsf{P}}, \mathcal{I}_{\mathsf{U}}, \mathcal{I}_{\mathsf{T}}),$$

where:

$$\mathcal{I}_{\mathsf{P}} = \textit{distinction, prime charge, and ledger provenance are preserved},$$

$$\mathcal{I}_{\mathsf{U}} = \textit{symmetry, unit boundary, and legal gauge are preserved},$$

and

$$\mathcal{I}_{\mathsf{T}} = \textit{recursion, finite-window closure, and unique readback are preserved.}$$

The invariant is not one of these rows in isolation. It is the closure condition that the three rows remain compatible under generation.

Definition 9413.608 (Triadic closed generation rule)**.** *Let R be a legal generation rule on RHRoute packets. The rule is* triadic closed *when it sends packets satisfying $\mathcal{I}_{\mathrm{BEDC}}$ to packets satisfying $\mathcal{I}_{\mathrm{BEDC}}$, and the output ledger records how the three components are transported:*

$$\mathsf{PrimeLedgerOK}, \qquad \mathsf{BoundaryGaugeOK}, \qquad \mathsf{RecursiveClosureOK}.$$

The first row records source provenance, prime-window data, and refusal of unlicensed collapse. The second row records mirror, unit-boundary, and compact gauge discipline. The third row records the recursive construction and its unique finite readback.

Theorem 9413.609 (Triadic closure is preserved by generated packets)**.** *If the source packets satisfy $\mathcal{I}_{\mathrm{BEDC}}$ and every legal generation rule is triadic closed, then every generated packet satisfies $\mathcal{I}_{\mathrm{BEDC}}$.*

Proof. This is structural induction on the generated packet. A source packet satisfies the invariant by hypothesis. For an inductive step, assume the input packets satisfy $\mathcal{I}_{\mathrm{BEDC}}$. Since the applied rule is triadic closed, its output carries the three transported rows PrimeLedgerOK, BoundaryGaugeOK, and RecursiveClosureOK. Hence the output satisfies $\mathcal{I}_{\mathrm{BEDC}}$. Repeating the argument along the finite generation tree gives the claim. □

Definition 9413.610 (Zeta readback of the triadic invariant)**.** *For a zeta-facing packet over*

$$s = \frac{1}{2} + r + i\gamma,$$

the local channel at a displayed node of height $h_a > 0$ is

$$U_a(s) = e^{-(s-1/2)h_a} = e^{-rh_a} e^{-i\gamma h_a}.$$

The zeta readback of $\mathcal{I}_{\mathrm{BEDC}}$ is:

$$\mathcal{I}_{\mathsf{P}} \rightsquigarrow \textit{the prime charge fixes } h_a,$$

$$\mathcal{I}_{\mathsf{U}} \rightsquigarrow \textit{the allowed gauge contains unit phase and compact prime fibres},$$

$$\mathcal{I}_{\mathsf{T}} \rightsquigarrow \textit{the packet is read through a finite or cofinal recursive tower.}$$

Under this readback, the real positive factor e^{-rh_a} is legal only when it is trivial.

Theorem 9413.611 (Triadic ontic readback gives fixed-half closure)**.** *For a zeta-facing generated packet, preservation of $\mathcal{I}_{\mathrm{BEDC}}$ implies the fixed-half readout*

$$r = 0.$$

Proof. The prime-ledger component supplies a positive height $h_a > 0$ for every active node. The recursive component supplies the finite or cofinal readback in which the same node is part of the generated packet. The boundary-gauge component allows the unit phase $e^{-i\gamma h_a}$ and compact prime-register fibres, but it does not allow an unledgered noncompact real positive scale. Therefore the factor

$$e^{-rh_a}$$

must be trivial on every zero-relevant generated packet. Since $h_a > 0$, this gives $r = 0$. □

Corollary 9413.612 (Fixed-half is a projection, not the primitive invariant)**.** *The fixed-half row used by RHRoute is the zeta projection of the triadic ontic invariant, not the primitive invariant of BEDC.*

Proof. The primitive invariant is the preservation of distinction provenance, legal boundary gauge, and recursive readback. In the zeta projection, these rows respectively determine the active heights, restrict the hidden carrier to unit phase and compact prime-register data, and make the finite or cofinal tower auditable. Their combined readback excludes the nontrivial real positive factor e^{-rh_a}. This exclusion is then read as $r = 0$, equivalently as the fixed-half row. Thus fixed-half is the output surface of the invariant under the zeta projection. □

Corollary 9413.613 (Generated-zero coverage remains the missing zeta row)**.** *Even if every generated RHRoute packet preserves $\mathcal{I}_{\mathrm{BEDC}}$, the RH fixed-half section still requires generated-zero coverage for the completed zeta zero ledger.*

Proof. By Definition 9413.611, a generated zeta-facing packet satisfying the triadic ontic invariant has fixed-half readout. To obtain a section over all completed critical-strip zero rows, each such zero must first be covered by a generated packet with the same zero readout. This is precisely the source row isolated in Definition 9413.601; it is not supplied by the invariant itself. □

Definition 9413.614 (Generated-zero internal section)**.** *The* generated-zero internal section *is the section over the generated RHRoute carrier*

$$\Phi_{\mathrm{gen}} : \mathcal{T}_\zeta \to \sum_{P:\mathcal{T}_\zeta} \mathsf{OnCritLine}(\mathsf{Read}(P)).$$

It asserts that every BEDC-generated zeta-facing packet has fixed-half readout. It is weaker than the RH fixed-half section, whose domain is the completed critical-strip zero carrier $\mathcal{Z}_\zeta$.

Theorem 9413.615 (Triadic closure gives only the generated section)**.** *If generated RHRoute packets preserve $\mathcal{I}_{\mathrm{BEDC}}$, then the generated-zero internal section exists.*

Proof. Let $P : \mathcal{T}_\zeta$ be a generated packet with zeta readout $s = 1/2 + r + i\gamma$. By preservation of $\mathcal{I}_{\mathrm{BEDC}}$ and Definition 9413.611, the noncompact real positive factor in the local channel is trivial. Thus $r = 0$, and the mirror-fixed readback gives $\mathsf{OnCritLine}(s)$. Assigning this witness to every generated packet gives Φ_{gen}. □

Definition 9413.616 (Coverage gap)**.** *The* coverage gap *is the difference between the generated carrier and the completed zero carrier:*

$$\mathcal{T}_\zeta \quad \textit{versus} \quad \mathcal{Z}_\zeta.$$

It is closed only by a row of the form

$$\mathsf{GeneratedZeroCoverage}_\zeta : \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{CritZero}(s) \to \sum_{P:\mathcal{T}_\zeta} \mathsf{SameZeroReadout}(P, s) \right).$$

This row is the same proof role as zero presentation completeness and active capture.

Theorem 9413.617 (Many generated zeros do not close the coverage gap)**.** *A displayed family of generated zero packets, even an infinite one, does not by itself imply* $\mathsf{GeneratedZeroCoverage}_\zeta$.

Proof. A displayed family gives a map from some index carrier I into $\mathcal{T}_\zeta$, hence a subset of completed zero readouts after projection. Coverage requires the opposite direction: every completed critical-strip zero row must admit a generated packet with the same readout. To derive that direction from an indexed family one must also prove that the indexing map is complete for the zero ledger, handles multiplicity and conjugation, and neither omits nor duplicates the zero rows in a way that loses the section target. These requirements are exactly a coverage theorem, not a consequence of having many generated examples. □

Corollary 9413.618 (Ordinary successor induction is not the coverage proof)**.** *The structural induction proving preservation of* $\mathcal{I}_{\mathrm{BEDC}}$ *is an induction on generated packets, not an induction over the completed zeta zero set.*

Proof. Structural induction consumes the constructors of $\mathcal{T}_\zeta$. It proves that every object already generated by those constructors preserves the triadic invariant. An induction over completed zeros would require a separately defined enumeration

$$\rho : \mathsf{Nat}^\uparrow \to \mathcal{Z}_\zeta$$

together with a proof that every completed zero occurs in that enumeration and that generated coverage passes from $\rho(n)$ to $\rho(n{+}1)$. Such data are not supplied by the generated-packet induction. Therefore the invariant proof and the coverage proof are logically distinct. □

Definition 9413.619 (Finite zero box)**.** *A* finite zero box *is a bounded rational rectangle*

$$\mathcal{B} \subseteq \left\{ s : \mathsf{Complex}^\uparrow : 0 \le \Re(s) \le 1 \right\}$$

whose boundary is separated from the completed zeta zero ledger. Its zero row is the finite packet

$$\mathcal{Z}_\zeta(\mathcal{B}) := \{ s \in \mathcal{B} : \mathsf{CritZero}(s) \},$$

with multiplicity, conjugation, and boundary-separation data carried in the ledger.

Definition 9413.620 (Box cover)**.** *For a finite zero box* $\mathcal{B}$*, the row*

$$\mathsf{BoxCover}(\mathcal{B})$$

means that every zero row in $\mathcal{Z}_\zeta(\mathcal{B})$ *is covered by a generated RHRoute packet:*

$$\prod_{s:\mathcal{Z}_\zeta(\mathcal{B})} \sum_{P:\mathcal{T}_\zeta} \mathsf{SameZeroReadout}(P, s).$$

This is a localized form of $\mathsf{GeneratedZeroCoverage}_\zeta$.

Definition 9413.621 (Box-cover induction row)**.** *A* box-cover induction row *consists of an increasing exhaustion*

$$\mathcal{B}_0 \subseteq \mathcal{B}_1 \subseteq \mathcal{B}_2 \subseteq \cdots$$

of the critical-strip zero ledger together with:

$$\mathsf{BoxCover}(\mathcal{B}_0),$$

$$\prod_{N:\mathsf{Nat}^{\uparrow}} (\mathsf{BoxCover}(\mathcal{B}_N) \to \mathsf{BoxCover}(\mathcal{B}_{N+1})),$$

and the exhaustion row

$$\prod_{s:\mathcal{Z}_\zeta} \sum_{N:\mathsf{Nat}^{\uparrow}} s \in \mathcal{B}_N.$$

The successor row is not a numerical-zero enumeration. It is a localized coverage step for all zero islands entering the next box.

Theorem 9413.622 (Box-cover induction gives generated coverage)**.** *A box-cover induction row implies*

$$\mathsf{GeneratedZeroCoverage}_\zeta.$$

Proof. By induction on N, the base row and successor row give

$$\mathsf{BoxCover}(\mathcal{B}_N)$$

for every $N : \mathsf{Nat}^{\uparrow}$. Let $s : \mathcal{Z}_\zeta$ be a completed critical-strip zero row. The exhaustion row supplies some N with $s \in \mathcal{B}_N$. Applying $\mathsf{BoxCover}(\mathcal{B}_N)$ to the corresponding localized zero row gives a generated packet $P : \mathcal{T}_\zeta$ with the same zero readout as s. Since s was arbitrary, generated-zero coverage follows. □

Definition 9413.623 (Active capture step)**.** *The* active capture step *for $\mathcal{B}_N \subseteq \mathcal{B}_{N+1}$ is the source row that covers each zero island in*

$$\mathcal{B}_{N+1} \setminus \mathcal{B}_N$$

by a canonical finite packet. For each such island D, it supplies

$$\Xi = F_D + T_D$$

on a boundary-separated disk around the island and the Rouché gap

$$|T_D| < |F_D| \qquad \text{on } \partial D.$$

It also supplies the interpretation of each zero of F_D as a generated RHRoute packet.

Corollary 9413.624 (Active capture steps are the coverage content)**.** *The box-cover induction row reduces generated-zero coverage to active capture steps for the boundary-separated zero islands of the exhaustion.*

Proof. The base box supplies the initial localized cover. For the transition from $\mathcal{B}_N$ to $\mathcal{B}_{N+1}$, all previously covered zero rows remain covered by restriction. The only uncovered rows lie in the added zero islands. An active capture step supplies Rouché capture and generated-packet interpretation for exactly those islands, hence constructs $\mathsf{BoxCover}(\mathcal{B}_{N+1})$ from $\mathsf{BoxCover}(\mathcal{B}_N)$. □

Corollary 9413.625 (Full RH requires coverage after invariant preservation)**.** *The route from the triadic ontic invariant to the RH fixed-half section has two independent stages:*

$$\mathcal{I}_{\mathrm{BEDC}} \text{ is preserved on } \mathcal{T}_\zeta \quad \Longrightarrow \quad \Phi_{\mathrm{gen}},$$

and

$$\mathsf{GeneratedZeroCoverage}_\zeta \quad \Longrightarrow \quad \Phi : \mathcal{Z}_\zeta \to \mathcal{H}_\zeta.$$

Proof. The first implication is Definition 9413.615. The second consumes the coverage row: for a completed zero s, choose a generated packet P with the same readout, use Φ_{gen} on P, and transport the fixed-half witness along the same-readout row. Without the coverage row, the generated section has the wrong domain for the RH fixed-half section. □

9413.48 Zero Packet Refinement Category

The coverage row can be organized categorically, but the categorical language must be used with a precise proof role. A category of finite zero packets supplies objects, refinement morphisms, and compatible towers. It does not by itself supply induction. Induction enters only after the generated carrier has an initial-algebra or structural recursion principle, and after the finite packet tower has a well-founded level structure whose refinement steps are explicitly audited.

Definition 9413.626 (Finite BEDC zero packet)**.** *A* finite BEDC zero packet *is a tuple*

$$P := (n, W, F, T, D, \mathcal{L}, \mathcal{B}, \Omega)$$

where n is a level or precision index, W is a finite prime or resonance window, F is a dominant finite packet, T is a tail packet, $D \subseteq \mathsf{Complex}^{\uparrow}$ is a rational zero box or zero island, $\mathcal{L}$ is the source, tail, phase, prime-register, and defect ledger, $\mathcal{B}$ is the boundary certificate, and Ω is the normal-defect readout attached to the packet.

Definition 9413.627 (Refinement morphism)**.** *For two finite zero packets P_m and P_n with $m \geq n$, a* refinement morphism

$$\phi_{m,n} : P_m \to P_n$$

is a projection from the finer packet to the coarser packet satisfying:

$$D_m \subseteq D_n, \qquad W_n \subseteq W_m,$$

$$\phi_{m,n}^* \mathcal{L}_n = \mathcal{L}_m|_n, \qquad \phi_{m,n}^* \mathcal{B}_n = \mathcal{B}_m|_n,$$

and

$$\Omega_m|_n = \Omega_n + \varepsilon_{m,n}$$

with an explicitly ledgered refinement error $\varepsilon_{m,n}$. The morphism says that P_m is a higher-resolution audit of P_n, not an independent replacement for it.

Definition 9413.628 (Zero packet refinement category)**.** *The* zero packet refinement category

$$\mathsf{Z}_{\mathrm{BEDC}}$$

has finite BEDC zero packets as objects and refinement morphisms as arrows. It is required to satisfy:

$$\phi_{n,n} = \mathrm{id}_{P_n},$$

and

$$\phi_{k,n} = \phi_{m,n} \circ \phi_{k,m} \qquad (k \geq m \geq n).$$

Theorem 9413.629 (Refinement packets form a category)**.** *If the refinement projections preserve zero boxes, windows, ledger data, boundary data, and defect readouts, and if they satisfy the identity and composition laws of Definition 9413.628, then the finite zero packets form the category* $\mathsf{Z}_{\mathrm{BEDC}}$*.*

Proof. The objects and arrows are given by Definition 9413.626 and Definition 9413.627. The identity arrow on P_n preserves every component by definitional readback. For composable refinements

$$P_k \xrightarrow{\phi_{k,m}} P_m \xrightarrow{\phi_{m,n}} P_n,$$

the inclusions of boxes and windows compose, and the pullback equations for ledger, boundary, and defect rows compose. The stipulated composition law identifies this composite with $\phi_{k,n}$. Thus the category axioms hold. □

Definition 9413.630 (BEDC zero tower)**.** *A* BEDC zero tower *is a functor*

$$P_\bullet : \mathsf{Nat}^{\uparrow op} \to \mathsf{Z}_{\mathrm{BEDC}}.$$

Equivalently, it is a compatible tower

$$P_0 \leftarrow P_1 \leftarrow P_2 \leftarrow \cdots$$

with refinement morphisms

$$\phi_{n+1,n} : P_{n+1} \to P_n.$$

Definition 9413.631 (Convergent zero tower)**.** *Let D_n be the zero box of P_n. A BEDC zero tower is* convergent *when*

$$D_{n+1} \subseteq D_n$$

and

$$\mathrm{diam}(D_n) \to 0.$$

When the boxes are nonempty and located-compact, the unique point in

$$\bigcap_n D_n$$

is denoted s_∞ and called the limit readout of the tower.

Theorem 9413.632 (Nested zero boxes have a unique limit readout)**.** *If the zero boxes of a BEDC zero tower are nonempty located-compact sets, satisfy $D_{n+1} \subseteq D_n$, and have diameter tending to zero, then the tower has a unique limit readout*

$$s_\infty \in \bigcap_n D_n.$$

Proof. The nested located-compact intersection supplies a point in the intersection. If x and y are both in every D_n, then

$$|x - y| \leq \mathrm{diam}(D_n)$$

for every n. Since the diameters tend to zero, $|x - y| = 0$, hence $x = y$. Thus the intersection has a unique point. □

Definition 9413.633 (Active-capture zero tower)**.** *A convergent BEDC zero tower is an* active-capture zero tower *when each level carries a decomposition*

$$\Xi = F_n + T_n$$

on a neighbourhood of D_n and a Rouché boundary gap

$$|T_n| < |F_n| \qquad \text{on } \partial D_n,$$

and the winding or local-degree row is preserved by the refinement morphisms.

Theorem 9413.634 (Active-capture convergence gives a completed zero)**.** *Let $P_\bullet$ be a convergent active-capture zero tower. If each D_n contains the same single completed-zero island of Ξ, then its limit readout satisfies*

$$\Xi(s_\infty) = 0.$$

Proof. By the Rouché boundary gap, F_n and Ξ have the same local zero count in D_n. The refinement maps preserve the local-degree row, and the boxes are nested, so the captured island is the same at each level. By Definition 9413.632, the boxes converge to s_∞. Since each box contains the same completed-zero island and the diameters tend to zero, the island readout is s_∞, hence $\Xi(s_\infty) = 0$. □

Definition 9413.635 (Boundary-stable zero tower)**.** *Let $s_\infty = 1/2+r+i\gamma$ be the limit readout of a zero tower. A convergent active-capture tower is* boundary-stable *when it carries defect extraction*

$$|\Omega_n(s_\infty)|^2 = r^2 W_n + o(W_n),$$

cofinal growth

$$W_n \to \infty,$$

and a zero-compatible bound

$$|\Omega_n(s_\infty)|^2 \le B$$

for a finite B independent of n.

Theorem 9413.636 (Boundary-stable zero towers have fixed-half limits)**.** *The limit readout of a boundary-stable zero tower satisfies*

$$r = 0.$$

Proof. If $r\#0$, then $r^2 > 0$. Cofinal growth gives

$$r^2 W_n \to \infty.$$

The defect extraction row gives

$$|\Omega_n(s_\infty)|^2 = r^2 W_n + o(W_n),$$

so the defect energy is unbounded. This contradicts the zero-compatible bound

$$|\Omega_n(s_\infty)|^2 \le B.$$

Hence $\neg(r\#0)$, and located fixed-half collapse gives $r = 0$. □

Corollary 9413.637 (Tower route separates convergence from coverage)**.** *A boundary-stable active-capture zero tower converges to a completed zero on the fixed-half surface. The remaining global row is that every completed critical-strip zero is the limit readout of such a tower.*

Proof. Definition 9413.634 gives the completed-zero row for the limit readout, while Definition 9413.636 gives the fixed-half row. This proves the statement for a tower once the tower is supplied. It does not construct a tower for every completed zero. That construction is the tower form of $\mathsf{GeneratedZeroCoverage}_\zeta$ and the active-capture source obligation of Definition 9413.623. □

9413.49 Prime-Adic Local Slicing

The prime-window and recursive-parity routes may be sharpened by reading each prime factor as a local slice. This is not a claim that the zeros of the Riemann zeta function are zeros of a p-adic zeta interpolation. The role of the p-adic language is local decomposition: each prime coordinate supplies a valuation direction and a unit direction, and the completed complex readout compresses all such local coordinates into the single complex parameter s.

Definition 9413.638 (Prime-adic slice)**.** *For a displayed prime p, the* prime-adic slice *is the local coordinate that records the p-valuation direction separately from the unit direction. Arithmetic factorization writes a nonzero rational row as*

$$x = \prod_p p^{v_p(x)} \cdot u,$$

with only finitely many nonzero valuation coordinates. In the p-local readout this becomes

$$x = p^{v_p(x)} u_p, \qquad u_p \in \mathbb{Z}_p^\times.$$

Thus the valuation $v_p(x)$ is the radial depth coordinate, while u_p is the unit coordinate. The word "slice" means this local valuation/unit separation; it does not introduce an additional global zero predicate.

Definition 9413.639 (Prime-adic Euler local coordinate)**.** *The Euler local factor at p is*

$$Z_p(s) := (1 - p^{-s})^{-1}.$$

On its convergence readout,

$$Z_p(s) = 1 + p^{-s} + p^{-2s} + p^{-3s} + \cdots .$$

The exponent k in p^{-ks} is the valuation depth in the p-slice. The centered local coordinate is

$$U_p(s) := p^{1/2-s}.$$

For

$$s = \frac{1}{2} + \delta + i\tau,$$

it decomposes as

$$U_p(s) = p^{-\delta} e^{-i\tau \log p}.$$

The factor $p^{-\delta}$ is the radial valuation readout and $e^{-i\tau \log p}$ is the unit-phase readout.

Theorem 9413.640 (The prime-adic unit surface is the fixed-half surface)**.** *For any displayed prime p and any complex row $s = \sigma + i\tau$,*

$$|U_p(s)| = 1 \quad \Longleftrightarrow \quad \sigma = \frac{1}{2}.$$

Consequently

$$\left(\prod_{p:\mathsf{Prime}^\uparrow} |U_p(s)| = 1 \right) \quad \Longleftrightarrow \quad \Re(s) = \frac{1}{2}.$$

Proof. By Definition 9413.639,

$$|U_p(s)| = |p^{1/2-s}| = p^{1/2-\sigma}.$$

Since $p > 1$, the equality $p^{1/2-\sigma} = 1$ holds exactly when $1/2-\sigma = 0$. This is $\sigma = 1/2$. The product statement follows because any displayed prime already detects the same exponent, and all prime slices read the same centered real displacement. □

Definition 9413.641 (Prime-adic finite-window defect)**.** *For a nonempty finite prime window S, the prime-adic finite-window defect is*

$$D_S^{\mathrm{loc}}(s) := \sum_{p\in S} \log |U_p(s)|.$$

Its normalized readout is

$$\overline{D}_S^{\mathrm{loc}}(s) := \frac{D_S^{\mathrm{loc}}(s)}{\sum_{p\in S} \log p}.$$

This is the same local slice data as the normalized prime-window defect of Definition 9413.166, written with the valuation/unit terminology exposed.

Theorem 9413.642 (Local slices read the same normal defect)**.** *If*

$$s = \frac{1}{2} + \delta + i\tau,$$

then for every nonempty finite prime window S,

$$\overline{D}_S^{\mathrm{loc}}(s) = -\delta.$$

Proof. For each $p \in S$,

$$\log |U_p(s)| = \log |p^{1/2-s}| = -\delta \log p.$$

Therefore

$$D_S^{\mathrm{loc}}(s) = -\delta \sum_{p\in S} \log p.$$

The denominator is positive because S is nonempty and every displayed prime has positive logarithm. Dividing gives the displayed formula. This is the local-slice form of Definition 9413.167. □

Corollary 9413.643 (Off-half rows are locally nonunit in every slice)**.** *If $\delta(s)\#0$, then every displayed prime slice is nonunit in the centered radial readout:*

$$|U_p(s)|\#1.$$

Equivalently, every nonempty finite prime window carries nonzero normalized local defect.

Proof. If $\delta(s)\#0$, then the formula

$$|U_p(s)| = p^{-\delta(s)}$$

is apart from 1 in the located radial readout. The finite-window statement follows from Definition 9413.642. □

Definition 9413.644 (Prime-adic local-global defect incompatibility)**.** *The prime-adic local-global defect incompatibility row is*

$$\mathsf{PrimeAdicLocalGlobalDefectIncompatibility}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \Bigg(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \sum_{S:\mathsf{FinitePrimeWindow}_{\neq\varnothing}} (\overline{D}_S^{\mathrm{loc}}(s$$

It states that a completed zeta zero cannot coexist with a nonunit local radial defect visible in any finite family of prime-adic slices.

Theorem 9413.645 (Prime-adic local-global incompatibility is conditionally sufficient)**.** *Together with the located fixed-half collapse row, prime-adic local-global defect incompatibility is sufficient for the RH fixed-half section.*

Proof. Let s carry a critical-strip zero row and write

$$s = \frac{1}{2} + \delta + i\tau.$$

Suppose $\delta\#0$. Choose any nonempty finite prime window S. By Definition 9413.642,

$$\overline{D}_S^{\mathrm{loc}}(s) = -\delta,$$

hence $\overline{D}_S^{\mathrm{loc}}(s)\#0$. This supplies the positive data excluded by Definition 9413.644. Therefore $\neg(\delta\#0)$. The located fixed-half collapse row gives $\delta = 0$, and Definition 9413.313 reads this as the fixed-half section. □

Corollary 9413.646 (Prime-adic slicing isolates the remaining local-global gap)**.** *Prime-adic slicing does not replace the zero problem by a theorem about p-adic zeta zeros. It identifies the remaining RH-facing gap as the local-global row asserting that nonunit local radial data cannot be classified as a completed global zeta zero.*

Proof. Definition 9413.640 identifies the fixed-half surface with simultaneous local unit readout. Definition 9413.642 shows that off-half displacement is visible in every finite family of prime slices. What is not supplied by either calculation is the zero-relevance bridge from visible local defect to exclusion of the completed zero ledger. That bridge is precisely Definition 9413.644, the local-slice form of the prime-sieve obstruction isolated in Definition 9413.484. □

9413.50 Prime-Adic Parity Energy Window

Prime-adic local slicing and recursive parity decomposition describe the same high-dimensional zeta carrier from two complementary directions. Prime-adic slicing separates the prime dimensions. Recursive parity decomposition separates the binary depth inside each prime dimension. The finite object inspected by the RH-facing defect route is therefore a finite window in $\mathsf{Prime}^\uparrow \times \mathsf{Nat}^\uparrow$, equipped with a normalized mirror-odd defect and its mirror-even second-order energy.

Definition 9413.647 (Prime-adic parity window)**.** *The* prime-adic parity tower *is the node carrier*

$$\mathsf{PAdicParityTower}_\zeta := \mathsf{Prime}^\uparrow \times \mathsf{Nat}^\uparrow.$$

For a node (p, j), the centered local-parity channel is

$$U_{p,j}^{\mathrm{pad}}(s) := p^{2j(1/2-s)}.$$

A prime-adic parity window *is a nonempty finite node family*

$$A \subset \mathsf{PAdicParityTower}_\zeta.$$

Its weight, signed defect, normalized signed defect, and second-order energy are

$$W_A^{\mathrm{pad}} := \sum_{(p,j)\in A} 2^j \log p,$$

$$D_A^{\mathrm{pad}}(s) := \sum_{(p,j)\in A} \log |U_{p,j}^{\mathrm{pad}}(s)|,$$

$$\overline{D}_A^{\mathrm{pad}}(s) := \frac{D_A^{\mathrm{pad}}(s)}{W_A^{\mathrm{pad}}}, \qquad E_A^{\mathrm{pad}}(s) := \left(\overline{D}_A^{\mathrm{pad}}(s)\right)^2.$$

Theorem 9413.648 (Prime-adic parity windows read one normal coordinate)**.** *If*

$$s = \frac{1}{2} + \delta + i\tau,$$

then every prime-adic parity window A satisfies

$$\overline{D}_A^{\mathrm{pad}}(s) = -\delta, \qquad E_A^{\mathrm{pad}}(s) = \delta^2.$$

Proof. For each node (p, j),

$$U_{p,j}^{\mathrm{pad}}(s) = p^{2^j(1/2-s)} = p^{-2^j\delta} e^{-i2^j\tau \log p}.$$

Thus

$$\log |U_{p,j}^{\mathrm{pad}}(s)| = -2^j \delta \log p.$$

Summing over A gives

$$D_A^{\mathrm{pad}}(s) = -\delta \sum_{(p,j)\in A} 2^j \log p = -\delta W_A^{\mathrm{pad}}.$$

Since A is nonempty, W_A^{pad} is a positive normalization row. Dividing gives $\overline{D}_A^{\mathrm{pad}}(s) = -\delta$, and squaring gives $E_A^{\mathrm{pad}}(s) = \delta^2$. □

Corollary 9413.649 (First-order defect is odd and second-order energy is even)**.** *For the mirror* $J(s) = 1 - \overline{s}$,

$$\overline{D}_A^{\mathrm{pad}}(J(s)) = -\overline{D}_A^{\mathrm{pad}}(s), \qquad E_A^{\mathrm{pad}}(J(s)) = E_A^{\mathrm{pad}}(s).$$

Proof. The mirror changes the normal coordinate from δ to $-\delta$ and keeps the time coordinate τ fixed. Apply Definition 9413.648 to s and $J(s)$. The normalized defect changes sign, while its square is unchanged. □

Theorem 9413.650 (Noncentrality is finite-window energy)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

the following rows are equivalent as defect readouts:

$$\delta(s)\#0, \qquad \sum_{A:\mathsf{PAdicParityWindow}_{\neq\varnothing}} (E_A^{\mathrm{pad}}(s)\#0).$$

Moreover, if $\delta(s)\#0$*, then every prime-adic parity window carries the same nonzero energy* $\delta(s)^2$*.*

Proof. For every nonempty finite window A, Definition 9413.648 gives

$$E_A^{\mathrm{pad}}(s) = \delta(s)^2.$$

Thus apartness of $\delta(s)$ from zero supplies nonzero energy in every window. Conversely, a nonzero energy row in some window is a nonzero square of the normalized defect, hence an apartness witness for $\delta(s)$ in the located real readout. □

Definition 9413.651 (No prime-adic parity energy zero)**.** *The* no prime-adic parity energy zero *row is*

$$\mathsf{NoPAdicParityEnergyZero}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \times \sum_{A:\mathsf{PAdicParityWindow}_{\neq\varnothing}} (E_A^{\mathrm{pad}}(s)\#0) \to \bot \right).$$

It says that a completed zeta zero cannot carry nonzero second-order mirror-even energy on any finite prime-adic parity window.

Theorem 9413.652 (Prime-adic parity energy refusal is conditionally sufficient)**.** *Together with the located fixed-half collapse row,*

$$\mathsf{NoPAdicParityEnergyZero}_\zeta$$

is sufficient for the RH fixed-half section.

Proof. Let s carry a critical-strip zero row and write

$$s = \frac{1}{2} + \delta + i\tau.$$

Suppose $\delta\#0$. Choose any prime-adic parity window A. By Definition 9413.650,

$$E_A^{\mathrm{pad}}(s)\#0.$$

Together with the zero row and critical-strip row, this is the positive data excluded by Definition 9413.651. Hence $\neg(\delta\#0)$. The located fixed-half collapse row yields $\delta = 0$, and Definition 9413.313 reads this as the fixed-half section. □

Corollary 9413.653 (Mirror balance does not remove prime-adic parity energy)**.** *If a mirror pair $s, J(s)$ has $\delta(s)\#0$, then signed prime-adic parity defects cancel in each finite window, but the second-order window energy remains nonzero on both sides.*

Proof. By Definition 9413.649, the normalized defects of s and $J(s)$ have opposite signs. Their sum is therefore zero. The same corollary also gives equal energies, and Definition 9413.650 gives nonzero energy when $\delta(s)\#0$. Thus mirror symmetry can balance the first-order sign, but not the second-order distance from the fixed-half surface. □

Corollary 9413.654 (Combined local window isolates the remaining obstruction)**.** *The combined prime-adic parity window does not prove the zero exclusion by itself. It isolates the exact zero-relevance row still required: a completed zeta zero must be incompatible with nonzero second-order prime-adic parity energy.*

Proof. Definition 9413.648 and Definition 9413.649 are readout calculations. They identify the finite local observable and its mirror parity. The remaining claim is the incompatibility between that observable and the completed zero ledger, stated in Definition 9413.651. This is the second-order local-window form of the prime-sieve obstruction in Definition 9413.484 and the local-global gap isolated in Definition 9413.646. □

9413.51 Prime-Adic Parity Sphere Invariant

The prime-adic parity energy window has the same geometric role as the unit circle in the Pythagorean carrier: it turns a normalization row into a unit-boundary equation. For a finite window $A \subset \mathsf{Prime}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$, the centered coordinates $U^{\mathrm{pad}}_{p,j}(s)$ define a weighted sphere. The fixed-half surface is exactly the boundary of this finite sphere, while off-half rows lie strictly on one side of the boundary in the located radial readout.

Definition 9413.655 (Prime-adic parity radius)**.** *For a prime-adic parity window A, define the node weight*

$$h_{p,j} := 2^j \log p$$

and the normalized node weight

$$\omega^A_{p,j} := \frac{h_{p,j}}{W^{\mathrm{pad}}_A}.$$

The prime-adic parity radius square *is*

$$R^2_A(s) := \sum_{(p,j)\in A} \omega^A_{p,j} \left| U^{\mathrm{pad}}_{p,j}(s) \right|^2.$$

Writing $U^{\mathrm{pad}}_{p,j}(s) = x_{p,j}(s) + iy_{p,j}(s)$, this is the weighted sphere equation

$$R^2_A(s) = \sum_{(p,j)\in A} \omega^A_{p,j} \left(x_{p,j}(s)^2 + y_{p,j}(s)^2 \right).$$

Theorem 9413.656 (The weighted sphere boundary is the fixed-half surface)**.** *For every prime-adic parity window A,*

$$R^2_A(s) = 1 \quad \Longleftrightarrow \quad \Re(s) = \frac{1}{2}.$$

Proof. Write

$$s = \frac{1}{2} + \delta + i\tau.$$

By Definition 9413.647,

$$\left| U^{\mathrm{pad}}_{p,j}(s) \right|^2 = \left| p^{2^j(1/2-s)} \right|^2 = p^{-2^{j+1}\delta}.$$

If $\delta = 0$, every term is 1, and the normalized weights satisfy

$$\sum_{(p,j)\in A} \omega^A_{p,j} = 1.$$

Thus $R^2_A(s) = 1$.

Conversely, if $\delta > 0$, then every term $p^{-2^{j+1}\delta}$ is strictly smaller than 1, so the weighted average $R^2_A(s)$ is strictly smaller than 1. If $\delta < 0$, every term is strictly larger than 1, so $R^2_A(s)$ is strictly larger than 1. Hence equality with 1 is possible only when $\delta = 0$, equivalently $\Re(s) = 1/2$. □

Corollary 9413.657 (Sphere radius and normal energy define the same boundary)**.** *For every prime-adic parity window A, the rows*

$$R^2_A(s) = 1 \qquad \textit{and} \qquad E^{\mathrm{pad}}_A(s) = 0$$

define the same fixed-half boundary.

Proof. Definition 9413.656 identifies $R_A^2(s) = 1$ with $\Re(s) = 1/2$. By Definition 9413.648,

$$E_A^{\mathrm{pad}}(s) = \delta(s)^2.$$

Thus $E_A^{\mathrm{pad}}(s) = 0$ is the same row as $\delta(s) = 0$, hence the same fixed-half boundary. □

Definition 9413.658 (Finite Hamiltonian sphere state)**.** *For a prime-adic parity window A, let $\mathcal{H}_A$ be the finite Hilbert readout with displayed basis $|p, j\rangle$ for $(p, j) \in A$. Define*

$$H_A|p, j\rangle = h_{p,j}|p, j\rangle$$

and the normalized reference vector

$$|\mathbf{1}_A\rangle := \sum_{(p,j)\in A} \sqrt{\omega_{p,j}^A}\, |p, j\rangle.$$

The centered finite Hamiltonian state is

$$|\psi_A(s)\rangle := e^{-(s-1/2)H_A}|\mathbf{1}_A\rangle.$$

Theorem 9413.659 (Finite Hamiltonian norm is the sphere radius)**.** *For every prime-adic parity window A,*

$$\|\psi_A(s)\|^2 = R_A^2(s).$$

Consequently the fixed-half surface is the finite Hamiltonian unitary surface.

Proof. The operator H_A is diagonal on the displayed basis, so

$$e^{-(s-1/2)H_A}|p, j\rangle = p^{2^j(1/2-s)}|p, j\rangle = U_{p,j}^{\mathrm{pad}}(s)|p, j\rangle.$$

Therefore

$$\|\psi_A(s)\|^2 = \sum_{(p,j)\in A} \omega_{p,j}^A \left|U_{p,j}^{\mathrm{pad}}(s)\right|^2 = R_A^2(s).$$

If $\Re(s) = 1/2$, then $s - 1/2 = i\tau$ and $e^{-(s-1/2)H_A} = e^{-i\tau H_A}$ is unitary. Conversely, Definition 9413.656 identifies preservation of the unit norm of this displayed reference state with the fixed-half surface. □

Definition 9413.660 (Zero boundary sphere row)**.** *The* zero boundary sphere row *is*

$$\mathsf{ZeroBoundarySphere}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \prod_{A:\mathsf{PAdicParityWindow}_{\neq\varnothing}} (R_A^2(s) = 1) \right).$$

It says that a completed zeta zero lies on the unit-boundary sphere of every finite prime-adic parity window.

Theorem 9413.661 (Zero boundary sphere is conditionally sufficient)**.** *Together with the located fixed-half collapse row,*

$$\mathsf{ZeroBoundarySphere}_\zeta$$

is sufficient for the RH fixed-half section.

Proof. Let s carry a critical-strip zero row. The zero boundary sphere row gives $R_A^2(s) = 1$ for every prime-adic parity window A. Choose one such window. By Definition 9413.656, this gives $\Re(s) = 1/2$. Equivalently, $\delta(s) = 0$, and Definition 9413.313 reads the row as the RH fixed-half section. □

Corollary 9413.662 (Sphere boundary is the geometric form of energy refusal)**.** *The zero boundary sphere row and the no prime-adic parity energy zero row are two geometric presentations of the same RH-facing obstruction.*

Proof. By Definition 9413.657, $R_A^2(s) = 1$ and $E_A^{\mathrm{pad}}(s) = 0$ identify the same fixed-half boundary on each finite window. Therefore requiring zeta zero rows to land on all sphere boundaries is the boundary-surface form of excluding nonzero second-order prime-adic parity energy, as stated in Definition 9413.651. □

9413.52 Zeta-Like Projection Taxonomy

The finite objects used in the zeta route do not all have the same projection status. Some are direct finite projections of the Riemann zeta prime tower. Others are finite projections of the same zeta-like spectral mechanism without being truncations of the Riemann zeta function itself. The distinction is essential: it prevents the finite quartic and elliptic examples from being misread as literal Riemann-zeta windows while preserving their role as closed laboratories for the same observation, recursion, spectrum, normalization, symmetry, zero-ledger, and far-end pattern.

Definition 9413.663 (Direct Riemann-zeta finite projection)**.** *A* direct Riemann-zeta finite projection *is a finite readout obtained by restricting the Euler prime dimensions, the occupation depths, or the recursive parity nodes of the Riemann zeta carrier. The basic prime-window projection is*

$$\zeta_S(s) := \prod_{p \in S} (1 - p^{-s})^{-1}.$$

The finite occupation-depth projection is

$$\zeta_{S,M}(s) := \prod_{p \in S} \left(1 + p^{-s} + p^{-2s} + \cdots + p^{-Ms}\right).$$

The prime-adic parity windows

$$A \subset \mathsf{Prime}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$$

of Definition 9413.647 are direct finite windows of the recursive parity expansion of the same Euler carrier.

Definition 9413.664 (Universal zeta-like carrier)**.** *The* universal zeta-like carrier *is the schematic packet*

$$\mathcal{Z}_\Omega := (\mathsf{Obs}, \mathsf{Rec}, \mathsf{Spectrum}, \mathsf{Normalize}, \mathsf{Sym}, \mathsf{ZeroLedger}, \mathsf{FarEnd}).$$

It records the mechanism by which finite observations are recursively folded into spectral data, normalized to a unit or boundary surface, transported by a symmetry row, constrained by a zero ledger, and kept separate from an apophatic far-end absorption row.

Definition 9413.665 (Zeta-like finite projection)**.** *A* zeta-like finite projection *is a finite carrier projection of $\mathcal{Z}_\Omega$ that displays the rows*

$$\mathsf{Obs}, \quad \mathsf{Rec}, \quad \mathsf{Spectrum}, \quad \mathsf{Normalize}, \quad \mathsf{Sym}, \quad \mathsf{ZeroLedger}$$

inside a finite laboratory. It need not be a truncation of the Riemann zeta Euler product. Its projection status depends on preserving the mechanism, not on sharing the same prime-indexed carrier.

Theorem 9413.666 (Direct windows are zeta-like projections)**.** *Every direct Riemann-zeta finite projection is a zeta-like finite projection, but not every zeta-like finite projection is a direct Riemann-zeta finite projection.*

Proof. The direct windows inherit their observation rows from finite prime sets, their recursion from Euler multiplication or occupation-depth extension, their spectrum from the finite Hamiltonian readouts of Definition 9413.150, their normalization from the centered channels, their symmetry from the fixed-half mirror, and their zero-relevance boundary from the completed zeta route. Hence they are zeta-like projections.

The converse fails because a finite carrier may realize the same mechanism without being a prime-window truncation of the Riemann zeta function. The quartic carrier of Definition 9413.89 is such a case: its recurrence, generating function, companion spectrum, elliptic normalization, real projection, dominance row, and endpoint-zero law are finite spectral rows, not a finite Euler product over primes. □

Theorem 9413.667 (The quartic carrier is a zeta-like finite projection)**.** *The fixed quartic spectral carrier is a zeta-like finite projection of $\mathcal{Z}_\Omega$, not a direct Riemann-zeta finite projection.*

Proof. The observation row is the rational generating-function source $Z(t, y) = N(t, y)/D(t, y)$. The recursion row is the order-four recurrence for $Z_m(y)$. The spectrum row is the companion-matrix and spectral polynomial readout

$$\det(\lambda I - T(y)) = \Pi(\lambda, y).$$

The normalization row is the elliptic transport to

$$E: \quad Y^2 = 4\lambda^3 - 4\lambda + 1.$$

The symmetry and zero-ledger rows are the real projection, branch dominance, and endpoint-zero law isolated in Definition 9413.485. These rows instantiate the zeta-like mechanism. None of them is a finite restriction of the Riemann-zeta prime-indexed Euler product. □

Definition 9413.668 (Projection status ledger)**.** *The* projection status ledger *records, for a finite carrier F, which of the following rows it carries:*

$$\mathsf{DirectRiemannWindow}(F), \qquad \mathsf{ZetaLikeFiniteProjection}(F), \qquad \mathsf{ZeroRelevantBoundary}(F).$$

The first row implies the second when the finite Riemann window is read with its spectral, normalized, and zero-boundary ledgers. The second row does not imply the first. The third row is additional: it records that the finite projection has identified the boundary surface that actually controls its zero ledger.

Corollary 9413.669 (Projection status separates analogy from truncation)**.** *The finite quartic, elliptic, and finite-field style zeta models should be compared with Riemann zeta through the zeta-like mechanism ledger, not through literal Euler-product truncation.*

Proof. A literal truncation must preserve the prime-indexed Euler carrier. The quartic model preserves recurrence, spectral normalization, symmetry, and zero-boundary rows instead. Therefore its correct comparison point is $\mathcal{Z}_\Omega$, not the direct finite Euler window $\zeta_S(s)$. This keeps the finite model useful without overstating its relation to Riemann zeta. □

Theorem 9413.670 (Finite projection energy is the completed-readout test)**.** *For the Riemann-zeta direct windows, an off-half critical-strip row is seen by every prime-adic parity window as nonzero second-order energy. Thus the RH-facing completed-readout test is whether this finite projection energy can coexist with the completed global zero ledger.*

Proof. By Definition 9413.650, if $s = 1/2+\delta+i\tau$ and $\delta(s)\#0$, then every prime-adic parity window A carries

$$E_A^{\mathrm{pad}}(s)\#0.$$

By Definition 9413.662, this is the same obstruction as failure to lie on the finite prime-adic parity unit sphere. The remaining completed-readout test is therefore not visibility of the defect, which is already finite, but zero-relevance of that defect in the completed zeta carrier. □

Corollary 9413.671 (Finite projections identify the no-absorption target)**.** *The finite-projection framework reduces the RH-facing gap to the claim that nonzero finite-projection normal energy cannot be absorbed by the infinite completed zeta readout as a zero row.*

Proof. Direct finite windows detect the normal energy by Definition 9413.670. Zeta-like finite projections such as the quartic carrier show why zero-relevance must be separately proved: a visible spectral branch or defect matters only after dominance, normalization, and zero-ledger rows identify the relevant boundary. Thus the remaining target is the no-absorption row already isolated by Definition 9413.180 and the defect-zero incompatibility row of Definition 9413.202. □

9413.53 Global Prime Energy and the No-Hair Boundary

The finite prime-window defect row is a first-order signed readout. As a signed row it can reverse under the mirror and can participate in global phase cancellation. The square of the same radial readout has a different status. It is a positive normal energy on each prime dimension. Positive energy has no opposite sign that could cancel it by mirror pairing, parity rearrangement, or movement of terms across a global equation.

Definition 9413.672 (Prime normal square energy)**.** *For the centered prime channel*

$$U_p(s) := p^{1/2-s},$$

define the prime normal defect and its square energy by

$$d_p(s) := \log|U_p(s)|, \qquad e_p(s) := d_p(s)^2.$$

For a nonempty finite prime window S, define the unnormalized square energy

$$\mathcal{E}_S(s) := \sum_{p\in S} e_p(s).$$

The global prime normal energy is the monotone extended readout

$$\mathcal{E}_{\mathbb{P}}(s) := \sum_{p \in \mathsf{Prime}^{\uparrow}} e_p(s),$$

understood as the supremum of the finite-window sums.

Theorem 9413.673 (Prime square energy is mirror-even)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

each displayed prime satisfies

$$d_p(s) = -\delta \log p, \qquad e_p(s) = \delta^2 (\log p)^2.$$

Moreover

$$d_p(J(s)) = -d_p(s), \qquad e_p(J(s)) = e_p(s).$$

Proof. The first equality is the prime-coordinate calculation of Definition 9413.469. Squaring gives

$$e_p(s) = d_p(s)^2 = \delta^2 (\log p)^2.$$

The mirror sends the normal coordinate δ to $-\delta$, hence changes the sign of d_p and leaves e_p unchanged. □

Theorem 9413.674 (Finite prime square energy is strictly positive off half)**.** *If $s = 1/2 + \delta + i\tau$, $\delta \# 0$, and S is a nonempty finite prime window, then*

$$\mathcal{E}_S(s) = \delta^2 \sum_{p \in S} (\log p)^2 \# 0.$$

Proof. Summing Definition 9413.673 over S gives

$$\mathcal{E}_S(s) = \delta^2 \sum_{p \in S} (\log p)^2.$$

The window is nonempty and every displayed prime has positive logarithm, so the finite sum of squares is positive. Apartness of δ from zero gives apartness of δ^2 from zero in the located real readout, hence the displayed energy is nonzero. □

Theorem 9413.675 (Global prime square energy diverges off half)**.** *If $s = 1/2 + \delta + i\tau$ and $\delta \# 0$, then the global prime normal energy is unbounded:*

$$\mathcal{E}_{\mathbb{P}}(s) = \infty$$

as an extended finite-window supremum.

Proof. For every nonempty finite window S,

$$\mathcal{E}_S(s) = \delta^2 \sum_{p \in S} (\log p)^2.$$

There are infinitely many displayed prime dimensions, and each $(\log p)^2$ is positive. As the finite window ranges over larger and larger prime sets, the partial sums

$$\sum_{p \in S} (\log p)^2$$

are unbounded. Multiplication by the positive row δ^2 preserves unboundedness. Therefore the extended supremum $\mathcal{E}_{\mathbb{P}}(s)$ is infinite. □

Definition 9413.676 (Composite rows add no cancellation direction)**.** *The* no composite cancellation direction *row says that a composite integer contributes no independent normal coordinate beyond the prime coordinates. If*

$$n = \prod_p p^{v_p(n)},$$

then

$$\log n = \sum_p v_p(n) \log p.$$

Thus composite logarithmic rows are finite linear combinations of prime logarithmic rows and do not add a further sign in which the positive prime square energy could cancel.

Theorem 9413.677 (Prime logarithmic directions are independent)**.** *For distinct displayed primes $p_1, \ldots, p_m$, a rational relation*

$$\sum_{i=1}^{m} q_i \log p_i = 0$$

forces $q_i = 0$ for every i.

Proof. Clear denominators to obtain integers a_i with

$$\sum_{i=1}^{m} a_i \log p_i = 0.$$

Exponentiating gives

$$\prod_{i=1}^{m} p_i^{a_i} = 1.$$

By unique factorization, all exponents a_i are zero. Hence every rational coefficient q_i is zero. □

Definition 9413.678 (Zeta no-hair boundary)**.** *The* zeta no-hair boundary *row is the assertion*

$$\mathsf{ZetaNoHair}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathcal{E}_{\mathbb{P}}(s) = 0\right).$$

A weaker finite-energy version replaces the conclusion by

$$\mathcal{E}_{\mathbb{P}}(s) < \infty.$$

Both rows say that a zero boundary state cannot carry infinite normal prime energy.

Theorem 9413.679 (No-hair boundary is conditionally sufficient)**.** *Together with the located fixed-half collapse row, either zeta no-hair boundary row is sufficient for the RH fixed-half section.*

Proof. Let s carry a critical-strip zero row and write

$$s = \frac{1}{2} + \delta + i\tau.$$

Suppose $\delta \# 0$. By Definition 9413.675, the global prime normal energy is infinite. This contradicts either the zero-energy conclusion $\mathcal{E}_{\mathbb{P}}(s) = 0$ or the weaker finite-energy conclusion $\mathcal{E}_{\mathbb{P}}(s) < \infty$. Hence $\neg(\delta \# 0)$. The located fixed-half collapse row yields $\delta = 0$, and Definition 9413.313 reads this as the RH fixed-half section. □

Corollary 9413.680 (Positive energy strengthens finite defect visibility)**.** *The global square-energy route strengthens the finite defect route by replacing a visible signed defect with a monotone positive obstruction.*

Proof. The finite defect route shows that $\delta\#0$ is visible in every finite prime window by a signed row such as $D_S(s)\#0$. The square-energy row shows more: the same off-half displacement contributes positive energy on every prime dimension and yields an unbounded global extended energy. Thus the remaining RH-facing issue is no longer detection of the defect, but the no-hair boundary claim that a completed zero row cannot carry that infinite normal energy. □

9413.54 Far-End Energy Unity Socket

The prime-adic parity energy window makes the non-point reading of the far end explicit. The far end is not a last node of $\mathsf{Prime}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$, not a final value of the tower, and not a hidden register in which a visible normal defect can be cancelled. It is the cofinal socket through which all finite prime-adic parity windows are read together. Consequently an energy row vanishes at the far end only when the finite-window energies become cofinally zero. No additional term at ∞ is available.

Definition 9413.681 (Prime-adic parity far-end socket)**.** *The* prime-adic parity far-end socket *is the cofinal boundary role of the finite-window directed system*

$$A \subset \mathsf{Prime}^{\uparrow} \times \mathsf{Nat}^{\uparrow}, \qquad A \text{ finite and nonempty.}$$

A cofinal energy condition on this socket is a row of the form

$$\prod_{\varepsilon>0} \sum_{A_0:\mathsf{PAdicParityWindow}_{\neq\varnothing}} \prod_{A\supseteq A_0} \left(E_A^{\mathrm{pad}}(s) < \varepsilon\right),$$

where A ranges over finite nonempty prime-adic parity windows. The symbol ∞ or $\mathsf{T}_{\mathrm{far}}$ names this cofinal compatibility role; it does not name an element A_∞.

Definition 9413.682 (Far-end energy unity)**.** *For a zeta readout s, define the* far-end energy unity *row by*

$$\mathsf{FarEndEnergyUnity}_{\zeta}(s) := \prod_{\varepsilon>0} \sum_{A_0:\mathsf{PAdicParityWindow}_{\neq\varnothing}} \prod_{A\supseteq A_0} \left(E_A^{\mathrm{pad}}(s) < \varepsilon\right).$$

It says that the normalized second-order prime-adic parity energy tends to zero cofinally through finite windows. It is not a statement that there exists an infinite window where a correction term is evaluated.

Definition 9413.683 (No hidden energy correction at the far end)**.** *The* no hidden energy correction *discipline is the refusal of an undisplayed decomposition*

$$E_\infty^{\mathrm{pad}}(s) = E_A^{\mathrm{pad}}(s) + C_\infty(s)$$

with $C_\infty(s)$ treated as a boundary term able to cancel $E_A^{\mathrm{pad}}(s)$. In the BEDC reading, the far end contributes only the cofinal quantifier pattern of Definition 9413.682. Any actual correction row must appear as positive carrier data, as in the archimedean completion row of Definition 9413.140; it cannot be borrowed from the apophatic socket.

Theorem 9413.684 (Far-end energy unity is fixed-half energy)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

the following rows are equivalent:

$$\mathsf{FarEndEnergyUnity}_{\zeta}(s), \qquad \delta^2 = 0.$$

Consequently, in the located real readout, far-end energy unity is equivalent to

$$\Re(s) = \frac{1}{2}.$$

Proof. By Definition 9413.648, every finite nonempty prime-adic parity window satisfies

$$E_A^{\mathrm{pad}}(s) = \delta^2.$$

If $\delta^2 = 0$, then $E_A^{\mathrm{pad}}(s) = 0$ for every finite window, so the cofinal condition of Definition 9413.682 holds.

Conversely, suppose $\mathsf{FarEndEnergyUnity}_{\zeta}(s)$ holds. If $\delta^2 \# 0$, choose ε below the positive row δ^2 in the located real readout. The cofinal condition would then require all sufficiently large finite windows to satisfy

$$E_A^{\mathrm{pad}}(s) < \varepsilon.$$

But every such window has

$$E_A^{\mathrm{pad}}(s) = \delta^2,$$

contradicting the choice of ε. Hence $\delta^2 = 0$. Located collapse gives $\delta = 0$, and Definition 9413.313 reads this as $\Re(s) = 1/2$. □

Definition 9413.685 (Unnormalized parity far-end energy)**.** *For a prime-adic parity window A, define the unnormalized parity energy by*

$$\mathcal{E}_A^{\mathrm{pad}}(s) := \sum_{(p,j)\in A} \left(\log \left|U_{p,j}^{\mathrm{pad}}(s)\right|\right)^2.$$

The corresponding far-end readout is the extended supremum over finite windows:

$$\mathcal{E}_{\mathrm{far}}^{\mathrm{pad}}(s) := \sup_A \mathcal{E}_A^{\mathrm{pad}}(s).$$

Theorem 9413.686 (Unnormalized parity energy diverges off half)**.** *If $s = 1/2 + \delta + i\tau$ and $\delta \# 0$, then*

$$\mathcal{E}_{\mathrm{far}}^{\mathrm{pad}}(s) = \infty.$$

Proof. For each node (p, j),

$$U_{p,j}^{\mathrm{pad}}(s) = p^{-2^j\delta} e^{-i2^j\tau\log p},$$

so

$$\log \left|U_{p,j}^{\mathrm{pad}}(s)\right| = -2^j\delta\log p.$$

Therefore

$$\mathcal{E}_A^{\mathrm{pad}}(s) = \delta^2 \sum_{(p,j)\in A} \left(2^j \log p\right)^2.$$

The directed carrier $\mathsf{Prime}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$ has cofinally unbounded finite node windows, and every displayed summand $\left(2^j \log p\right)^2$ is positive. If $\delta \# 0$, multiplication by δ^2 preserves unboundedness in the extended readout. Hence the far-end supremum is infinite. □

Definition 9413.687 (Zero far-end energy unity target)**.** *The* zero far-end energy unity target *is*

$$\mathsf{ZeroFarEndEnergyUnity}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \Big(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{FarEndEnergyUnity}_\zeta(s)\Big).$$

It says that a completed critical-strip zero is a far-end energy-unified boundary state.

Theorem 9413.688 (Zero far-end energy unity is conditionally sufficient)**.** *If* $\mathsf{ZeroFarEndEnergyUnity}_\zeta$ *holds, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s. The zero row and critical-strip row of z give

$$\mathsf{FarEndEnergyUnity}_\zeta(s)$$

by Definition 9413.687. By Definition 9413.684, this implies $\Re(s) = 1/2$. Therefore z has the fixed-half lift required by Definition 9413.844, and the section equivalence of Definition 9413.199 gives the RH fixed-half section. □

Corollary 9413.689 (Energy unity is the socket form of no-hair)**.** *The zero far-end energy unity target is the cofinal finite-window form of the zeta no-hair boundary.*

Proof. Definition 9413.678 states that a critical-strip zero cannot carry global normal prime energy. The present socket formulation states the same obstruction through normalized prime-adic parity energies: the finite-window energy family has the constant value δ^2, so cofinal vanishing is possible exactly on the fixed-half surface. The unnormalized form of Definition 9413.686 recovers the infinite-energy reading of Definition 9413.675 with binary depth included. □

Corollary 9413.690 (No point at infinity can absorb parity energy)**.** *An off-half row cannot be made far-end energy-unified by adding a correction at* ∞*.*

Proof. By Definition 9413.681, the far end is a cofinal socket for finite windows, not an element. By Definition 9413.684, the finite-window energy family is cofinally zero exactly when $\delta^2 = 0$. Thus an off-half row has stable positive normalized energy in every finite window and unbounded unnormalized energy by Definition 9413.686. The prohibited hidden term of Definition 9413.683 would therefore be precisely a point-reification of the apophatic far end, which is excluded by Definition 9413.141. □

9413.55 Finite-to-Infinite Phase-Energy Tower

The prime phase-radial readback separates two finite-to-infinite phenomena. Finite prime windows display simultaneous phase rotation: each displayed prime contributes a unit phase with frequency $\log p$ on the critical surface. The infinite passage relevant to the RH-facing obstruction is not the signed phase row, because signed phase can cancel in a completed projection. The stable row is the positive second-order normal energy. It is monotone on finite prime windows and becomes unbounded whenever the normal displacement is nonzero.

Definition 9413.691 (Finite phase-energy window)**.** *For a nonempty finite prime window* S*, the* finite phase-energy window *at*

$$s = \frac{1}{2} + \delta + i\tau$$

is the packet

$$\mathsf{PhaseEnergy}_S(s) := (\Phi_S(\tau), \mathcal{E}_S(s)),$$

where $\Phi_S(\tau)$ is the finite phase profile of Definition 9413.296 and

$$\mathcal{E}_S(s) = \sum_{p \in S} \left(\log |p^{1/2-s}|\right)^2$$

is the finite prime normal square energy of Definition 9413.672.

Theorem 9413.692 (Finite prime phase windows have no nonzero common period)**.** *Let S be a finite prime window containing two distinct primes. There is no nonzero real time T such that*

$$e^{-iT \log p} = 1$$

for every $p \in S$.

Proof. Suppose such a nonzero T exists. For any two distinct primes $p, q \in S$, there are integers m_p, m_q with

$$T \log p = 2\pi m_p, \qquad T \log q = 2\pi m_q.$$

Since $T \# 0$ and both logarithms are positive, neither integer can be zero. Hence

$$\frac{\log p}{\log q} = \frac{m_p}{m_q} \in \mathbb{Q}.$$

This is a nontrivial rational relation between two prime logarithmic directions, contradicting Definition 9413.677. □

Corollary 9413.693 (Finite phase closure is quasi-periodic data)**.** *Finite prime phase windows may exhibit approximate recurrence and projected cancellation, but they do not carry an exact common period once at least two prime frequencies are displayed.*

Proof. Approximate recurrence belongs to the finite torus face $\mathbb{T}_S$ of Definition 9413.293. Exact common periodicity would require a nonzero T satisfying the condition excluded by Definition 9413.692. Thus finite phase cancellation is not an exact periodic clock for the prime tower. □

Theorem 9413.694 (Finite normal energy is monotone in the window)**.** *If $S \subseteq T$ are nonempty finite prime windows, then*

$$\mathcal{E}_S(s) \le \mathcal{E}_T(s).$$

Moreover, if $s = 1/2 + \delta + i\tau$ and $\delta \# 0$, then every nonempty finite window has positive normal energy, and enlarging the window adds only nonnegative terms.

Proof. By definition,

$$\mathcal{E}_T(s) = \sum_{p \in T} \left(\log |p^{1/2-s}|\right)^2.$$

All summands are squares, hence nonnegative. Splitting the sum over S and $T \setminus S$ gives

$$\mathcal{E}_T(s) = \mathcal{E}_S(s) + \sum_{p \in T \setminus S} \left(\log |p^{1/2-s}|\right)^2,$$

which proves monotonicity. If $s = 1/2 + \delta + i\tau$, then Definition 9413.674 gives

$$\mathcal{E}_S(s) = \delta^2 \sum_{p \in S} (\log p)^2 \# 0$$

for every nonempty finite window when $\delta \# 0$. □

Theorem 9413.695 (Finite-to-infinite energy divergence)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

if $\delta \# 0$*, then the finite-window normal energies form an unbounded cofinal tower:*

$$\sup_{S:\mathsf{FinitePrimeWindow}_{\neq\varnothing}} \mathcal{E}_S(s) = \infty.$$

Proof. For every nonempty finite window S,

$$\mathcal{E}_S(s) = \delta^2 \sum_{p\in S} (\log p)^2$$

by Definition 9413.673. The finite sums

$$\sum_{p\in S} (\log p)^2$$

are unbounded as S ranges cofinally over finite prime windows, since there are infinitely many displayed prime rows and each displayed square is positive. Because $\delta \# 0$, multiplication by δ^2 preserves unboundedness. This is the same extended supremum readout as Definition 9413.675. □

Definition 9413.696 (Finite normal energy boundary)**.** *The* finite normal energy boundary *row for completed critical-strip zeros is*

$$\mathsf{FiniteNormalEnergyBoundary}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \sup_{S:\mathsf{FinitePrimeWindow}_{\neq\varnothing}} \mathcal{E}_S(s) < \infty \right).$$

It says that a completed zero boundary state cannot carry unbounded normal prime energy along the finite-window tower.

Theorem 9413.697 (Finite normal energy boundary is conditionally sufficient)**.** *If* $\mathsf{FiniteNormalEnergyBoundary}_\zeta$ *holds, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s, and write

$$s = \frac{1}{2} + \delta + i\tau.$$

The zero and critical-strip rows of z give

$$\sup_{S:\mathsf{FinitePrimeWindow}_{\neq\varnothing}} \mathcal{E}_S(s) < \infty$$

by Definition 9413.696. If $\delta \# 0$, then Definition 9413.695 gives the opposite extended readout, namely an infinite supremum. Hence $\neg(\delta \# 0)$. The located fixed-half collapse row gives $\delta = 0$, and Definition 9413.313 reads this as $\Re(s) = 1/2$. Varying z supplies the fixed-half section. □

Corollary 9413.698 (Finite-to-infinite tracking identifies the proof load)**.** *The finite-to-infinite tower separates detection from zero relevance. Off-half displacement is detected by positive finite-window energies and becomes unbounded cofinally; the remaining RH-facing claim is that completed zeta zero rows satisfy the finite normal energy boundary.*

Proof. Definition 9413.694 shows that the finite-window energy is positive off the fixed-half surface, and Definition 9413.695 shows that the cofinal tower is unbounded. These are readout facts, not zero-exclusion facts. The zero-exclusion content is exactly Definition 9413.696, equivalently the finite-energy form of the zeta no-hair boundary in Definition 9413.678. □

Corollary 9413.699 (Finite models mark the zero-relevance gap)**.** *The finite-to-infinite energy tower has the same proof-role shape as the quartic finite spectral carrier: visible finite data become zero-relevant only after a boundary or dominance ledger identifies which visible row controls the zero law.*

Proof. The quartic carrier does not infer endpoint zeros from the mere presence of spectral branches; it uses normalization, real projection, dominance, and fixed-window separation as in Definition 9413.485. In the zeta tower, the visible row is positive normal energy on finite prime windows. The missing zero-relevance ledger is the boundary assertion that a completed zero cannot carry unbounded cofinal normal energy, as stated in Definition 9413.696. □

Concretized in §9002: Finite energy tower packets realize finite prime-window phase rows, positive normal-energy rows, monotone window extension, Real/Complex readback, and nonescape ledgers as NameCert data.

9413.56 Infinite Prime Torus and Far-End Compatibility

The circular image must be calibrated before it is used for the zeta carrier. A circle may arise from a genuine periodic quotient, but it may also arise from a far-end closure of a line. The zeta prime carrier does not have a nonzero time at which all prime phases return to their initial positions. Its infinite closure is instead an interface of compatible finite prime-window readings. The far end is therefore not a period point; it is the cofinal compatibility socket of the infinite prime torus.

Definition 9413.700 (Periodic circle and far-end circle)**.** *The* periodic circle *is the quotient readout*

$$\mathsf{Real}^{\uparrow}/2\pi\mathsf{Int}^{\uparrow} \cong S^1,$$

where the identification is a genuine period row

$$\theta \sim \theta + 2\pi.$$

The far-end circle *is the closure readout*

$$\mathsf{Real}^{\uparrow} \cup \{\infty\} \cong S^1,$$

where ∞ names the closure point of the unbounded line rather than a time period of the flow.

Definition 9413.701 (Finite prime torus projection system)**.** *For a nonempty finite prime window S, let*

$$\mathbb{T}_S := \prod_{p \in S} S^1.$$

If $S \subseteq T$, the projection

$$\pi_{T,S} : \mathbb{T}_T \to \mathbb{T}_S$$

forgets the coordinates in $T \setminus S$. The finite prime tori and forgetful maps form the finite-window projection system of the zeta prime phase carrier.

Definition 9413.702 (Infinite prime torus)**.** *The* infinite prime torus *is the compatible finite-window carrier*

$$\mathbb{T}_{\mathsf{Prime}^\uparrow} := \varprojlim_{S \Subset \mathsf{Prime}^\uparrow} \mathbb{T}_S.$$

Equivalently, it is the cofinal product

$$\mathbb{T}_{\mathsf{Prime}^\uparrow} = \prod_{p \in \mathsf{Prime}^\uparrow} S^1$$

read only through its finite projections

$$\pi_S : \mathbb{T}_{\mathsf{Prime}^\uparrow} \to \mathbb{T}_S.$$

Thus a finite prime window is not an independent small object; it is a finite readout of the infinite prime torus.

Theorem 9413.703 (Prime phase flow lands in the inverse-limit torus)**.** *The phase profile*

$$\Phi_{\mathsf{Prime}^\uparrow}(\tau) = \left(e^{-i\tau \log p}\right)_{p \in \mathsf{Prime}^\uparrow}$$

is a point of the infinite prime torus, and its finite projection is

$$\pi_S\big(\Phi_{\mathsf{Prime}^\uparrow}(\tau)\big) = \Phi_S(\tau).$$

Proof. For each prime p, the coordinate $e^{-i\tau \log p}$ lies in S^1. Thus the family lies in the product $\prod_{p \in \mathsf{Prime}^\uparrow} S^1$. For any inclusion $S \subseteq T$, forgetting the coordinates outside S sends the finite profile on T to the finite profile on S. Hence the finite profiles are compatible under the projection maps of Definition 9413.701, and the cofinal family is an element of the inverse-limit torus. □

Theorem 9413.704 (The infinite prime torus has no common period point)**.** *There is no nonzero real time T such that*

$$\Phi_{\mathsf{Prime}^\uparrow}(\tau + T) = \Phi_{\mathsf{Prime}^\uparrow}(\tau)$$

for every time τ.

Proof. If such a T existed, then every finite prime window containing two distinct primes would have the same nonzero common period. This is excluded by Definition 9413.692. Therefore the infinite prime torus is not a periodic circle with a single return time for all prime coordinates. □

Definition 9413.705 (Prime far-end compatibility)**.** *The* prime far-end compatibility *row is the assertion that an infinite prime-phase state is specified by a compatible family*

$$(x_S)_{S \Subset \mathsf{Prime}^\uparrow}, \qquad x_S \in \mathbb{T}_S,$$

such that for every $S \subseteq T$,

$$\pi_{T,S}(x_T) = x_S.$$

The far end of the prime tower is this compatibility interface. It is not an additional prime, a final finite window, or a hidden coordinate.

Theorem 9413.706 (Far-end compatibility is not phase periodicity)**.** *For the zeta prime phase carrier, far-end closure means compatibility of all finite torus projections, not exact return of all prime phases to a common time origin.*

Proof. Compatibility is the inverse-limit condition of Definition 9413.705. Exact common return would supply a nonzero period for every finite window, hence a nonzero common period for the infinite prime torus. The latter is excluded by Definition 9413.704. Thus the far-end closure role is closer to far-end completion than to a periodic quotient. □

Theorem 9413.707 (Stable normal defect is the common finite-window readout)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

every nonempty finite prime window satisfies

$$\overline{D}_S(s) = -\delta.$$

Consequently the finite windows need not agree in phase, but they do agree on the normalized normal defect.

Proof. The normalized defect calculation is exactly Definition 9413.167. It uses the radial row

$$\log |p^{1/2-s}| = -\delta \log p$$

and divides by the finite logarithmic weight $\sum_{p\in S} \log p$. The phase coordinates $e^{-i\tau \log p}$ need not be periodic across the window. The stable cofinal datum is instead the common normalized normal defect $-\delta$. □

Corollary 9413.708 (Off-half rows are visible in every finite torus readout)**.** *If $\delta\#0$, then every nonempty finite prime window reads a nonzero normalized normal defect and positive normalized second-order energy.*

Proof. By Definition 9413.707, $\overline{D}_S(s) = -\delta$ for every nonempty finite window. Hence $\delta\#0$ gives a nonzero normalized defect in every finite projection. Squaring gives the positive normalized energy δ^2, as in Definition 9413.648 for the parity-refined windows and in Definition 9413.468 for prime-window energy. □

Corollary 9413.709 (The zeta far end cannot be a hidden defect absorber)**.** *The infinite prime torus far end cannot be used to absorb a nonzero normal defect that is visible in every finite window.*

Proof. The far end is the compatibility interface of Definition 9413.705, not an element with an additional coordinate. If $\delta\#0$, then Definition 9413.708 shows that every finite projection reads the same nonzero normalized normal defect, while Definition 9413.695 shows that the unnormalized positive energy is unbounded cofinally. Absorbing this row at the far end would reify the compatibility socket as a hidden correction point, contrary to Definition 9413.683 and Definition 9413.141. □

Corollary 9413.710 (RH as unit infinite-torus zero boundary)**.** *The RH-facing geometric form is that completed zeta zero rows in the critical strip are supported on the unit infinite prime torus, not on a radially deformed prime-torus layer.*

Proof. On the fixed-half surface, the prime phase-radial readback lies in $\mathbb{T}_{\mathsf{Prime}^\uparrow}$ by Definition 9413.703. Off the fixed-half surface, the same finite phase profile is multiplied by the radial row $(p^{-\delta})_{p\in\mathsf{Prime}^\uparrow}$. The latter is detected by every finite normalized defect readout and by the cofinal energy tower of section 9413.55. To prove the RH section is therefore to prove the zero-relevance boundary: completed zero rows cannot live on the radially deformed layer. □

9413.57 Far-End Identity Boundary

The non-point far end can be sharpened once the circular analogy is read correctly. A circular closure is not a reservoir that absorbs an unwanted term. It is an identity action on the displayed boundary coordinate. The equality

$$e^{i(\theta+2\pi)} = e^{i\theta}$$

does not add a compensating correction; it says that the full turn acts as the identity on phase. If a point has radius $r\#1$, the same full turn returns the same radius. Closure does not repair the radius.

Definition 9413.711 (Circular identity closure)**.** *A* circular identity closure *is a closure row whose monodromy acts as the identity on the displayed closed coordinate:*

$$\mathsf{Close}_{S^1}(\theta) = \theta$$

in the quotient readout, or equivalently

$$e^{i(\theta+2\pi)} = e^{i\theta}.$$

It is not a row of the form

$$x \longmapsto x + C_\infty$$

for an undisplayed correction term C_∞.

Definition 9413.712 (Far-end identity)**.** *The* far-end identity *row for the zeta prime-torus carrier is*

$$\mathsf{FarEndIdentity}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{FarEndClosed}_\zeta(s) \to \prod_{A:\mathsf{PAdicParityWindow}_{\neq\varnothing}} (E_A^{\mathrm{pad}}(s) = E_A^{\mathrm{pad}}(\mathsf{Close}_{\mathrm{far}}(s))) \right).$$

It says that far-end closure preserves the finite-window normal energy readouts. The far end may identify compatible phase data, but it does not introduce a normal correction row.

Definition 9413.713 (Far-end identity boundary for zeros)**.** *The* far-end identity boundary *for completed zeta zeros is*

$$\mathsf{FarEndIdentityBoundary}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \Big(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathsf{FarEndEnergyUnity}_\zeta(s) \Big).$$

It asserts that a completed zero row reaches the far end through identity closure of the finite energy readouts, not through a hidden boundary reservoir. This is the zero-facing form of Definition 9413.682.

Theorem 9413.714 (Circular identity does not repair radial displacement)**.** *For $r > 0$ and $r\#1$, circular identity closure preserves the off-unit radius:*

$$re^{i(\theta+2\pi)} = re^{i\theta}.$$

Thus circular closure can identify phase after a full turn, but it does not turn an off-unit radius into a unit radius.

Proof. The identity row gives

$$e^{i(\theta+2\pi)} = e^{i\theta}.$$

Multiplying by the displayed positive radius r gives

$$re^{i(\theta+2\pi)} = re^{i\theta}.$$

No term in this equality changes r. Therefore the apartness row $r\#1$ is preserved by the phase closure. □

Theorem 9413.715 (Far-end identity preserves normal energy)**.** *Assume* $\mathsf{FarEndIdentity}_\zeta$*. If*

$$s = \frac{1}{2} + \delta + i\tau$$

and $\delta^2\#0$*, then no far-end closure of* s *can have all finite prime-adic parity energies equal to zero.*

Proof. For every nonempty prime-adic parity window A, Definition 9413.648 gives

$$E_A^{\mathrm{pad}}(s) = \delta^2.$$

If $\delta^2\#0$, this finite-window energy is nonzero. The far-end identity row preserves each finite energy readout under the closure operation. Hence the closed far-end readout still has

$$E_A^{\mathrm{pad}} = \delta^2\#0$$

for every finite window. It therefore cannot satisfy the cofinal zero-energy condition of Definition 9413.682. □

Corollary 9413.716 (Far-end identity excludes hidden energy absorption)**.** *Far-end identity is the geometric form of no hidden energy correction: a stable positive finite-window energy cannot be removed by passing to the compatibility far end.*

Proof. The hidden correction pattern of Definition 9413.683 would replace a displayed finite-window energy by an altered boundary value. Far-end identity instead preserves the displayed finite-window energy under closure. Therefore the far end acts like the identity closure of Definition 9413.711, not like a reservoir for the nonzero row. □

Theorem 9413.717 (Far-end identity boundary is conditionally sufficient)**.** *If* $\mathsf{FarEndIdentityBoundary}_\zeta$ *holds, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s. The zero row and critical-strip row of z give

$$\mathsf{FarEndEnergyUnity}_\zeta(s)$$

by Definition 9413.713. By Definition 9413.684, this gives $\delta^2 = 0$, hence $\delta = 0$ in the located real readout. Thus

$$\Re(s) = \frac{1}{2}.$$

The section equivalence of Definition 9413.199 supplies the RH fixed-half section. □

Corollary 9413.718 (The proof load is identity closure for zero rows)**.** *The RH-facing proof load may be stated as the claim that completed zeta zero rows use the far end as identity closure of compatible finite readouts, not as a hidden correction mechanism.*

Proof. Definition 9413.709 shows that the infinite prime-torus far end is a compatibility interface. Definition 9413.715 shows that identity closure cannot remove a positive normal energy row. Therefore the remaining zero-specific assertion is that zeta zero rows indeed satisfy the identity-boundary condition of Definition 9413.713. Once that row is supplied, the preceding theorem gives the fixed-half section. □

9413.58 Prime Spiral Projection Kernel

The prime-torus picture should not be read as a common-period picture. The zeta zero row is not a moment at which all prime frequencies synchronize. It is a low-dimensional projection row: an infinite prime-indexed phase-radial state is read through the completed zeta projection, and that projection may vanish. The information hidden by the projection is not thereby absent from the carrier. The RH-facing claim is that no zero projection may hide a nonzero normal height.

Definition 9413.719 (Prime spiral carrier)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

the prime spiral carrier *is the prime-indexed phase-radial row*

$$\mathcal{U}_{\mathsf{Prime}^\uparrow}(s) := \left(p^{1/2-s}\right)_{p\in\mathsf{Prime}^\uparrow} = \left(p^{-\delta}e^{-i\tau\log p}\right)_{p\in\mathsf{Prime}^\uparrow}.$$

Its unit phase part is $\Phi_{\mathsf{Prime}^\uparrow}(\tau)$*, and its normal radial part is the family* $(p^{-\delta})_{p\in\mathsf{Prime}^\uparrow}$*.*

Definition 9413.720 (Completed zeta projection)**.** *The* completed zeta projection *is the schematic projection ledger*

$$\Pi_\zeta : \mathcal{U}_{\mathsf{Prime}^\uparrow}(s) \longmapsto \xi(s),$$

where

$$\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$$

is the completed zeta readout of Definition 9413.140. The notation records a paper-side projection relation between the high-dimensional prime carrier and the completed complex value; it is not a claim that the complex value is the whole carrier.

Definition 9413.721 (Projection zero and ontic balance)**.** *For a critical-strip row* s*, the* projection-zero *row is*

$$\mathsf{ProjectionZero}_\zeta(s) := \Pi_\zeta(\mathcal{U}_{\mathsf{Prime}^\uparrow}(s)) = 0.$$

The ontic-balance *row is*

$$\mathsf{OnticBalance}_\zeta(s) := \delta^2 = 0.$$

Projection zero is a completed complex readout. Ontic balance is a normal-energy readout of the high-dimensional prime spiral carrier.

Theorem 9413.722 (Zero projection is not coordinate synchronization)**.** *A completed zeta zero row states that*

$$\Pi_\zeta(\mathcal{U}_{\mathsf{Prime}^\uparrow}(s)) = 0.$$

It does not state that all prime phase coordinates have a common period or have returned to a common phase.

Proof. The absence of a nonzero common phase period is Definition 9413.704. The zero row belongs instead to the completed projection of Definition 9413.720. By Definition 9413.295, zerohood is a global cancellation in the completed readout, not a local vanishing or synchronization of prime coordinates. □

Definition 9413.723 (Projection kernel ambiguity)**.** *A* projection kernel ambiguity *for the zeta projection is a hypothetical pair of rows*

$$\Pi_\zeta(\mathcal{U}_{\mathsf{Prime}^\uparrow}(s)) = 0, \qquad \delta^2 \# 0.$$

It says that the completed complex projection has vanished while the high-dimensional prime spiral carrier still has nonzero normal height.

Theorem 9413.724 (Off-half projection zeros carry infinite normal energy)**.** *If a projection kernel ambiguity holds for*

$$s = \frac{1}{2} + \delta + i\tau,$$

then the high-dimensional prime spiral carrier carries infinite normal energy:

$$\mathcal{E}_{\mathbb{P}}(s) = \infty.$$

Proof. The ambiguity includes $\delta^2 \# 0$, hence $\delta \# 0$ in the located real readout. For every displayed prime,

$$\log |p^{1/2-s}| = -\delta \log p.$$

Therefore the finite-window square energy is

$$\mathcal{E}_S(s) = \delta^2 \sum_{p \in S} (\log p)^2.$$

As finite prime windows range cofinally, this energy is unbounded by Definition 9413.695, or equivalently by Definition 9413.675. □

Definition 9413.725 (No hidden normal height)**.** *The* no hidden normal height *row for the completed zeta projection is*

$$\mathsf{NoHiddenNormalHeight}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \mathcal{E}_{\mathbb{P}}(s) < \infty)\,.$$

It says that a completed zero projection cannot arise from a high-dimensional prime spiral state with infinite normal energy.

Theorem 9413.726 (No hidden normal height is conditionally sufficient)**.** *If* $\mathsf{NoHiddenNormalHeight}_\zeta$ *holds, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s, and write

$$s = \frac{1}{2} + \delta + i\tau.$$

The zero and critical-strip rows give

$$\mathcal{E}_{\mathbb{P}}(s) < \infty$$

by Definition 9413.725. If $\delta \# 0$, then Definition 9413.675 gives $\mathcal{E}_{\mathbb{P}}(s) = \infty$, a contradiction. Hence $\neg(\delta \# 0)$. Located fixed-half collapse gives $\delta = 0$, and Definition 9413.313 reads this as $\Re(s) = 1/2$. Varying z supplies the RH fixed-half section. □

Corollary 9413.727 (Projection zero needs a zero-relevance boundary)**.** *The RH-facing target is not to prevent phase cancellation in the completed projection. It is to prove that the zero projection cannot hide nonzero normal height in the prime spiral carrier.*

Proof. Phase cancellation is exactly what a completed zero projection records. By Definition 9413.722, this does not imply common prime-period synchronization. By Definition 9413.724, an off-half zero projection would carry infinite normal energy. Thus the missing row is the zero-relevance boundary Definition 9413.725, equivalently the finite-energy form of the no-hair boundary in Definition 9413.678. □

Corollary 9413.728 (Quartic dominance is the finite analogue)**.** *The quartic spectral carrier illustrates the same proof-role distinction: a projected zero law requires a zero-relevant dominant boundary, not merely a visible projected cancellation.*

Proof. The fixed quartic chain identifies endpoint zeros only after the positive-axis dominant sheet and fixed-window separation rows have been displayed, as recorded in Definition 9413.485. In the zeta carrier, the analogous issue is whether a completed zero projection can come from a prime spiral state with hidden normal height. The no-hidden-normal-height row is the infinite prime-tower analogue of that zero-relevance boundary. □

9413.59 Prime Resonance Chord and No-Hair Boundary

The prime spiral projection is better read as a resonance problem than as a common-period problem. Prime logarithms supply distinct frequencies. At a given time, a finite family of prime-adic parity nodes can interfere in the completed complex projection. A zero row is therefore analogous to a projected resonance silence: the first-order complex sum can vanish. The RH-facing obstruction is that this silence must not be produced by a resonance family carrying nonzero normal energy.

Definition 9413.729 (Prime resonance family)**.** *A* prime resonance family *is a nonempty finite window*

$$A \subset \mathsf{Prime}^{\uparrow} \times \mathsf{Nat}^{\uparrow}$$

together with complex weights

$$a_{p,j} \in \mathsf{Complex}^{\uparrow} \qquad ((p,j) \in A).$$

The node frequency is

$$\omega_{p,j} := 2^j \log p,$$

and the node channel is

$$U^{\mathrm{pad}}_{p,j}(s) = p^{-2^j\delta} e^{-i2^j\tau \log p}$$

when $s = 1/2 + \delta + i\tau$.

Definition 9413.730 (Finite resonance chord)**.** *For a prime resonance family* (A, a)*, the* finite resonance chord *is*

$$C_A(s) := \sum_{(p,j)\in A} a_{p,j} U^{\mathrm{pad}}_{p,j}(s).$$

The row

$$C_A(s) = 0$$

is a finite projected silence row: the displayed complex chord closes in the projection, while the individual node channels remain nonzero.

Definition 9413.731 (Hamiltonian resonance island)**.** *For a prime resonance family* (A, a)*, the* Hamiltonian resonance island *is the finite diagonal carrier*

$$\mathcal{H}_A := \operatorname{span}\{|p, j\rangle : (p, j) \in A\}$$

with Hamiltonian

$$H_A|p, j\rangle = h_{p,j}|p, j\rangle, \qquad h_{p,j} := 2^j \log p.$$

For

$$|\psi_A\rangle := \sum_{(p,j)\in A} a_{p,j}|p, j\rangle, \qquad \langle \mathbf{1}_A|p, j\rangle := 1,$$

the finite resonance chord is equivalently

$$C_A(s) = \langle \mathbf{1}_A|e^{-(s-1/2)H_A}|\psi_A\rangle.$$

Thus a projected silence row is a finite Hamiltonian interference row seen through the displayed evaluation covector.

Theorem 9413.732 (The critical line is the unitary resonance surface)**.** *For a Hamiltonian resonance island and*

$$s = \frac{1}{2} + \delta + i\tau,$$

the finite evolution decomposes as

$$e^{-(s-1/2)H_A} = e^{-\delta H_A} e^{-i\tau H_A}.$$

It is unitary exactly on the fixed-half surface $\delta = 0$*.*

Proof. The Hamiltonian H_A is diagonal with real eigenvalues $h_{p,j}$. Since $s - 1/2 = \delta + i\tau$, exponentiating each displayed eigenrow gives the stated factorization. If $\delta = 0$, the evolution is $e^{-i\tau H_A}$, hence every node contributes only a phase. If $\delta\#0$, the factor $e^{-\delta H_A}$ is a real amplitude-bias row, with eigenvalue $e^{-\delta h_{p,j}} = p^{-2^j\delta}$ on node (p, j). This is exactly the nonunitary radial detuning read in Definition 9413.734. □

Theorem 9413.733 (Chord silence is a Pythagorean interference identity)**.** *Let*

$$v_{p,j} := a_{p,j} U^{\mathrm{pad}}_{p,j}(s).$$

If $C_A(s) = 0$*, then*

$$0 = \sum_{(p,j)\in A} |v_{p,j}|^2 + 2 \sum_{(p,j)<(q,k)} \operatorname{Re}\left(v_{p,j}\overline{v_{q,k}}\right),$$

where the second sum ranges over unordered distinct node pairs in A*.*

Proof. The square of the projected chord is

$$\left|\sum_{(p,j)\in A} v_{p,j}\right|^2.$$

Expanding the Hermitian square gives

$$\left|\sum_{(p,j)\in A} v_{p,j}\right|^2 = \sum_{(p,j)\in A} |v_{p,j}|^2 + 2 \sum_{(p,j)<(q,k)} \operatorname{Re}\left(v_{p,j}\overline{v_{q,k}}\right).$$

When $C_A(s) = \sum v_{p,j} = 0$, the left side is zero, giving the stated identity. Thus projected silence is an exact balance between positive node magnitudes and phase interference terms. □

Definition 9413.734 (Detuned resonance energy)**.** *The* normal detuning *of a node is*

$$d_{p,j}(s) := \log |U_{p,j}^{\mathrm{pad}}(s)| = -2^j \delta \log p.$$

The unnormalized normal energy of a resonance family is

$$\mathcal{E}_A^{\mathrm{res}}(s) := \sum_{(p,j)\in A} d_{p,j}(s)^2.$$

The normalized normal energy is

$$E_A^{\mathrm{res}}(s) := \left(\frac{\sum_{(p,j)\in A} d_{p,j}(s)}{\sum_{(p,j)\in A} 2^j \log p} \right)^2.$$

Theorem 9413.735 (Detuned resonance reads the normal coordinate)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

every prime resonance family satisfies

$$E_A^{\mathrm{res}}(s) = \delta^2.$$

If $\delta \# 0$, then every nonempty resonance family has positive normalized normal energy.

Proof. By Definition 9413.734,

$$\sum_{(p,j)\in A} d_{p,j}(s) = -\delta \sum_{(p,j)\in A} 2^j \log p.$$

The denominator is the positive prime-adic parity weight of Definition 9413.647. Dividing gives $-\delta$, and squaring gives $E_A^{\mathrm{res}}(s) = \delta^2$. Hence apartness of δ from zero gives positive normalized normal energy for every nonempty family. □

Definition 9413.736 (Centered Hamiltonian variance energy)**.** *Assume the coefficient vector of a prime resonance family is nonzero. Set*

$$P_{p,j} := \frac{|a_{p,j}|^2}{\sum_{(q,k)\in A} |a_{q,k}|^2}.$$

The weighted Hamiltonian mean and variance are

$$\langle H_A \rangle_\psi := \sum_{(p,j)\in A} P_{p,j} h_{p,j},$$

$$\mathrm{Var}_\psi(H_A) := \sum_{(p,j)\in A} P_{p,j} \left(h_{p,j} - \langle H_A \rangle_\psi \right)^2.$$

The centered Hamiltonian detuning energy is

$$\mathcal{Q}_A^\psi(s) := \delta^2 \, \mathrm{Var}_\psi(H_A).$$

Theorem 9413.737 (Prime Hamiltonian levels are separated)**.** *If $(p,j) \neq (q,k)$, then*

$$2^j \log p \neq 2^k \log q.$$

Proof. If $p = q$, positivity of $\log p$ gives $2^j = 2^k$, hence $j = k$. If $p \neq q$, equality would give the nontrivial rational linear relation

$$2^j \log p - 2^k \log q = 0,$$

contradicting Definition 9413.677. Thus distinct prime-adic parity nodes have distinct Hamiltonian levels. □

Theorem 9413.738 (Centered nonunitary cost is variance energy)**.** *For a nonzero coefficient vector, define*

$$N_A^\circ(\delta, \psi) := \sum_{(p,j)\in A} P_{p,j} e^{-2\delta(h_{p,j} - \langle H_A \rangle_\psi)}.$$

Then

$$N_A^\circ(0, \psi) = 1, \qquad \frac{d}{d\delta} N_A^\circ(0, \psi) = 0,$$

and

$$\frac{1}{2} \frac{d^2}{d\delta^2} N_A^\circ(0, \psi) = 2 \operatorname{Var}_\psi(H_A).$$

Consequently the first nonzero centered nonunitary cost is the positive quadratic variance row.

Proof. At $\delta = 0$, all exponential factors are 1, and the weights $P_{p,j}$ sum to 1. The first derivative is

$$-2 \sum_{(p,j)\in A} P_{p,j} \left(h_{p,j} - \langle H_A \rangle_\psi\right),$$

which is zero by the definition of the weighted mean. The second derivative at zero is

$$4 \sum_{(p,j)\in A} P_{p,j} \left(h_{p,j} - \langle H_A \rangle_\psi\right)^2 = 4 \operatorname{Var}_\psi(H_A).$$

Taking one half gives the stated coefficient. Thus centering removes the signed first-order bias, while the second-order Hamiltonian spread remains. □

Corollary 9413.739 (Nontrivial resonance support has positive variance)**.** *If the nonzero coefficients of a prime resonance family include two distinct nodes, then*

$$\operatorname{Var}_\psi(H_A) > 0.$$

Hence $\delta \# 0$ gives

$$\mathcal{Q}_A^\psi(s) > 0.$$

Proof. By Definition 9413.737, the two displayed nonzero nodes have distinct Hamiltonian levels. A weighted finite distribution supported on at least two distinct real levels has positive variance. Multiplying by δ^2 gives positive centered Hamiltonian detuning energy whenever $\delta \# 0$. □

Theorem 9413.740 (Projected silence does not cancel detuning energy)**.** *The chord silence row*

$$C_A(s) = 0$$

does not imply

$$E_A^{\mathrm{res}}(s) = 0.$$

It only states first-order complex projection cancellation.

Proof. Definition 9413.733 shows that projected silence balances positive complex magnitudes against phase-interference cross terms. The detuning energy of Definition 9413.734 is instead the square of the normal logarithmic radial readout. By Definition 9413.735, that normalized energy is δ^2 independently of the phase interference. Therefore projected silence does not remove normal detuning. Equivalently, after centering the Hamiltonian island, Definition 9413.738 shows that the first surviving nonunitary cost is the variance row. □

Definition 9413.741 (Stable zero-relevant resonance family)**.** *A* stable zero-relevant resonance family *for a critical-strip row s is a cofinal family of finite resonance chords whose projected silence rows are compatible with the completed zero ledger*

$$\mathsf{ZetaZero}(s).$$

The definition is a proof-role placeholder: it names the resonance families that a completed zero proof actually uses, and it does not assert that every visible finite chord is zero-relevant. For such a witness ρ, write $E_\rho^{\mathrm{res}}(s)$ for the normalized normal energy inherited from the finite resonance chords in that family.

Definition 9413.742 (Resonance no-hair boundary)**.** *The* resonance no-hair boundary *is*

$$\mathsf{ResonanceNoHair}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \prod_{\rho:\mathsf{StableResFam}_\zeta(s)} \Big(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to E_\rho^{\mathrm{res}}(s) = 0\Big).$$

It says that any resonance family that is genuinely zero-relevant for the completed zeta ledger must carry zero normalized normal detuning.

Corollary 9413.743 (Resonance no-hair is stable unitarity)**.** *Under* $\mathsf{ResonanceNoHair}_\zeta$*, every stable zero-relevant resonance family for a critical-strip zero is forced onto the unitary resonance surface.*

Proof. For a stable zero-relevant family ρ, resonance no-hair gives $E_\rho^{\mathrm{res}}(s) = 0$. The finite readout inherited by ρ is the normalized detuning readout of Definition 9413.735, so $E_\rho^{\mathrm{res}}(s) = \delta^2$. Hence $\delta = 0$ by located collapse. By Definition 9413.732, the associated Hamiltonian evolution is unitary. □

Theorem 9413.744 (Resonance no-hair is conditionally sufficient)**.** *If every critical-strip zero row carries a stable zero-relevant resonance family and* $\mathsf{ResonanceNoHair}_\zeta$ *holds for those families, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s, and write

$$s = \frac{1}{2} + \delta + i\tau.$$

By the stable-family hypothesis, let ρ be a stable zero-relevant resonance family associated to the completed zero row of z. The resonance no-hair boundary gives

$$E_\rho^{\mathrm{res}}(s) = 0.$$

By Definition 9413.735, the same energy is δ^2. Hence $\delta^2 = 0$, and located collapse gives $\delta = 0$. Therefore $\Re(s) = 1/2$, and the fixed-half section is obtained by Definition 9413.199. □

Corollary 9413.745 (Quartic endpoint zeros are finite resonance guidance)**.** *The fixed quartic endpoint-zero law is a finite model for the zero-relevant resonance distinction: branch interference produces zeros only after the active dominant family has been identified.*

Proof. Definition 9413.102 states that the endpoint-zero law is obtained from active local branches, amplitudes, a cosine interference model, and Rouché isolation. Definition 9413.99 shows that not every branch collision is zero-relevant; dominance is the additional ledger. The resonance no-hair boundary plays the analogous role for zeta: not every projected chord is the proof object, and a stable zero-relevant resonance family must satisfy the normal-energy boundary. □

Corollary 9413.746 (The resonance formulation refines the projection-kernel gap)**.** *The projection-kernel ambiguity of Definition 9413.723 can be read as a detuned resonance family whose projected chord is silent while its normal energy remains nonzero.*

Proof. The projection-kernel ambiguity combines completed projection zero with nonzero normal height. A finite resonance chord models the same pattern locally: $C_A(s) = 0$ is projected silence, while Definition 9413.735 reads the hidden normal height as $E_A^{\mathrm{res}}(s) = \delta^2$. Thus the resonance formulation does not replace the no-hair target; it expresses the same target at the level of zero-relevant chord families. □

9413.60 Local Half-Split Certificate

The resonance picture should not be read as if an entire infinite prime spiral suddenly collapses to zero. A zero-relevant event is local: after dominance and normalization have been displayed, the completed read is cut by a finite two-branch interference island. The RH-facing content is that a stable local cut must be a half-split. The real coordinate controls length balance; the imaginary coordinate records the remaining phase quantization.

Theorem 9413.747 (Two-vector silence is equal length and opposite phase)**.** *For nonzero complex vectors $A, B \in \mathsf{Complex}^{\uparrow}$, the row*

$$A + B = 0$$

is equivalent to

$$|A| = |B|$$

and

$$\arg(A) - \arg(B) \equiv \pi \pmod{2\pi}.$$

Proof. If $A + B = 0$, then $A = -B$, so the two vectors have equal modulus and opposite phase. Conversely, equal modulus and phase difference π give $A = -B$, hence $A + B = 0$. □

Concretized in §8881: Finite NameCert carrier for the local two-branch half-split certificate.

Definition 9413.748 (Local two-branch zero island)**.** *A* local two-branch zero island *for a critical-strip row s is a local decomposition*

$$\Xi(u) = A_n(u) + B_n(u) + R_n(u)$$

on a disk D_n around s, together with rows saying that A_n and B_n are the two dominant branches and that the remainder satisfies the Rouché boundary discipline required to preserve the local zero count. The row is zero-relevant only after these dominance and tail rows are displayed; a visible two-term split without them is merely a projection model.

Definition 9413.749 (Half-split coordinate)**.** *For a local two-branch zero island, the* half-split coordinate *at s is the length-balance row*

$$|A_n(s)| = |B_n(s)|.$$

Equivalently, the zero cuts the normalized local segment into two equal halves. The complementary phase row is

$$\arg(A_n(s)/B_n(s)) \equiv (2k_n - 1)\pi \pmod{2\pi}.$$

The half-split row records the real-length constraint, while the phase row records the height or time quantization.

Definition 9413.750 (Real-defect split formula)**.** *A local two-branch zero island has a* real-defect split formula *when there is a positive branch-separation scale H_n and a bounded correction row ε_n such that*

$$\log \frac{|A_n(s)|}{|B_n(s)|} = -2\delta H_n + \varepsilon_n$$

for

$$s = \frac{1}{2} + \delta + i\tau.$$

The term $-2\delta H_n$ is the normal length bias. The correction ε_n belongs to amplitude normalization, finite-window tail control, or coordinate choice; it is not allowed to encode a hidden noncompact real scale along a cofinal tower.

Definition 9413.751 (Zeta local half-split certificate)**.** *For a critical-strip zeta zero s, a* zeta local half-split certificate *consists of a cofinal family of local two-branch zero islands with:*

$$\mathsf{DominantTwoBranch}(A_n, B_n), \qquad \mathsf{RoucheTailControl}(R_n),$$

$$\mathsf{HalfSplit}(A_n, B_n, s), \qquad \mathsf{RealDefectSplitFormula}(H_n, \varepsilon_n),$$

and a no-hidden-real-correction row saying that ε_n cannot cofinally cancel $-2\delta H_n$ when $\delta \# 0$ and the displayed branch-separation scales remain unbounded or otherwise non-negligible.

Theorem 9413.752 (Local half-split certificates are conditionally sufficient)**.** *If every critical-strip zeta zero carries a zeta local half-split certificate, then the RH fixed-half section exists.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

The certificate supplies local islands with

$$|A_n(s)| = |B_n(s)|.$$

Thus

$$\log \frac{|A_n(s)|}{|B_n(s)|} = 0.$$

The real-defect split formula gives

$$0 = -2\delta H_n + \varepsilon_n.$$

If $\delta \# 0$, the normal term cannot be cofinally cancelled by ε_n by the no-hidden-real-correction row. This contradicts the half-split equation. Hence $\neg(\delta \# 0)$, and located fixed-half collapse gives $\delta = 0$. Therefore $\Re(s) = 1/2$, and the fixed-half section follows from Definition 9413.199. □

Corollary 9413.753 (Phase carries the remaining zero data)**.** *Once a zero-relevant local island has been normalized to a half-split, the remaining zero-location data are phase data.*

Proof. By Definition 9413.747, the local zero condition for the dominant pair is equal length together with opposite phase. The half-split certificate supplies the equal length row. The remaining equation is therefore

$$\arg(A_n(s)/B_n(s)) \equiv (2k_n - 1)\pi \pmod{2\pi}.$$

If the active branches have phase factors of the form

$$A_n(s) \sim C_+ e^{-i\tau H_+}, \qquad B_n(s) \sim C_- e^{-i\tau H_-},$$

then the height coordinate τ is determined by the corresponding phase congruence. The real part supplies length balance; the imaginary part records phase quantization. □

Corollary 9413.754 (Quartic endpoint zeros supply the finite template)**.** *The fixed quartic endpoint-zero law is the finite model for the local half-split certificate.*

Proof. In the quartic carrier, endpoint zeros are obtained only after the positive-axis dominant branches, local Puiseux expansions, partial-fraction amplitudes, and Rouché tail control are displayed, as recorded in Definition 9413.102. The active two-branch sum is transported to a shifted cosine model, whose zeros occur at odd half-periods. This is precisely the finite half-split pattern: equal dominant lengths with phase difference an odd multiple of π. The quartic result remains a fixed-window finite template, not a global zeta theorem. □

Corollary 9413.755 (Local half-split refines resonance no-hair)**.** *The local half-split certificate refines the resonance no-hair boundary by identifying the finite zero island on which the normal-energy condition is zero-relevant.*

Proof. The resonance no-hair boundary of Definition 9413.742 states that a stable zero-relevant resonance family has zero normalized detuning. The local half-split certificate explains what makes the family zero-relevant: a two-branch dominant island, Rouché tail control, length equality, and a real-defect split formula. Thus the certificate prevents projected silence from being mistaken for a proof object; it requires the local segment on which the zero actually acts. □

Corollary 9413.756 (Relation to solenoid and selector routes)**.** *The split-prime, Dedekind, and Zeckendorf solenoid routes supply possible source mechanisms for the branch-separation scale H_n in a local half-split certificate.*

Proof. In the fixed split-prime route, H_n is supplied by the repeated local rows above a rational prime q. In the Dedekind route, it is supplied by the prime-ideal rows in the lifted tower. In the Zeckendorf selector route, it is supplied by the golden-cofinal prime family selected by the no-adjacent grammar. Each route contributes a source for the length ledger; solenoid compatibility and Lee–Yang stability are then the candidate mechanisms preventing a hidden real correction from absorbing a nonzero δ. □

9413.61 Endpoint Bisection Certificate

The infinite spiral picture is too coarse if it is read as a literal endpoint of the full Dirichlet polyline. The zero-relevant object must be a finite endpoint model equipped with dominance, tail control, and a distinguished segment on which the zero acts. The fixed quartic carrier supplies the finite

template: endpoint zeros are produced by active branch interference after a dominant endpoint window and a Rouché ledger have been displayed. For zeta, the corresponding candidate is the Riemann–Siegel or approximate-functional-equation endpoint window, where the completed read is split into two finite arms and a controlled remainder.

Definition 9413.757 (Normalized zeta segment channel)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau$$

and $n \geq 1$*, the* normalized zeta segment channel *is*

$$u_n(s) := n^{1/2-s} = n^{-\delta} e^{-i\tau \log n}.$$

Its straightened log-length defect is

$$\ell_n(s) := \log |u_n(s)| = -\delta \log n.$$

The raw Dirichlet or eta segment may have a baseline length such as $n^{-1/2}$*; the normalized channel removes that baseline and records only the unitary versus radial component. Thus the critical line is the row*

$$|u_n(s)| = 1$$

for every displayed n*.*

Theorem 9413.758 (Weighted endpoint energy reads the normal displacement)**.** *For* $N \geq 2$*, define*

$$\mathcal{E}_N^{\zeta}(s) := \sum_{1 \leq n \leq N} \frac{1}{n} \left(\log |n^{1/2-s}| \right)^2.$$

If $s = 1/2 + \delta + i\tau$*, then*

$$\mathcal{E}_N^{\zeta}(s) = \delta^2 \sum_{1 \leq n \leq N} \frac{(\log n)^2}{n}.$$

Consequently, if $\delta \# 0$*, then*

$$\sup_N \mathcal{E}_N^{\zeta}(s) = \infty.$$

Proof. By Definition 9413.757,

$$\log |n^{1/2-s}| = -\delta \log n.$$

Squaring and summing with weight $1/n$ gives the displayed identity. The positive summands $(\log n)^2/n$ are unbounded in total: for $N \geq 2$,

$$\sum_{2 \leq n \leq N} \frac{(\log n)^2}{n}$$

dominates a cofinal subseries obtained by grouping n into dyadic blocks, and the block contributions diverge. Multiplication by $\delta^2 > 0$ preserves divergence in the located positive readout. □

Definition 9413.759 (Finite endpoint segment and bisection parameter)**.** *Let*

$$P_m(s) := \sum_{1 \leq n \leq m} v_n(s)$$

be a finite partial read in a displayed endpoint model. The endpoint segment *at m is the affine segment*

$$P_{m-1}(s) + \lambda v_m(s), \qquad 0 \le \lambda \le 1.$$

If the segment contains the origin, its bisection parameter $\lambda_m(s)$ *is the value satisfying*

$$P_{m-1}(s) + \lambda_m(s) v_m(s) = 0.$$

Theorem 9413.760 (Endpoint bisection is endpoint symmetry)**.** *Assume that a finite endpoint segment contains the origin. Then*

$$\lambda_m(s) = \frac{1}{2}$$

if and only if

$$P_m(s) = -P_{m-1}(s).$$

Proof. The origin condition is

$$P_{m-1}(s) + \lambda_m(s) v_m(s) = 0.$$

If $\lambda_m(s) = 1/2$, then

$$P_{m-1}(s) = -\frac{1}{2} v_m(s),$$

and hence

$$P_m(s) = P_{m-1}(s) + v_m(s) = \frac{1}{2} v_m(s) = -P_{m-1}(s).$$

Conversely, if $P_m(s) = -P_{m-1}(s)$, then

$$2P_{m-1}(s) + v_m(s) = 0,$$

so the origin is reached at $\lambda = 1/2$. □

Definition 9413.761 (Riemann–Siegel endpoint model row)**.** *A* Riemann–Siegel endpoint model row *for a completed zeta read at height τ consists of:*

$$N(\tau) \sim \sqrt{\frac{\tau}{2\pi}},$$

two finite arms of approximate-functional-equation type

$$\sum_{n \le x} n^{-s}, \qquad \chi(s) \sum_{n \le y} n^{s-1}, \qquad xy \sim \frac{\tau}{2\pi},$$

a symmetric endpoint choice $x \sim y \sim N(\tau)$, and a remainder row. On the critical line this row is transported to a real finite Riemann–Siegel read of the form

$$2 \sum_{n \le N(\tau)} n^{-1/2} \cos(\theta(\tau) - \tau \log n)$$

plus the displayed remainder. The row is a candidate zero-relevant endpoint model only when dominance and tail bounds identify a local zero island.

Definition 9413.762 (Endpoint bisection certificate)**.** *For a critical-strip zeta zero $s = 1/2+\delta+i\tau$, a* zeta endpoint bisection certificate *consists of a cofinal family of canonical finite endpoint models $F_N(s)$ with endpoint segments $e_N(s)$ and positive endpoint scales h_N, together with rows:*

$$\Xi(s) = F_N(s) + T_N(s), \qquad \mathsf{RoucheGap}(F_N, T_N),$$

$$\mathsf{ZeroRelevantEndpoint}(e_N, s), \qquad \lambda_N(s) \to \frac{1}{2},$$

$$\lambda_N(s) = \frac{1}{2} \Longleftrightarrow |e^{-(s-1/2)h_N}| = 1,$$

and a cofinal growth row such as

$$h_N \to \infty.$$

The Rouché row prevents a projected finite chord from being treated as a zero certificate. The straightened equivalence says that bisection in the endpoint segment is the unit-length condition in the normalized normal coordinate.

Theorem 9413.763 (Endpoint bisection certificates are conditionally sufficient)**.** *If every critical-strip zeta zero carries a zeta endpoint bisection certificate whose limiting bisection row forces*

$$\log |e^{-(s-1/2)h_N}| \to 0,$$

then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

The certificate supplies positive scales h_N with $h_N \to \infty$ and the limiting straightened read

$$\log |e^{-(s-1/2)h_N}| \to 0.$$

But

$$\log |e^{-(s-1/2)h_N}| = -\delta h_N.$$

If $\delta \# 0$, then the displayed expression cannot converge to 0 along a cofinal sequence with $h_N \to \infty$. Hence $\neg(\delta \# 0)$. Located fixed-half collapse gives $\delta = 0$. Therefore $\Re(s) = 1/2$, and Definition 9413.199 gives the fixed-half section. □

Corollary 9413.764 (Endpoint bisection refines local half-split)**.** *The endpoint bisection certificate refines the local half-split certificate by specifying a zeta-native finite endpoint model in which the half-split is to be read.*

Proof. Definition 9413.751 requires a local two-branch zero island, Rouché tail control, length equality, and a real-defect split formula. The endpoint bisection certificate adds a candidate source for that local island: a Riemann–Siegel or approximate-functional-equation endpoint window with a distinguished endpoint segment. Thus the half-split row is no longer attached to an arbitrary finite chord; it is attached to a completed zeta endpoint model whose tail and dominance ledgers are part of the certificate. □

Corollary 9413.765 (The quartic endpoint row is the finite bisection template)**.** *The fixed quartic endpoint-zero row is the finite template for the zeta endpoint bisection route.*

Proof. By Definition 9413.102, the quartic endpoint zeros are obtained only after the active colliding branches, endpoint scale, amplitude rows, and Rouché isolation are displayed. The resulting shifted cosine zeros are finite half-period interference points. The zeta endpoint bisection certificate asks for the analogous finite endpoint structure in the completed zeta read: not a bare infinite polyline endpoint, but a zero-relevant endpoint window with a distinguished bisection segment and a controlled remainder. □

Corollary 9413.766 (Solenoid fibres do not hide real scale)**.** *In an endpoint bisection certificate, solenoid-compatible hidden data may carry phase and prime-register information, but not the real positive scale* $e^{-\delta h_N}$*.*

Proof. The solenoid route records compact phase together with prime-adic fibre data, as in Definition 9413.780. The normal endpoint factor

$$e^{-\delta h_N}$$

belongs to the noncompact positive real scale direction. The straightened equivalence in Definition 9413.762 therefore cannot be discharged by placing δ inside the hidden solenoid fibre. The fibre may preserve residue or phase information; it is not a reservoir for the real radial defect. □

Concretized in §8940: Endpoint bisection certificates are realized as finite NameCert data over RHRoute endpoint intervals, branch choices, preservation rows, and local half-split handoff.

9413.62 Zeta Resonance Bound Stability

The resonance no-hair boundary names the obstruction, but the route out of circularity is an upper-bound theorem. The desired zeta analogue of a Lee–Yang location theorem is not another restatement of the critical line. It is a stability row saying that any resonance family which is actually zero-relevant for the completed zeta ledger has bounded normal energy along its finite prime-adic windows. Off the fixed-half surface, the same finite-window energy is forced to diverge; therefore a genuine upper-bound theorem would place stable completed zeros on the unitary boundary.

Definition 9413.767 (Resonance window square energy)**.** *For a finite prime-adic parity window*

$$B \subset \mathsf{Prime}^{\uparrow} \times \mathsf{Nat}^{\uparrow},$$

the resonance window square energy *is*

$$\mathcal{N}_B(s) := \sum_{(p,j)\in B} \Big(\log |U_{p,j}^{\mathrm{pad}}(s)|\Big)^2 .$$

This is the unnormalized positive normal energy of the displayed Hamiltonian levels in the resonance family.

Theorem 9413.768 (Finite resonance energy reads the off-half displacement)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

every finite prime-adic parity window B *satisfies*

$$\mathcal{N}_B(s) = \delta^2 \sum_{(p,j)\in B} (2^j \log p)^2.$$

Proof. By the prime-adic parity channel definition,

$$U_{p,j}^{\mathrm{pad}}(s) = p^{2^j(1/2-s)} = p^{-2^j\delta}e^{-i2^j\tau\log p}.$$

Thus

$$\log|U_{p,j}^{\mathrm{pad}}(s)| = -2^j\delta\log p.$$

Squaring and summing over B gives the displayed formula. □

Definition 9413.769 (Cofinal resonance support)**.** *A stable zero-relevant resonance family ρ has* cofinal prime-adic support *when its finite windows contain a cofinal subsystem of prime-adic parity windows whose square weights*

$$\sum_{(p,j)\in B}(2^j\log p)^2$$

are unbounded.

Theorem 9413.770 (Off-half cofinal resonance energy is unbounded)**.** *Let ρ have cofinal prime-adic support. If*

$$s = \frac{1}{2} + \delta + i\tau$$

and $\delta\#0$, then

$$\sup_{B\preceq\rho}\mathcal{N}_B(s) = \infty,$$

where $B \preceq \rho$ ranges over the finite windows displayed by the family.

Proof. By Definition 9413.768, each finite displayed window satisfies

$$\mathcal{N}_B(s) = \delta^2\sum_{(p,j)\in B}(2^j\log p)^2.$$

The cofinal support hypothesis says that the square-weight sums are unbounded along the family. Since $\delta\#0$, multiplication by δ^2 preserves unboundedness in the located positive readout. □

Definition 9413.771 (Zeta resonance bound)**.** *The* zeta resonance bound *is the row*

$$\mathsf{ZetaResonanceBound}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow}\prod_{\rho:\mathsf{StableResFam}_\zeta(s)}\left(\mathsf{ZetaZero}(s)\times\mathsf{InCritStrip}(s)\to\sup_{B\preceq\rho}\mathcal{N}_B(s)<\infty\right).$$

It says that every stable resonance family actually used by a completed zero proof has a uniform finite normal-energy bound. The row is zero-relevance data: it does not require all visible finite chords to be controlled by one common window, and it allows different zero rows to use different stable resonance families.

Theorem 9413.772 (The zeta resonance bound is conditionally sufficient)**.** *Assume every critical-strip completed zero carries a stable zero-relevant resonance family with cofinal prime-adic support. If*

$$\mathsf{ZetaResonanceBound}_\zeta$$

holds for those families, then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s, and write

$$s = \frac{1}{2} + \delta + i\tau.$$

Let ρ be the stable zero-relevant resonance family attached to the completed zero row. The zeta resonance bound gives

$$\sup_{B \preceq \rho} \mathcal{N}_B(s) < \infty.$$

If $\delta \# 0$, then Definition 9413.770 gives the contradictory extended readout

$$\sup_{B \preceq \rho} \mathcal{N}_B(s) = \infty.$$

Thus $\neg(\delta \# 0)$. Located collapse gives $\delta = 0$, and Definition 9413.199 supplies the fixed-half section. □

Theorem 9413.773 (Strict non-archimedean dominance prevents finite silence)**.** *Let $|\cdot|_\nu$ be a non-archimedean absolute value on a finite field of coefficients. For a finite family $(x_a)_{a \in A}$, if one term strictly dominates,*

$$|x_{a_0}|_\nu > \max_{a \neq a_0} |x_a|_\nu,$$

then

$$\sum_{a \in A} x_a \neq 0.$$

Proof. The strong triangle inequality gives

$$\left| \sum_{a \neq a_0} x_a \right|_\nu \leq \max_{a \neq a_0} |x_a|_\nu < |x_{a_0}|_\nu.$$

Hence the sum of the remaining terms cannot equal $-x_{a_0}$. Therefore the full finite sum is nonzero. □

Definition 9413.774 (Lee–Yang type resonance stability certificate)**.** *A* Lee–Yang type resonance stability certificate *for a stable resonance family ρ consists of four displayed rows:*

$$\mathsf{DominantFamily}(\rho), \qquad \mathsf{NoStrictLocalDominance}(\rho),$$

$$\mathsf{TailBound}(\rho), \qquad \mathsf{FarEndEnergyBound}(\rho).$$

The dominance row identifies which finite spectral or prime-adic levels are zero-relevant. The no-strict-local-dominance row is the non-archimedean or tropical analogue of the preceding theorem: a finite zero can occur only where dominant levels tie rather than where one level strictly dominates. The tail-bound row prevents non-dominant levels from changing the zero ledger. The far-end energy-bound row is the uniform bound consumed by Definition 9413.771.

Theorem 9413.775 (Lee–Yang type stability supplies the resonance bound)**.** *If every stable zero-relevant resonance family for a completed critical-strip zero carries a Lee–Yang type resonance stability certificate, then*

$$\mathsf{ZetaResonanceBound}_\zeta$$

holds for those families.

Proof. The certificate explicitly contains the row

$$\mathsf{FarEndEnergyBound}(\rho),$$

which is the finite uniform bound on

$$\sup_{B \preceq \rho} \mathcal{N}_B(s).$$

The other rows explain why this bound is zero-relevant rather than a bound on an arbitrary visible chord: dominance selects the active family, local non-archimedean or tropical stability prevents strict-dominance zeros, and the tail bound preserves the finite zero ledger through the far-end passage. Therefore the bound row is exactly Definition 9413.771. □

Corollary 9413.776 (The quartic carrier is the finite stability template)**.** *The fixed quartic spectral carrier supplies the finite template for the zeta resonance-bound target: zero location is controlled by dominance, local branch interference, and a tail estimate, not by a bare projection zero.*

Proof. Definition 9413.99 separates the zero-relevant dominant branch from other visible branch data. Definition 9413.102 then uses active amplitudes, local interference, and Rouché isolation to locate endpoint zeros. Thus the quartic row has the same proof-role shape as Definition 9413.774: dominance, stability of the active family, and a remainder bound precede the zero-location conclusion. □

Corollary 9413.777 (The bound target avoids a fixed-window assumption)**.** *The zeta resonance-bound route does not assert that all completed zeros are controlled by one finite prime window. It quantifies over the stable resonance family attached to each zero row.*

Proof. The quantified family $\rho : \mathsf{StableResFam}_\zeta(s)$ in Definition 9413.771 is indexed by the zero coordinate s. Different completed zero rows may therefore expose different finite windows, different prime-adic depths, and different dominant resonance islands. The common assertion is only the stability bound: whichever family becomes zero-relevant must have finite normal energy at the completed far end. □

9413.63 Solenoid Lee–Yang Resonance Boundary

The prime-torus and prime-adic slicing pictures can be joined by a solenoid carrier. A solenoid is a compact phase object whose visible face is a unit circle and whose hidden fibres record the admitted prime-adic directions. This is the natural place to state the Lee–Yang-like zeta target: if the zero-relevant resonance data of a completed zeta zero is really realized inside such a compact solenoid phase carrier, then there is no room for an additional real positive normal scale.

Definition 9413.778 (S-localization)**.** *For a displayed prime family $S \subseteq \mathsf{Prime}^{\uparrow}$, the S-localization of the integers is*

$$\mathbb{Z}[S^{-1}] := \left\{ \frac{a}{b} \in \mathbb{Q} : a \in \mathbb{Z},\ b \in \mathbb{N},\ \mathsf{PrimeDiv}(b) \subseteq S \right\}.$$

The inclusion

$$\iota : \mathbb{Z} \hookrightarrow \mathbb{Z}[S^{-1}]$$

records the ordinary integer phase row, while primes in S are declared invertible gates in the localized carrier.

Definition 9413.779 (S-solenoid over the unit circle)**.** *The* S-solenoid *is the compact abelian phase carrier*

$$\Sigma_S := \widehat{\mathbb{Z}[S^{-1}]},$$

the Pontryagin dual of the localized integer carrier. Dualizing ι *gives the visible unit-circle projection*

$$\pi_S : \Sigma_S \twoheadrightarrow \widehat{\mathbb{Z}} \cong \mathbb{T}.$$

Its invisible fibre is

$$K_S := \ker(\pi_S).$$

For finite S *with* $N = \prod_{p \in S} p$*, the same carrier may be read as the inverse-limit solenoid*

$$\Sigma_S \cong \varprojlim \left(\mathbb{T} \xleftarrow{z \mapsto z^N} \mathbb{T} \xleftarrow{z \mapsto z^N} \mathbb{T} \xleftarrow{z \mapsto z^N} \cdots \right).$$

Thus Σ_S *packages the visible unit phase together with the* S*-prime fibre registers behind that phase.*

Definition 9413.780 (Solenoid-compatible resonance lift)**.** *Let* $s = 1/2 + \delta + i\tau$*. A stable zero-relevant resonance family* $\rho : \mathsf{StableResFam}_\zeta(s)$ *has a* solenoid-compatible resonance lift *when there is a nonempty prime family* S_ρ*, a compact phase carrier* Σ_{S_ρ}*, and a factorization of the zero-relevant phase data through*

$$\Sigma_{S_\rho} \twoheadrightarrow \mathbb{T}$$

such that every displayed node

$$a = (p, j), \qquad p \in S_\rho,$$

has local coordinate

$$U_a(s) = p^{2^j(1/2-s)} = e^{-\delta h_a} e^{-i\tau h_a}, \qquad h_a := 2^j \log p,$$

and the real positive modulus row

$$|U_a(s)| = e^{-\delta h_a}$$

is required to come from a continuous real positive character of the compact solenoid phase carrier, rather than from an additional noncompact scale coordinate. Write $\mathsf{SolenoidCompatible}(\rho, s)$ *for the existence of such a lift.*

Lemma 9413.781 (Compact phase carriers have no nontrivial positive scale character)**.** *Let* G *be a compact group. Every continuous group homomorphism*

$$\rho : G \to \mathsf{Real}^{\uparrow}_{>0}$$

is trivial:

$$\rho(g) = 1 \qquad (g \in G).$$

Proof. The image $\rho(G)$ is a compact subgroup of $\mathsf{Real}^{\uparrow}_{>0}$. Applying the logarithm gives a compact subgroup

$$\log \rho(G) \subseteq (\mathsf{Real}^{\uparrow}, +).$$

The additive real line has no nontrivial compact subgroup: if a nonzero element x were present, then the infinite set $\{nx : n \in \mathbb{Z}\}$ would be an unbounded subgroup. Hence $\log \rho(G) = \{0\}$, so $\rho(G) = \{1\}$. □

Theorem 9413.782 (Solenoid-compatible resonance has no normal scale)**.** *Let $s = 1/2 + \delta + i\tau$ and suppose a stable zero-relevant resonance family for s has a solenoid-compatible resonance lift. Then*

$$\delta = 0.$$

Proof. For each displayed node $a = (p, j)$ in the lift,

$$|U_a(s)| = e^{-\delta h_a} = p^{-2^j \delta}.$$

By the solenoid-compatibility hypothesis, this modulus row comes from a continuous real positive character of the compact solenoid carrier. By Definition 9413.781, the character is trivial, so $|U_a(s)| = 1$. Thus

$$p^{-2^j \delta} = 1.$$

Since $2^j \log p > 0$, taking logarithms gives

$$-2^j \delta \log p = 0,$$

hence $\delta = 0$. □

Definition 9413.783 (Zeta solenoid Lee–Yang row)**.** *The* zeta solenoid Lee–Yang row *is the assertion*

$$\mathsf{ZetaSolenoidLeeYang}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \left(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \sum_{\rho:\mathsf{StableResFam}_\zeta(s)} \mathsf{SolenoidCompatible}(\rho, s) \right).$$

It says that every completed critical-strip zero is carried by some stable zero-relevant resonance family whose phase data factors through a compact S-solenoid and has no extra noncompact real positive scale coordinate.

Theorem 9413.784 (Solenoid Lee–Yang is conditionally sufficient)**.** *If*

$$\mathsf{ZetaSolenoidLeeYang}_\zeta$$

holds, then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s, and write

$$s = \frac{1}{2} + \delta + i\tau.$$

The zeta solenoid Lee–Yang row supplies a stable resonance family ρ with a solenoid-compatible lift. By Definition 9413.782,

$$\delta = 0.$$

Therefore $\Re(s) = 1/2$, and the fixed-half section is obtained through Definition 9413.199. □

Corollary 9413.785 (Solenoid compatibility is a compact-form no-hair row)**.** *The solenoid-compatible form of the RH-facing obstruction is the disappearance of the noncompact real positive component in*

$$U_{p,j}(s) = e^{-\delta h_{p,j}} e^{-i\tau h_{p,j}}.$$

Proof. The phase factor $e^{-i\tau h_{p,j}}$ belongs to the visible unit-circle projection of the solenoid. The hidden p-adic fibre records compact local phase data behind that projection. The factor $e^{-\delta h_{p,j}}$ is different: it is a real positive scale row. By Definition 9413.781, such a row cannot be supplied nontrivially by a compact phase carrier. Thus solenoid compatibility is exactly the compact-carrier version of the no-hair condition. □

Corollary 9413.786 (The unclosed part is the zeta-specific dominance theorem)**.** *The compact solenoid argument does not by itself prove the zeta solenoid Lee–Yang row. The unclosed content is the zeta-specific dominance theorem constructing, for each completed zero, a stable zero-relevant resonance family whose phase data is solenoid-compatible.*

Proof. Definition 9413.782 is conditional on the existence of a solenoid-compatible lift. It does not construct the lift from the completed zero ledger. The construction requires the same proof-role ingredients isolated in Definition 9413.774: dominance of the active resonance family, exclusion of strict local dominance, a tail bound, and far-end energy control. Thus the remaining claim is not another algebraic restatement of $\delta = 0$; it is the zeta-specific Lee–Yang or dominance theorem which produces the compact solenoid-compatible carrier for the zero-relevant data. □

Corollary 9413.787 (Representation-theoretic analogy)**.** *The solenoid route has the same proof-role shape as a compactness criterion for a semisimple representation row: a decomposition into a compact unitary component and a noncompact real component is forced onto the compact side once the zero-relevant data are known to lie on the unit-circle boundary.*

Proof. In a representation-theoretic Lee–Yang row one reads

$$g = \exp(\mu)u,$$

with u in a compact direction and μ in a noncompact direction. Unit-circle zero data forces the fundamental weights to vanish on μ, hence $\mu = 0$. In the zeta solenoid row the corresponding decomposition is

$$U_{p,j}(s) = e^{-\delta h_{p,j}} e^{-i\tau h_{p,j}},$$

where the second factor is compact phase and the first is real positive scale. Solenoid compatibility and Definition 9413.781 force the scale component to be trivial, hence $\delta = 0$. □

Concretized in §9075: The SolenoidPhaseUp packet realizes the S-localization and compact solenoid phase carrier as finite NameCert rows.

9413.64 Zeta Solenoid Lee–Yang Bound

The solenoid boundary and the resonance-bound boundary describe two faces of the same RH-facing proof role. The solenoid face says that a zero-relevant phase state realized in a compact S-solenoid cannot carry an additional real positive scale. The bound face says that a zero-relevant resonance family must have uniformly bounded normal energy along its finite prime-adic windows. The combined target is therefore a zeta-specific Lee–Yang theorem with both parts displayed: each completed zero must be captured by a stable dominant resonance tower whose phase data is solenoid-compatible and whose normal energy is bounded at the far end.

Definition 9413.788 (Zero-specific cofinal resonance tower)**.** *For a critical-strip row s, a* zero-specific cofinal resonance tower *is a stable zero-relevant resonance family*

$$\rho : \mathsf{StableResFam}_\zeta(s)$$

whose finite windows

$$B \preceq \rho, \qquad B \subset \mathsf{Prime}^\uparrow \times \mathsf{Nat}^\uparrow,$$

form a cofinal prime-adic support in the sense of Definition 9413.769. The tower is indexed by the zero row s; different completed zero rows may have different displayed windows, depths, and dominant resonance islands.

Definition 9413.789 (Solenoid Lee–Yang bound witness)**.** *For a critical-strip row s, a* solenoid Lee–Yang bound witness *is a stable zero-relevant resonance family ρ together with the rows*

$$\mathsf{SolenoidCompatible}(\rho, s),$$

$$\mathsf{CofinalPAdicSupport}(\rho),$$

and

$$\sup_{B \preceq \rho} \mathcal{N}_B(s) < \infty.$$

The first row is the compact solenoid phase condition of Definition 9413.780. The second row says that the finite windows of ρ are cofinal in the prime-adic resonance sense. The third row is the uniform normal-energy bound of Definition 9413.771. Write $\mathsf{SolenoidLeeYangBoundWitness}(\rho, s)$ *for this displayed packet.*

Definition 9413.790 (Zeta solenoid Lee–Yang bound)**.** *The* zeta solenoid Lee–Yang bound *is the row*

$$\mathsf{ZetaSolenoidLeeYangBound}_\zeta := \prod_{s:\mathsf{Complex}^\uparrow} \Bigg(\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \sum_{\rho:\mathsf{StableResFam}_\zeta(s)} \mathsf{SolenoidLeeYangBoundWi}$$

It asserts that every completed critical-strip zero is carried by some zero-specific stable dominant resonance tower whose phase data lies in a compact solenoid and whose normal energy remains bounded along its cofinal finite windows.

Theorem 9413.791 (The solenoid Lee–Yang bound is conditionally sufficient)**.** *If*

$$\mathsf{ZetaSolenoidLeeYangBound}_\zeta$$

holds, then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s, and write

$$s = \frac{1}{2} + \delta + i\tau.$$

The zeta solenoid Lee–Yang bound supplies a witness ρ for the zero row of s. In particular it supplies

$$\mathsf{SolenoidCompatible}(\rho, s).$$

By Definition 9413.782, this gives $\delta = 0$. Hence $\Re(s) = 1/2$, and Definition 9413.199 supplies the fixed-half section. □

Theorem 9413.792 (The bound component gives the same exclusion)**.** *Let a completed critical-strip zero carry a solenoid Lee–Yang bound witness ρ. Then the normal-energy component alone excludes $\delta\#0$.*

Proof. The witness includes cofinal prime-adic support and the bound

$$\sup_{B\preceq\rho}\mathcal{N}_B(s)<\infty.$$

If $\delta\#0$, then Definition 9413.770 gives

$$\sup_{B\preceq\rho}\mathcal{N}_B(s)=\infty,$$

contradicting the bound. Thus $\neg(\delta\#0)$, and the located fixed-half collapse row gives $\delta=0$. □

Corollary 9413.793 (Two noncircular readings of the same target)**.** *The zeta solenoid Lee–Yang bound can be attacked either as a compact phase theorem or as a finite-to-infinite energy theorem.*

Proof. The compact phase reading uses Definition 9413.781: a compact solenoid phase carrier has no nontrivial real positive character, so a solenoid-compatible zero-relevant state cannot retain the factor $e^{-\delta h_{p,j}}$. The energy reading uses Definition 9413.768 and Definition 9413.770: off-half displacement forces unbounded positive normal energy along any cofinal prime-adic resonance tower. Both readings are proof roles for the same zero-relevance claim rather than restatements of the target surface. □

Definition 9413.794 (Dominant solenoid resonance certificate)**.** *A* dominant solenoid resonance certificate *for a completed zero row consists of the following displayed data:*

$$\mathsf{StableResFam}_\zeta(s),\qquad \mathsf{DominantFamily}(\rho),$$

$$\mathsf{SolenoidCompatible}(\rho,s),\qquad \mathsf{FarEndEnergyBound}(\rho).$$

The stable-family row says which resonance tower is zero-relevant. The dominance row separates that tower from visible but irrelevant resonance data. The solenoid row supplies the compact phase carrier. The bound row supplies the finite-to-infinite normal-energy control. Write $\mathsf{DominantSolenoidResonanceCertificate}(\rho,s)$ *for this certificate packet.*

Theorem 9413.795 (Dominant solenoid certificates supply the combined bound)**.** *If every completed critical-strip zero carries a dominant solenoid resonance certificate with cofinal prime-adic support, then*

$$\mathsf{ZetaSolenoidLeeYangBound}_\zeta$$

holds.

Proof. For a zero row s, the certificate supplies the stable family ρ, its dominance row, its solenoid compatibility row, and its far-end energy bound. Cofinal prime-adic support supplies the tower condition in Definition 9413.788. The far-end energy bound is exactly the inequality

$$\sup_{B\preceq\rho}\mathcal{N}_B(s)<\infty.$$

Thus the displayed data are precisely a solenoid Lee–Yang bound witness for s. □

Corollary 9413.796 (Finite spectral and tower-splitting templates)**.** *The combined target keeps the roles of the finite templates distinct: quartic spectral geometry models dominance and local zero isolation, while prime-splitting tower patterns model why a zero-specific resonance family may expose many local prime rows without being a single fixed finite window.*

Proof. The quartic carrier is used only as a finite dominance template, as in Definition 9413.776: zero location follows after the zero-relevant dominant family and its remainder bound are displayed. A prime-splitting tower is a different template: one displayed rational prime can generate many local prime rows in higher layers, so the resonance family attached to a zero should be allowed to grow through a tower. Neither template proves the zeta claim by itself. Together they explain why Definition 9413.790 quantifies over a zero-specific cofinal resonance tower rather than over one universal finite prime window. □

Theorem 9413.797 (The remaining proof load is zeta-specific dominance)**.** *The unclosed content of the combined route is the implication*

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s) \to \sum_{\rho:\mathsf{StableResFam}_\zeta(s)} \mathsf{DominantSolenoidResonanceCertificate}(\rho, s).$$

Proof. All subsequent consequences are already displayed. A dominant solenoid resonance certificate gives the combined bound by Definition 9413.795. The combined bound gives the RH fixed-half section by Definition 9413.791. What is not supplied by the zero predicate itself is the construction of the stable dominant resonance family, its solenoid-compatible phase carrier, and its far-end energy bound. That construction is the zeta-specific Lee–Yang theorem targeted by this route. □

9413.65 Solenoid Lee–Yang Source Gap

The combined solenoid Lee–Yang target must be read as a source theorem, not as another name for the fixed-half surface. A row of the form "completed zeta zero implies zero normal displacement" has the same logical shape as RH unless it is backed by an independent mechanism that constructs the zero-relevant resonance carrier. The route becomes noncircular only when the zero predicate is connected to a stable dominant resonance family, a tail-isolated local zero island, a compact solenoid phase lift, and a far-end energy bound.

Definition 9413.798 (Fixed-half alias row)**.** *For a critical-strip zero coordinate s, write*

$$\mathsf{CritZero}(s) := \mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s).$$

A proposed RH-facing row is a fixed-half alias row *when its only zero-specific content is one of the fixed-surface readouts*

$$\mathsf{OnCritLine}(s), \qquad \delta(s) = 0, \qquad \delta(s)^2 = 0,$$

or a direct equivalent such as zero normal energy or no normal hair, without a displayed source mechanism producing these rows from dominance, stability, solenoid compatibility, or tail control.

Theorem 9413.799 (Fixed-half aliases do not discharge the proof load)**.** *A fixed-half alias row does not by itself prove the RH fixed-half section.*

Proof. The RH section asks for a total assignment

$$\prod_{s:\mathsf{Complex}^{\uparrow}} (\mathsf{CritZero}(s) \to \mathsf{OnCritLine}(s)).$$

A fixed-half alias row names the output surface of this assignment, or a readout equivalent to that surface. It does not supply a contradiction to the hidden normal-coordinate counterform of Definition 9413.853, since that counterform is precisely a zero-source row with $\delta\#0$ whose normal coordinate has not yet been linked to the zero ledger. By Definition 9413.854, rewriting the fixed surface in mirror, prime-window, modulus, or energy coordinates leaves the counterform unexcluded until a zero-relevance mechanism is supplied. □

Definition 9413.800 (Dominant solenoid source mechanism)**.** *A* dominant solenoid source mechanism *for a critical-strip zero coordinate s is a packet consisting of a resonance family*

$$\rho : \mathsf{StableResFam}_{\zeta}(s),$$

together with the displayed rows

$$\mathsf{DominantFamily}(\rho), \qquad \mathsf{TailBound}(\rho), \qquad \mathsf{RoucheGap}(\rho),$$

$$\mathsf{SolenoidCompatible}(\rho, s), \qquad \mathsf{FarEndEnergyBound}(\rho).$$

The dominance row identifies the zero-relevant family. The tail and Rouché rows make the local zero island stable under the completed readout. The solenoid row places the visible phase and the hidden prime-adic registers inside a compact S-solenoid. The far-end bound controls the normal energy along the cofinal prime-adic windows of the same family.

Theorem 9413.801 (Source mechanisms are the noncircular content)**.** *The RH-facing solenoid Lee–Yang route is noncircular exactly at the point where it supplies a dominant solenoid source mechanism from the completed zero ledger.*

Proof. The compact solenoid argument is already structural: by Definition 9413.782, a solenoid-compatible zero-relevant family has no nontrivial positive scale character, hence no δ-scale. The finite-to-infinite energy argument is also structural: by Definition 9413.770, an off-half coordinate forces unbounded square energy along cofinal prime-adic support. Neither argument constructs the zero-relevant family from the zero predicate.

A dominant solenoid source mechanism supplies the missing source data. Dominance separates the active family from arbitrary projected chords. The tail and Rouché rows ensure that the family controls a local zero island of the completed readout. Solenoid compatibility puts the hidden degrees of freedom in the compact prime-adic fibre rather than in a noncompact real scale coordinate. The far-end energy bound then becomes a theorem about the same zero-relevant family, not an asserted synonym for $\delta = 0$. □

Corollary 9413.802 (The combined bound must be read as a source theorem)**.** *The row*

$$\mathsf{ZetaSolenoidLeeYangBound}_{\zeta}$$

is noncircular only in its source reading: every critical-strip zero comes with a stable dominant solenoid resonance source.

Proof. If the combined bound is read only as

$$\mathsf{CritZero}(s) \to \delta(s) = 0$$

or as

$$\mathsf{CritZero}(s) \to \sup_{B \preceq \rho} \mathcal{N}_B(s) < \infty$$

with no independently constructed ρ, it is a fixed-half alias row in the sense of Definition 9413.798. In contrast, Definition 9413.790 quantifies over a displayed stable family and a solenoid Lee–Yang bound witness. Definition 9413.794 then refines the witness into dominance, solenoid compatibility, and far-end energy data. Under that reading, the row is a zeta-specific source theorem rather than a relabeling of the fixed-half output. □

Theorem 9413.803 (The source gap is the remaining theorem)**.** *The remaining theorem for the solenoid Lee–Yang route is the source construction*

$$\mathsf{CritZero}(s) \to \sum_{\rho:\mathsf{StableResFam}_\zeta(s)} \mathsf{DominantSolenoidSource}(\rho, s),$$

where $\mathsf{DominantSolenoidSource}(\rho, s)$ *denotes the packet of Definition 9413.800.*

Proof. Once such a source packet is supplied, its solenoid row gives $\delta = 0$ by Definition 9413.782. Its far-end bound also gives $\delta = 0$ by the unbounded-energy contradiction in Definition 9413.792. Thus the downstream implication to the RH fixed-half section is already accounted for by Definition 9413.791. What remains is not another surface equivalence, but the construction of the source packet from the completed zero row: the active family, its dominance, its local Rouché gap, its compact solenoid phase carrier, and its far-end bound. □

Corollary 9413.804 (Finite templates are source templates)**.** *The quartic spectral carrier and prime-splitting tower patterns support the source theorem only as templates for dominance and carrier growth; they are not substitutes for the zeta-specific source construction.*

Proof. The quartic carrier contributes the finite pattern recorded in Definition 9413.776: zero location follows after a dominant family, local interference, and a Rouché remainder bound have been displayed. The prime-splitting tower pattern contributes the carrier-growth pattern recorded in Definition 9413.796: one prime source can expose many local rows through a tower, so the zeta family should be allowed to be cofinal rather than a single fixed finite window. These templates identify the shape of the source certificate. They do not prove that every completed zeta zero carries such a certificate. □

9413.66 Fixed-Prime Split Resonance Tower

The solenoid source gap can be sharpened by separating two tasks that are often conflated. The zero-relevant resonance family need not begin as a window over all rational primes. A more economical source pattern fixes one rational prime q attached to the zero row, lets that prime split through a tower of arithmetic carriers, and reads the resulting local prime rows as the cofinal resonance support. This mirrors the unit-distance tower pattern: one split rational prime can generate many local prime rows while a global discriminant bound keeps the tower auditable.

Definition 9413.805 (Fixed split-prime tower)**.** *Let $q : \mathsf{Prime}^{\uparrow}$ be a displayed rational prime. A* fixed split-prime tower *for q is a chain of number-field rows*

$$K_0 \subset K_1 \subset K_2 \subset \cdots$$

with degree rows

$$f_n := [K_n : \mathbb{Q}],$$

such that

$$f_n \to \infty,$$

and q splits completely in each K_n:

$$q\mathcal{O}_{K_n} = \mathfrak{q}_{n,1} \cdots \mathfrak{q}_{n,f_n}.$$

The tower is globally controlled *when it carries a uniform root discriminant bound*

$$\mathrm{rd}(K_n) := |\operatorname{Disc}(K_n)|^{1/f_n} \le C$$

for a constant C independent of n.

Definition 9413.806 (q-split resonance nodes)**.** *For a fixed split-prime tower and a depth row $j : \mathsf{Nat}^{\uparrow}$, the displayed local resonance nodes at level n are*

$$a = (\mathfrak{q}_{n,i}, j), \qquad 1 \le i \le f_n.$$

Their Hamiltonian levels are

$$h_a := 2^j \log N\mathfrak{q}_{n,i}.$$

Since q splits completely,

$$N\mathfrak{q}_{n,i} = q,$$

so the level readout is

$$h_a = 2^j \log q.$$

A finite q-split resonance window at level n is a finite set

$$A_n \subset \{\mathfrak{q}_{n,1}, \ldots, \mathfrak{q}_{n,f_n}\} \times \mathsf{Nat}^{\uparrow}.$$

Definition 9413.807 (Positive-density split support)**.** *A family of q-split resonance windows (A_n) has* positive-density split support *when there are constants $c > 0$ and $j_0 : \mathsf{Nat}^{\uparrow}$ such that, for all sufficiently large n, at least cf_n nodes of the form*

$$(\mathfrak{q}_{n,i}, j_0)$$

belong to A_n.

Definition 9413.808 (q-split normal energy)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau,$$

the local channel of a q-split node a is

$$U_a(s) := \exp(-(s - 1/2)h_a) = e^{-\delta h_a} e^{-i\tau h_a}.$$

The normal logarithmic defect is

$$d_a(s) := \log |U_a(s)| = -\delta h_a,$$

and the q-split window energy is

$$\mathcal{E}^{(q)}_{A_n}(s) := \sum_{a \in A_n} d_a(s)^2.$$

Theorem 9413.809 (One split prime detects off-half displacement)**.** *Let (K_n) be a fixed split-prime tower for q, and let (A_n) have positive-density split support. If*

$$s = \frac{1}{2} + \delta + i\tau$$

and $\delta \# 0$, then

$$\mathcal{E}^{(q)}_{A_n}(s) \to \infty$$

along the tower.

Proof. Choose the depth j_0 and density constant c from Definition 9413.807. For every displayed node

$$a = (\mathfrak{q}_{n,i}, j_0),$$

complete splitting gives

$$h_a = 2^{j_0} \log q.$$

Hence

$$d_a(s)^2 = \delta^2 (2^{j_0} \log q)^2.$$

For all sufficiently large n, at least cf_n such nodes belong to A_n, so

$$\mathcal{E}^{(q)}_{A_n}(s) \geq cf_n \delta^2 (2^{j_0} \log q)^2.$$

The tower has $f_n \to \infty$, and the coefficient is positive when $\delta \# 0$. Therefore the displayed energy is unbounded and tends to the far end. □

Definition 9413.810 (q-solenoid resonance compatibility)**.** *Let q be a fixed rational prime. The associated one-prime solenoid is*

$$\Sigma_q := \widehat{\mathbb{Z}[q^{-1}]}$$

with projection

$$\pi_q : \Sigma_q \twoheadrightarrow \mathbb{T}$$

and hidden fibre

$$K_q := \ker(\pi_q) \cong \mathbb{Z}_q.$$

A q-split resonance tower is q-solenoid-compatible *for s when its phase data factors through π_q, its hidden registers are carried by the q-adic fibre rows generated by the split local primes, and it introduces no additional $\mathsf{Real}^{\uparrow}_{>0}$ scale coordinate.*

Theorem 9413.811 (q-solenoid compatibility has unit boundary)**.** *If a stable zero-relevant q-split resonance tower is q-solenoid-compatible for*

$$s = \frac{1}{2} + \delta + i\tau,$$

then $\delta = 0$.

Proof. For every displayed node a in the tower,

$$|U_a(s)| = e^{-\delta h_a}$$

is a real positive scale readout. By q-solenoid compatibility, such a readout must arise from the compact solenoid phase carrier rather than from a noncompact scale coordinate. The compact carrier has no nontrivial continuous positive scale character by Definition 9413.781. Thus $|U_a(s)| = 1$ for each zero-relevant displayed node. Since $h_a > 0$, the equality $e^{-\delta h_a} = 1$ gives $\delta = 0$. □

Definition 9413.812 (Resonance counting lower row)**.** *For a fixed split-prime tower and resonance windows* (A_n)*, the* resonance counting function *is*

$$N_\rho(n) := |A_n|.$$

In the pure split-prime case at a fixed depth, the tower count is

$$N_q(n) := f_n = [K_n : \mathbb{Q}],$$

because complete splitting gives one displayed local prime row $\mathfrak{q}_{n,i}$ *for each embedding degree slot. A resonance family has a* counting lower row *when there are constants* $c > 0$ *and* $j_0 : \mathsf{Nat}^{\uparrow}$ *such that*

$$N_\rho(n) \geq cN_q(n)$$

along the displayed fixed-depth split nodes for all sufficiently large n*.*

Theorem 9413.813 (Counting lower rows force off-half energy growth)**.** *Let a* q*-split resonance family have a counting lower row. If*

$$s = \frac{1}{2} + \delta + i\tau$$

and $\delta\#0$*, then there is a constant* $c_q > 0$ *such that, for all sufficiently large* n*,*

$$\mathcal{E}^{(q)}_{A_n}(s) \geq c_q\, N_q(n).$$

In particular, if $N_q(n) \to \infty$*, then*

$$\mathcal{E}^{(q)}_{A_n}(s) \to \infty.$$

Proof. The counting lower row supplies a fixed depth j_0 and a positive density constant c. Each displayed split node at that depth has

$$h_a = 2^{j_0} \log q,$$

so

$$d_a(s)^2 = \delta^2 (2^{j_0} \log q)^2.$$

Thus the contribution of the counted split nodes is at least

$$cN_q(n)\delta^2(2^{j_0} \log q)^2.$$

Set

$$c_q := c\delta^2(2^{j_0} \log q)^2.$$

Since q is prime and $\delta\#0$, this constant is positive. The displayed lower bound follows, and divergence follows when $N_q(n) \to \infty$. □

Definition 9413.814 (Solenoid upper row)**.** *For a zero-relevant* q*-split resonance family, a* solenoid upper row *is a packet consisting of:*

$$\mathsf{QSolenoidCompatible}(\rho, s), \qquad \mathsf{TailBound}(\rho), \qquad \mathsf{RoucheGap}(\rho),$$

and a finite constant B_s *with*

$$\forall n, \qquad \mathcal{E}^{(q)}_{A_n}(s) \leq B_s.$$

The compatibility row places the hidden registers in the compact q*-adic fibre of* Σ_q*. The tail and Rouché rows ensure that the same resonance family is zero-relevant for the completed readout, rather than merely visible in a finite projection.*

Definition 9413.815 (Zeta prime-count solenoid bound)**.** *The* zeta prime-count solenoid bound *is the source row*

$$\mathsf{ZetaPrimeCountSolenoidBound}_\zeta$$

asserting that every critical-strip zero coordinate s carries a zero-relevant fixed-prime resonance packet consisting of a rational prime q, a fixed split-prime tower for q, a stable dominant resonance family (A_n), a counting lower row, and a solenoid upper row.

Theorem 9413.816 (Prime-count lower and solenoid upper rows are conditionally sufficient)**.** *If*

$$\mathsf{ZetaPrimeCountSolenoidBound}_\zeta$$

holds, then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

The prime-count solenoid bound supplies a fixed rational prime q, a split tower, a zero-relevant resonance family, a counting lower row, and a solenoid upper row. The upper row gives a finite constant B_s with

$$\mathcal{E}^{(q)}_{A_n}(s) \le B_s$$

for all n. Suppose $\delta \# 0$. By Definition 9413.813, the counting lower row gives

$$\mathcal{E}^{(q)}_{A_n}(s) \to \infty,$$

because the split-prime tower has $N_q(n) \to \infty$. This contradicts the uniform upper bound. Hence $\neg(\delta \# 0)$, and located fixed-half collapse gives $\delta = 0$. Therefore $\Re(s) = 1/2$, and the fixed-half section follows from Definition 9413.199. □

Corollary 9413.817 (The prime-count solenoid row is a source theorem)**.** *The zeta prime-count solenoid bound is not a fixed-half alias row.*

Proof. The row does not assert directly that a zero has $\delta = 0$, zero normal energy, or no normal hair. It asserts the existence of a zero-relevant source packet with two independent pieces of structure: a counting lower row supplied by split-prime growth, and a solenoid upper row supplied by compact fibre compatibility together with tail and Rouché control. Only after these two rows are combined does off-half displacement become impossible. Thus the row has the noncircular source shape isolated in Definition 9413.801. □

Corollary 9413.818 (Strong-triangle dominance explains the upper row)**.** *The p-adic strong triangle inequality supplies the finite dominance template behind the solenoid upper row.*

Proof. For a non-archimedean absolute value, if one term is strictly larger than all others, then the finite sum cannot vanish, as recorded in Definition 9413.773. Thus zero-relevant finite cancellation must occur at a boundary where dominant levels tie rather than at an arbitrary projected cancellation. This is the same proof-role shape as the quartic maximal-modulus boundary in Definition 9413.776. The solenoid upper row imports this dominance discipline into the fixed-prime tower setting: the compact q-adic fibre supplies legal hidden registers, while the Rouché and tail rows certify that the dominant finite family controls the completed zero island. □

Definition 9413.819 (Zeta fixed-prime tower Lee–Yang bound)**.** *The* zeta fixed-prime tower Lee–Yang bound *is the source row*

$$\mathsf{ZetaFixedPrimeTowerLeeYang}_{\zeta}$$

asserting that every critical-strip zero coordinate s carries a packet consisting of:

$$q : \mathsf{Prime}^{\uparrow}, \qquad \mathsf{FixedSplitPrimeTower}(q), \qquad (A_n),$$

with positive-density split support, a stable local decomposition

$$\Xi(s') = F_n(s') + T_n(s')$$

on a zero island around s, a Rouché boundary gap

$$|T_n| < |F_n|,$$

a q-solenoid-compatible phase lift, and a uniform normal-energy bound

$$\sup_n \mathcal{E}^{(q)}_{A_n}(s) < \infty.$$

Theorem 9413.820 (The fixed-prime tower bound is conditionally sufficient)**.** *If*

$$\mathsf{ZetaFixedPrimeTowerLeeYang}_{\zeta}$$

holds, then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

The fixed-prime tower Lee–Yang bound supplies a rational prime q, a fixed split-prime tower, positive-density split support, and the bound

$$\sup_n \mathcal{E}^{(q)}_{A_n}(s) < \infty.$$

If $\delta \# 0$, then Definition 9413.809 gives

$$\mathcal{E}^{(q)}_{A_n}(s) \to \infty,$$

contradicting the displayed bound. Thus $\neg(\delta \# 0)$, and located fixed-half collapse gives $\delta = 0$. Hence $\Re(s) = 1/2$, and the fixed-half section follows from Definition 9413.199. □

Corollary 9413.821 (Fixed-prime towers refine the source gap)**.** *The fixed-prime tower route refines the dominant solenoid source gap by replacing an all-prime starting window with a single zero-relevant split prime whose tower generates the needed cofinal support.*

Proof. Definition 9413.803 identifies the remaining theorem as the construction of a dominant solenoid source from the completed zero row. The fixed-prime tower route proposes a more explicit source shape: first select the rational prime q, then construct the split tower, the positive-density node family, the local Rouché gap, the q-solenoid phase lift, and the far-end energy bound. The divergence theorem above shows why this is enough once the source is constructed: one split rational prime already yields unbounded normal energy off the fixed-half surface. □

9413.67 Dedekind Split-Tower Lift

The fixed-prime tower mechanism becomes more concrete when the zero-relevant carrier is not an abstract resonance tower but a tower of Dedekind zeta reads. The intended source theorem is then not a bare finite-energy assertion. It says that a Riemann zero can be lifted through a controlled Galois tower, that the fixed rational prime q splits into many local prime-ideal rows in that tower, and that the Dedekind zero islands are captured by solenoid-compatible Lee–Yang dominance data.

Definition 9413.822 (Admissible q-split Dedekind tower)**.** *An* admissible q-split Dedekind tower *is a fixed split-prime tower of Definition 9413.805 together with the additional rows*

$$\mathsf{Galois}(K_n/\mathbb{Q}) \qquad (n \in \mathsf{Nat}^{\uparrow}),$$

and

$$\mathsf{DedekindRead}(K_n, \zeta_{K_n}, \Lambda_{K_n}),$$

where ζ_{K_n} is the Dedekind zeta read and Λ_{K_n} is the completed Dedekind read. The Galois row is part of the source data: it places the tower in the range where the Riemann zeta factor is a visible factor of the Dedekind read and where quotient-entireness is supplied by the displayed tower ledger rather than by a non-Galois quotient assumption.

Definition 9413.823 (Dedekind quotient lift row)**.** *Let ρ be a critical-strip coordinate. A tower level K_n carries a* Dedekind quotient lift row at ρ *when there is a holomorphic local quotient row Ψ_n on a neighbourhood of ρ such that*

$$\zeta_{K_n}(s) = \zeta(s)\Psi_n(s)$$

on that neighbourhood. Write

$$\mathsf{DedekindLift}_{K_n}(\rho)$$

for the resulting row

$$\mathsf{ZetaZero}(\rho) \to \zeta_{K_n}(\rho) = 0.$$

Theorem 9413.824 (Dedekind quotient rows lift Riemann zeros)**.** *If K_n carries a Dedekind quotient lift row at ρ, then*

$$\mathsf{ZetaZero}(\rho) \to \zeta_{K_n}(\rho) = 0.$$

Proof. The quotient row gives a local factorization

$$\zeta_{K_n}(s) = \zeta(s)\Psi_n(s)$$

with Ψ_n holomorphic at ρ. If $\zeta(\rho) = 0$, then substitution gives

$$\zeta_{K_n}(\rho) = \zeta(\rho)\Psi_n(\rho) = 0.$$

□

Definition 9413.825 (q-split Dedekind normal energy)**.** *Let*

$$\rho = \frac{1}{2} + \delta + i\gamma$$

and let q split completely in K_n:

$$q\mathcal{O}_{K_n} = \mathfrak{q}_{n,1} \cdots \mathfrak{q}_{n,f_n}.$$

For each split prime-ideal row set

$$U_{n,i}(\rho) := q^{1/2-\rho}.$$

The normal defect is

$$d_{n,i}(\rho) := \log |U_{n,i}(\rho)| = -\delta \log q,$$

and the q-split Dedekind normal energy is

$$\mathcal{E}_{q,n}^{\mathrm{Ded}}(\rho) := \sum_{i=1}^{f_n} d_{n,i}(\rho)^2.$$

Theorem 9413.826 (Dedekind split counts amplify off-half energy)**.** *Let (K_n) be an admissible q-split Dedekind tower. If*

$$\rho = \frac{1}{2} + \delta + i\gamma$$

and $\delta \# 0$, then

$$\mathcal{E}_{q,n}^{\mathrm{Ded}}(\rho) = [K_n : \mathbb{Q}]\delta^2(\log q)^2$$

and therefore

$$\mathcal{E}_{q,n}^{\mathrm{Ded}}(\rho) \to \infty.$$

Proof. Complete splitting gives exactly

$$f_n = [K_n : \mathbb{Q}]$$

split prime-ideal rows above q, each with norm q. For each such row,

$$d_{n,i}(\rho)^2 = \delta^2(\log q)^2.$$

Summing over $i = 1, \ldots, f_n$ gives

$$\mathcal{E}_{q,n}^{\mathrm{Ded}}(\rho) = f_n\delta^2(\log q)^2 = [K_n : \mathbb{Q}]\delta^2(\log q)^2.$$

The tower degree tends to infinity, while the coefficient is positive when $\delta \# 0$ and q is prime. Hence the energy diverges. □

Definition 9413.827 (q-tower Lee–Yang dominance certificate)**.** *Let ρ be a Riemann critical-strip zero. A* q-tower Lee–Yang dominance certificate *for ρ consists of an admissible q-split Dedekind tower and, for each level n, a local zero island D_n around ρ with a decomposition*

$$\Lambda_{K_n}(s) = F_n(s) + T_n(s)$$

on a neighbourhood of D_n, together with the rows

$$\mathsf{DedekindLift}_{K_n}(\rho), \qquad \mathsf{DominantFamily}(F_n), \qquad \mathsf{RoucheGap}(F_n, T_n, D_n),$$

$$\mathsf{QSolenoidCompatible}(F_n, \rho), \qquad \exists B_\rho < \infty,\ \forall n,\ \mathcal{E}_{q,n}^{\mathrm{Ded}}(\rho) \le B_\rho.$$

The certificate states that the lifted Dedekind zero is not merely a projection zero: it is captured by a dominant local piece, protected by a Rouché gap, carried by the q-solenoid phase register, and bounded in normal energy along the same split-prime tower.

Definition 9413.828 (Dedekind q-tower Lee–Yang bound)**.** *The* Dedekind q-tower Lee–Yang bound *is the source row*

$$\mathsf{DedekindQTowerLeeYangBound}_\zeta$$

asserting that every Riemann critical-strip zero ρ admits a rational prime q, an admissible q-split Dedekind tower, and a q-tower Lee–Yang dominance certificate for ρ.

Theorem 9413.829 (Dedekind tower Lee–Yang bound is conditionally sufficient)**.** *If*

$$\mathsf{DedekindQTowerLeeYangBound}_\zeta$$

holds, then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate

$$\rho = \frac{1}{2} + \delta + i\gamma.$$

The Dedekind tower Lee–Yang bound supplies q, an admissible q-split Dedekind tower, and a certificate with a finite bound

$$\mathcal{E}^{\mathrm{Ded}}_{q,n}(\rho) \leq B_\rho$$

for all n. Suppose $\delta \# 0$. By Definition 9413.826, the same tower satisfies

$$\mathcal{E}^{\mathrm{Ded}}_{q,n}(\rho) \to \infty,$$

contradicting the bound. Thus $\neg(\delta \# 0)$, and located fixed-half collapse gives $\delta = 0$. Hence $\Re(\rho) = 1/2$, and the fixed-half section follows from Definition 9413.199. □

Corollary 9413.830 (The Dedekind lift is the zero-source bridge)**.** *The Dedekind tower route refines Definition 9413.815 by making the zero-relevant source carrier explicit.*

Concretized in §9016: Finite boundary packet for q-split Dedekind lift rows without Dedekind-cut or RH closure.

Proof. The fixed-prime route already separates the counting lower row from the solenoid upper row. The Dedekind lift adds the missing zero-source bridge: the Riemann zero is carried into each Dedekind read by the Galois quotient factorization, and the split prime q supplies $[K_n : \mathbb{Q}]$ local prime-ideal rows at level n. The remaining work is precisely the certificate data in Definition 9413.827: dominant local capture, Rouché isolation, solenoid compatibility, and the uniform normal-energy bound. □

Corollary 9413.831 (Explicit formula search direction)**.** *The natural analytic search surface for the Dedekind tower route is an explicit-formula comparison in which split-prime contributions, Dedekind zeros, discriminant terms, and archimedean factors appear in one ledger.*

Proof. The split-prime side supplies a lower row through Definition 9413.826. The admissibility side supplies global control through bounded root discriminant and the completed Dedekind read. An explicit formula is the standard analytic surface on which zeros, prime ideals, discriminant, and gamma factors can be compared in the same equation. Thus it is the appropriate place to try to prove the dominance and bounded-energy rows required by Definition 9413.827, rather than another reformulation of the fixed-half surface. □

9413.68 Zeckendorf Solenoid Selector

The fixed-prime and Dedekind split-tower routes choose a resonance source by selecting one rational prime and amplifying it through a tower. A different discrete source mechanism is available from the Axis-Zeckendorf side: use the no-adjacent Fibonacci grammar as a legal prime-family selector, read the selected primes as a prime-register ledger, and then ask whether the resulting family admits a solenoid phase lift and a Lee–Yang stability certificate. This is a selector route, not a direct proof of RH.

Definition 9413.832 (Prime ledger read)**.** *The* prime ledger *is the free integer register*

$$\mathcal{L}_{\mathbb{P}} := \bigoplus_{p \in \mathsf{Prime}^{\uparrow}} \mathbb{Z} e_p.$$

A positive integer

$$n = \prod_p p^{v_p(n)}$$

has ledger row

$$\nu(n) := \sum_p v_p(n) e_p.$$

For

$$s = \frac{1}{2} + \delta + i\tau,$$

the centered zeta channel on this ledger is

$$n^{1/2-s} = \exp\left(-\delta \sum_p v_p(n) \log p\right) \exp\left(-i\tau \sum_p v_p(n) \log p\right).$$

Definition 9413.833 (FRACTRAN ledger transition)**.** *A FRACTRAN instruction a/b acts on the prime ledger by the affine translation*

$$x \mapsto x + \nu(a) - \nu(b)$$

whenever the displayed state admits the instruction. Thus FRACTRAN supplies a finite, auditable dynamics on the same prime-exponent ledger used by Euler factors. It does not choose the zero-relevant resonance family; it supplies the ledger language in which such a choice can be tracked.

Definition 9413.834 (Zeckendorf–Godel prime selector)**.** *Let*

$$X_m := \{z \in \{0,1\}^m : \ z_k z_{k+1} = 0\}$$

be the no-adjacent Zeckendorf window of length m, and let

$$X_\varphi := \{z \in \{0,1\}^{\mathbb{N}} : \ z_k z_{k+1} = 0\}$$

be the golden-mean selector space. The Zeckendorf–Godel selector sends

$$z \mapsto S_z := \{p_k : z_k = 1\}, \qquad g_z := \prod_k p_k^{z_k}.$$

For finite m, the window cardinality is

$$|X_m| = F_{m+2}$$

as in Definition 9347.16. The selector is legal because the no-adjacent word is recoverable from the squarefree non-adjacent prime code by unique Zeckendorf expansion and unique prime factorization.

Definition 9413.835 (Golden-cofinal selector)**.** *A selector $z \in X_\varphi$ is* golden-cofinal *when*

$$\sum_k z_k (\log p_k)^2 = \infty.$$

This is the cofinality row consumed by the zeta energy argument. It is independent of the zero predicate and belongs to the selector's prime-ledger growth.

Definition 9413.836 (Zeckendorf zeta normal energy)**.** *For $z \in X_\varphi$, define the Zeckendorf zeta normal energy by*

$$\mathcal{E}_z(s) := \sum_k z_k \left(\log |p_k^{1/2-s}|\right)^2.$$

For

$$s = \frac{1}{2} + \delta + i\tau,$$

this reads

$$\mathcal{E}_z(s) = \delta^2 \sum_k z_k (\log p_k)^2.$$

Theorem 9413.837 (Golden-cofinal selectors detect off-half energy)**.** *If z is golden-cofinal and*

$$s = \frac{1}{2} + \delta + i\tau$$

with $\delta \# 0$, then

$$\mathcal{E}_z(s) = \infty.$$

Proof. By Definition 9413.836,

$$\mathcal{E}_z(s) = \delta^2 \sum_k z_k (\log p_k)^2.$$

The selector is golden-cofinal, so the sum diverges. Since $\delta \# 0$, multiplication by the positive factor δ^2 preserves divergence. □

Definition 9413.838 (Euler-log solenoid factorization)**.** *Let S_z be a Zeckendorf–Godel prime family. An* Euler-log solenoid factorization *for S_z is a weight map*

$$w : \mathcal{L}_{S_z} \to \mathbb{Z}[S_z^{-1}]$$

and a solenoid phase character

$$\sigma : \mathbb{Z}[S_z^{-1}] \to \mathbb{T}$$

such that the zeta phase read

$$e_p \mapsto e^{-i\tau \log p}$$

factors as

$$\mathcal{L}_{S_z} \xrightarrow{w} \mathbb{Z}[S_z^{-1}] \xrightarrow{\sigma} \mathbb{T}$$

on the zero-relevant family. This is an explicit bridge requirement: the multiplicative Euler-log phase does not automatically equal the additive localization phase of

$$\Sigma_{S_z} := \widehat{\mathbb{Z}[S_z^{-1}]}.$$

Definition 9413.839 (Zeckendorf solenoid Lee–Yang certificate)**.** *For a critical-strip zero coordinate s, a* Zeckendorf solenoid Lee–Yang certificate *consists of:*

$$z \in X_\varphi, \qquad \mathsf{GoldenCofinal}(z), \qquad \mathsf{Captures}(z, s),$$

$$\mathsf{EulerLogSolenoidFactorization}(z, s), \qquad \mathsf{ZeckendorfLeeYangStability}(z, s),$$

and a finite bound

$$\mathcal{E}_z(s) \le B_s < \infty.$$

The capture row says that the selected prime family is the stable zero-relevant resonance family. The factorization row places the zeta phase into the solenoid carrier. The stability row is the finite Lee–Yang or hard-core path-model input inherited from the no-adjacent Fibonacci grammar, after the prime weights and the zeta phase have been accounted for.

Definition 9413.840 (Zeta Zeckendorf solenoid bound)**.** *The* zeta Zeckendorf solenoid bound *is the source row*

$$\mathsf{ZetaZeckendorfSolenoidBound}_\zeta$$

asserting that every critical-strip zeta zero s carries a Zeckendorf solenoid Lee–Yang certificate.

Theorem 9413.841 (The Zeckendorf solenoid bound is conditionally sufficient)**.** *If*

$$\mathsf{ZetaZeckendorfSolenoidBound}_\zeta$$

holds, then the RH fixed-half section exists.

Proof. Let $z_0 : \mathcal{Z}_\zeta$ have complex coordinate

$$s = \frac{1}{2} + \delta + i\tau.$$

The Zeckendorf solenoid bound supplies a certificate with selector $z \in X_\varphi$, golden cofinality, and a finite bound

$$\mathcal{E}_z(s) \le B_s.$$

If $\delta \# 0$, then Definition 9413.837 gives

$$\mathcal{E}_z(s) = \infty,$$

contradicting the bound. Hence $\neg(\delta \# 0)$, so located fixed-half collapse gives $\delta = 0$. Therefore $\Re(s) = 1/2$, and the fixed-half section follows from Definition 9413.199. □

Corollary 9413.842 (Selector and split-tower routes are complementary)**.** *The Zeckendorf selector route and the fixed split-prime tower route are different source mechanisms for the same solenoid Lee–Yang proof role.*

Proof. The split-tower route fixes one rational prime q and obtains cofinal growth from its splitting into many prime-ideal rows, as in Definition 9413.826. The Zeckendorf route instead chooses a legal prime family S_z by the golden-mean grammar and obtains cofinal growth from Definition 9413.835. In both cases the downstream proof role is the same: a counting or cofinality lower row makes off-half normal energy unbounded, while solenoid compatibility and Lee–Yang stability are expected to supply the zero-relevant upper row. □

Corollary 9413.843 (The three open rows)**.** *The Zeckendorf solenoid route leaves three source rows open: capture, Euler-log solenoid factorization, and prime-weighted Zeckendorf Lee–Yang stability.*

Proof. Golden cofinality is a selector-growth row, and the energy divergence calculation is Definition 9413.837. What is not supplied by the zero predicate is the construction of a selector that actually captures the completed zero, the factorization of the Euler-log phase through a solenoid-compatible weight map, and the Lee–Yang stability theorem for the prime-weighted no-adjacent family. These are source claims, not aliases for $\delta = 0$. □

9413.69 Conditional RH Sufficiency Boundary

The preceding sections isolate two equivalent proof roles. The first is signature-theoretic: the zeta zero source has no independent mirror-odd observable beyond its atom, spectral-time, and symmetry-slot signature. The second is prime-sieve analytic: a finite prime-window mirror-odd defect cannot coexist with a completed zeta zero ledger. Each role is sufficient for the RH fixed-half section. Neither role is supplied by the definition of the zero predicate itself.

Definition 9413.844 (Zeta zero source as the RH input carrier)**.** *The RH input carrier is the critical-strip zero source*

$$\mathcal{Z}_\zeta := \sum_{s:\mathsf{Complex}^\uparrow} (\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)) .$$

The RH output carrier is the fixed-half lift

$$\mathcal{H}_\zeta := \sum_{z:\mathcal{Z}_\zeta} \mathsf{OnCritLine}(\pi_s z),$$

where $\pi_s z$ is the complex coordinate of the zero-source row.

Definition 9413.845 (Conditional sufficiency row)**.** *A row P_ζ is* conditionally sufficient for the RH section *when, together with the structural zero-ledger, mirror, same-source, and located fixed-half rows already displayed in the RH route, it gives a section*

$$\Phi_P : \mathcal{Z}_\zeta \to \mathcal{H}_\zeta.$$

This is a proof-role classification. It does not assert that P_ζ has been proved without further zeta-specific input.

Definition 9413.846 (Core-completeness sufficiency row)**.** *The* core-completeness sufficiency row *is the packet*

$$\mathsf{CoreComplete}(\mathcal{Z}_\zeta) + \mathsf{MirrorEven}(\Sigma_Z) + \mathsf{MirrorOdd}(\delta) + \mathsf{ZeroObservable}(\delta),$$

where Σ_Z is the zero ontic signature and

$$\delta(s) := \Re(s) - \frac{1}{2}.$$

The first component means that every public zero observable in the displayed class factors through Σ_Z.

Theorem 9413.847 (Core completeness and mirror oddness are sufficient)**.** *The core-completeness sufficiency row is conditionally sufficient for the RH fixed-half section.*

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s. Core completeness applied to the public zero observable δ gives a factorization

$$\delta(s) = f(\Sigma_Z(s)).$$

Mirror closure supplies the companion zero-source row at $J(s)$. The mirror-even signature row gives

$$\Sigma_Z(J(s)) = \Sigma_Z(s),$$

and therefore

$$\delta(J(s)) = f(\Sigma_Z(J(s))) = f(\Sigma_Z(s)) = \delta(s).$$

The direct mirror calculation gives

$$\delta(J(s)) = -\delta(s).$$

Thus $\delta(s) = -\delta(s)$, hence $\delta(s) = 0$ in the characteristic-zero real readout. By Definition 9413.313, this is the fixed-half row for s. The construction is exactly the section shape of Definition 9413.199. □

Corollary 9413.848 (Core completeness implies the RH predicate conditionally)**.** *Under the structural rows of Definition 9413.847, core completeness of the zeta zero source implies the BEDC RH predicate.*

Proof. The theorem supplies a lift

$$\Phi : \mathcal{Z}_\zeta \to \mathcal{H}_\zeta.$$

Unfolding Definition 9413.844, this is a total assignment sending each row

$$\mathsf{ZetaZero}(s) \times \mathsf{InCritStrip}(s)$$

to $\mathsf{OnCritLine}(s)$. This is the RH predicate as identified by Definition 9413.199. □

Definition 9413.849 (Prime-sieve sufficiency row)**.** *The* prime-sieve sufficiency row *is*

$$\mathsf{PrimeSieveOddExactness}_\zeta,$$

the finite-sieve exactness target of Definition 9413.477. It asserts that a nonzero finite prime-window mirror-odd defect cannot coexist with a critical-strip zero row in the completed zeta carrier.

Theorem 9413.850 (Prime-sieve odd exactness is sufficient)**.** *Assume prime-sieve odd exactness and the located fixed-half collapse row*

$$\neg(\delta(s)\#0) \to \delta(s) = 0.$$

Then the RH fixed-half section exists.

Proof. Let $z : \mathcal{Z}_\zeta$ have complex coordinate s. It suffices to exclude $\delta(s)\#0$. Suppose $\delta(s)\#0$. Choose any nonempty finite prime window S. By Definition 9413.473,

$$D_S(s)\#0.$$

Hence the finite-window existential defect row in Definition 9413.477 holds. Applying $\mathsf{PrimeSieveOddExactness}_\zeta$ to the zero row, the critical-strip row, and this finite defect gives $\bot$. Therefore

$$\neg(\delta(s)\#0).$$

The located fixed-half collapse row gives $\delta(s) = 0$, and Definition 9413.313 turns this into $\mathsf{OnCritLine}(s)$. Varying z gives the desired section. □

Corollary 9413.851 (Prime-sieve exactness implies the RH predicate conditionally)**.** *Under located fixed-half collapse, prime-sieve odd exactness implies the BEDC RH predicate.*

Proof. Definition 9413.850 constructs the fixed-half section. The equivalence with the BEDC RH predicate is Definition 9413.199. □

Theorem 9413.852 (The conditional rows are the unclosed content)**.** *The preceding sufficiency theorems do not prove the unconditional RH predicate. Their unclosed content is the zeta-specific row*

$$\mathsf{CoreComplete}(\mathcal{Z}_\zeta)$$

or, in finite-sieve analytic form,

$$\mathsf{PrimeSieveOddExactness}_\zeta.$$

Proof. The zero predicate supplies a zero ledger and the critical-strip row supplies the input domain. The fixed-surface readout equivalences of Definition 9413.464 identify the target surface, but they do not place zero rows on that surface. Core completeness would place every public zero observable, including δ, behind the mirror-even zero signature. Prime-sieve odd exactness would exclude the finite prime-window defect generated by any nonzero δ. These are exactly the remaining rows identified by Definition 9413.461 and Definition 9413.484. □

Definition 9413.853 (Hidden normal-coordinate counterform)**.** *The* hidden normal-coordinate counterform *is a hypothetical zero-source pair*

$$s = \frac{1}{2} + \delta + i\gamma, \qquad J(s) = \frac{1}{2} - \delta + i\gamma, \qquad \delta \# 0,$$

such that

$$\Sigma_Z(J(s)) = \Sigma_Z(s)$$

but δ does not factor through Σ_Z. It is the form of a fourth observable ledger separating mirror companions after the displayed zero signature has already agreed.

Theorem 9413.854 (The hidden normal coordinate is the circularity boundary)**.** *Any route that only rewrites the fixed-half surface in mirror, prime, or Laplace coordinates leaves the hidden normal-coordinate counterform unexcluded.*

Proof. The equalities

$$\Re(s) = \frac{1}{2}, \qquad |p^{1/2-s}| = 1, \qquad J(s) = s$$

describe the fixed surface. For the counterform, these rows fail precisely because $\delta \# 0$. Rewriting their equivalence does not contradict the zero ledger, since the zero ledger has not yet been linked to the absence of δ. The contradiction appears only after either core completeness forces δ to factor through the mirror-even signature, or prime-sieve odd exactness makes the finite prime-window defect zero-incompatible. □

Corollary 9413.855 (Zero relevance is the proof load)**.** *The proof load of the RH route is zero relevance of the mirror-odd defect, not visibility of that defect.*

Proof. Visibility is supplied by finite prime windows through Definition 9413.473. The quartic spectral carrier shows the same distinction: branch visibility requires a dominance and interference ledger before it becomes an endpoint zero law, as recorded in Definition 9413.485. For zeta, the corresponding zero-relevance row is prime-sieve odd exactness, equivalently the no-fourth-ledger or defect-zero incompatibility boundary. □

9413.70 BEDC–Langlands Closure Packet

The Langlands interface is read here as a unified-reality packet with two visible projections: a Galois–Frobenius projection and an automorphic–Hecke projection. The section records a conditional closure theorem. It proves the detection, uniqueness, and no-hidden-residual shape of the packet. It does not assert the existence theorems, trace formula comparisons, local classifications, endoscopic transfers, geometric equivalences, or functorial lifts required by the full Langlands programme.

Definition 9413.856 (BEDC–Langlands packet)**.** *Let F be a global field, let G be a connected reductive group, and let ${}^LG$ be the associated L-group. A BEDC–Langlands packet is a certificate row*

$$\mathcal{O}^{\uparrow} = (\pi, \phi, \Lambda_{\mathcal{O}}, N_{\mathcal{O}})$$

where π is an automorphic-side object for $G(\mathbb{A}_F)$,

$$\phi : W_F' \longrightarrow {}^LG$$

is a parameter-side object, $\Lambda_{\mathcal{O}}$ is the ledger for ramification, monodromy, endoscopy, continuous spectrum, boundary, nilpotent support, and functorial transport, and $N_{\mathcal{O}}$ is the NameCert-style source, pattern, classifier, stability, and ledger surface. The packet is a two-projection carrier, not an assertion that all existence and transfer problems have been solved.

Definition 9413.857 (Hecke–Frobenius finite detector)**.** *For an unramified place v and a finite-dimensional representation*

$$r : {}^LG \longrightarrow GL(V_r),$$

the Hecke–Frobenius finite detector (v, r) reads the automorphic side by

$$\lambda_{v,r}(\pi) := \operatorname{tr} r(s_v(\pi)),$$

where $s_v(\pi)$ is the Satake parameter, and reads the parameter side by

$$a_{v,r}(\phi) := \operatorname{tr} r(\phi(\mathrm{Frob}_v)).$$

Its mismatch residual is

$$D_{v,r}(\pi, \phi) := \lambda_{v,r}(\pi) - a_{v,r}(\phi).$$

Definition 9413.858 (Langlands ledger residual)**.** *A Langlands ledger residual is a non-finite-detector obstruction carried by one of the displayed boundary rows:*

$$\mathsf{Ramification},\quad \mathsf{Monodromy},\quad \gamma/\epsilon\text{-}factor,\quad \mathsf{Endoscopy},\quad \mathsf{ContinuousSpectrum},$$

$$\mathsf{ArthurSL}_2,\quad \mathsf{Boundary},\quad \mathsf{NilpotentSupport},\quad \mathsf{SingularSupport}.$$

Such a residual is admissible only as recorded scope data, discharged data, or explicitly not-claimed boundary. It is not hidden equality between the two projections.

Definition 9413.859 (No-hidden Langlands residual)**.** *A BEDC–Langlands packet satisfies no-hidden Langlands residual when every nonzero mismatch between the Galois–Frobenius and automorphic–Hecke projections has one of two addresses: either some finite detector (v, r) has*

$$D_{v,r}(\pi, \phi) \neq 0,$$

or the obstruction is recorded in the Langlands ledger of Definition 9413.858.

Theorem 9413.860 (Tannakian finite detectors separate semisimple classes)**.** *Let $g, h \in {}^L G$ be semisimple elements. If*

$$\operatorname{tr} r(g) = \operatorname{tr} r(h)$$

for every finite-dimensional representation r of ${}^L G$, then g and h have the same semisimple conjugacy class.

Proof. Characters of finite-dimensional representations are regular class functions and generate the coordinate algebra of the semisimple conjugacy quotient

$${}^L G /\!/ \operatorname{conj}.$$

Equality of all character values therefore says that g and h define the same point of that quotient. For semisimple elements, the closed orbit attached to a quotient point is the semisimple conjugacy class. Thus the two semisimple conjugacy classes agree. □

Theorem 9413.861 (Chebotarev–Tannakian uniqueness)**.** *Let $\phi, \phi' : W_F' \to {}^L G$ be semisimple parameter rows. If for almost all unramified places v and every finite-dimensional representation r,*

$$\operatorname{tr} r(\phi(\mathrm{Frob}_v)) = \operatorname{tr} r(\phi'(\mathrm{Frob}_v)),$$

then the semisimplified parameter rows have the same Frobenius readout; equivalently, they agree up to the usual semisimple parameter classification on the displayed scope.

Proof. For each displayed unramified v, the preceding theorem gives equality of the semisimple conjugacy classes of

$$\phi(\mathrm{Frob}_v) \qquad \text{and} \qquad \phi'(\mathrm{Frob}_v).$$

Chebotarev density makes the Frobenius conjugacy classes dense in the global Galois source on the unramified scope. Since the parameter rows are semisimple and the character readouts agree on this dense Frobenius set, the semisimplified parameter readouts agree on the declared scope. □

Theorem 9413.862 (Closed Langlands packets have no hidden mismatch)**.** *Let $\mathcal{O}^{\uparrow} = (\pi, \phi, \Lambda_{\mathcal{O}}, N_{\mathcal{O}})$ be a BEDC–Langlands packet with three-properties ledger discipline and no-hidden Langlands residual. If the packet is closed against unresolved Langlands ledger rows, then*

$$D_{v,r}(\pi, \phi) = 0$$

for every unramified finite detector (v, r) outside the declared bad ledger.

Proof. Assume that for some unramified finite detector outside the declared bad ledger,

$$D_{v,r}(\pi, \phi) \neq 0.$$

Then the detector itself supplies a finite mismatch address. By ledger discipline, this mismatch must be recorded as a finite Hecke–Frobenius mismatch row. If it is not recorded, the packet violates the ledger property. If it is recorded but unresolved, the packet is not closed against unresolved Langlands ledger rows. Both alternatives contradict the hypotheses. Therefore no such finite mismatch exists. □

Corollary 9413.863 (Parameter uniqueness from a closed automorphic packet)**.** *If (π, ϕ) and (π, ϕ') are closed BEDC–Langlands packets for the same automorphic-side row and both satisfy the no-hidden residual condition on the same unramified scope, then ϕ and ϕ' have the same semisimplified parameter readout on that scope.*

Proof. By Definition 9413.862, both parameter rows match the same Hecke readouts

$$\lambda_{v,r}(\pi)$$

for almost all unramified v and every finite-dimensional r. Hence their Frobenius character readouts agree. Apply Definition 9413.861. □

Definition 9413.864 (BEDC reciprocity certificate)**.** *For a class $\mathcal{C}$ of automorphic-side rows, a BEDC reciprocity certificate assigns to every $\pi \in \mathcal{C}$ a parameter row*

$$\phi_\pi : W'_F \to {}^L G$$

such that (π, ϕ_π) forms a closed BEDC–Langlands packet, satisfies no-hidden Langlands residual, and carries all bad-place and non-finite residual rows in its ledger.

Theorem 9413.865 (Conditional BEDC reciprocity)**.** *If a class $\mathcal{C}$ carries a BEDC reciprocity certificate, then each $\pi \in \mathcal{C}$ has a unique semisimplified parameter readout ϕ_π^{ss} on the certified unramified scope, and*

$$\operatorname{tr} r(s_v(\pi)) = \operatorname{tr} r(\phi_\pi(\mathrm{Frob}_v))$$

for almost all unramified places v and all finite-dimensional representations r.

Proof. Existence of the parameter row is part of the reciprocity certificate. The equality of finite Hecke and Frobenius readouts follows from Definition 9413.862. Uniqueness of the semisimplified parameter readout follows from Definition 9413.863. □

Definition 9413.866 (BEDC functoriality certificate)**.** *Let*

$$\eta : {}^L H \longrightarrow {}^L G$$

be an L-group homomorphism. A BEDC functoriality certificate for η assigns to each closed packet (π_H, ϕ_H) a closed packet (π_G, ϕ_G) such that

$$\phi_G = \eta \circ \phi_H$$

on the certified parameter scope, and every transfer, endoscopic, ramified, continuous-spectrum, or boundary residual enters the functoriality ledger.

Theorem 9413.867 (Conditional BEDC functoriality)**.** *If $\eta : {}^L H \to {}^L G$ carries a BEDC functoriality certificate, then for the associated closed packet (π_G, ϕ_G) and every unramified finite detector (v, r) outside the transfer ledger,*

$$\lambda_{v,r}(\pi_G) = \operatorname{tr} r(\eta(\phi_H(\mathrm{Frob}_v))).$$

Proof. The functoriality certificate gives $\phi_G = \eta \circ \phi_H$. Since (π_G, ϕ_G) is closed and satisfies the no-hidden residual condition on the certified scope, Definition 9413.862 gives

$$\lambda_{v,r}(\pi_G) = \operatorname{tr} r(\phi_G(\mathrm{Frob}_v)).$$

Substituting $\phi_G = \eta \circ \phi_H$ gives the displayed equality. □

Definition 9413.868 (Geometric Langlands closure certificate)**.** *For a smooth complete curve X and dual group $\check{G}$, a geometric Langlands closure certificate is a categorical equivalence row between the automorphic category and the spectral local-system category together with ledgers for Hecke modification time, spectral local-system readout, nilpotent singular support, stack boundary, Eisenstein and constant-term rows, and endoscopic residuals.*

Theorem 9413.869 (Geometric Langlands closure has no hidden residual)**.** *If a geometric Langlands equivalence row carries the closure certificate of Definition 9413.868, then a closed geometric Langlands packet has no hidden residual outside the displayed Hecke, singular-support, boundary, Eisenstein, and endoscopic ledgers.*

Proof. A residual visible under Hecke modification is a finite categorical detector and must be recorded in the Hecke ledger. A residual not visible there must occur in one of the displayed categorical boundary ledgers: singular support, stack boundary, Eisenstein or constant term, or endoscopy. Omitting the row violates ledger discipline; carrying it unresolved violates closedness. Hence no hidden residual remains in a closed packet. □

Theorem 9413.870 (Quadratic splitting is the abelian seed)**.** *For an odd prime p,*

$$p = a^2 + b^2 \quad \Longleftrightarrow \quad p \equiv 1 \pmod 4 \quad \Longleftrightarrow \quad p \text{ splits in } \mathbb{Q}(i).$$

Equivalently, the quadratic character χ_{-4} has $\chi_{-4}(p) = 1$.

Proof. Fermat's two-square theorem gives the equivalence between representation by $a^2 + b^2$ and $p \equiv 1 \pmod 4$ for odd primes. In the quadratic extension $\mathbb{Q}(i)/\mathbb{Q}$, a prime $p \neq 2$ splits exactly when -1 is a square modulo p, which is equivalent to $p \equiv 1 \pmod 4$. The same splitting law is recorded by the quadratic character χ_{-4}. □

Corollary 9413.871 (Langlands as a two-projection closure principle)**.** *On any category where the reciprocity, functoriality, local, ramified, continuous-spectrum, endoscopic, and boundary certificates are supplied, the Langlands correspondence can be read as the statement that Galois–Frobenius and automorphic–Hecke data are two projections of one closed three-properties packet.*

Proof. The finite detectors match the two projections outside the declared ledger by Definition 9413.865 and Definition 9413.867. The Tannakian and Chebotarev rows give parameter uniqueness, while the ledger rows prevent ramified, endoscopic, continuous, boundary, or categorical residuals from being hidden as equality. Therefore the correspondence is exactly a closed two-projection packet on the certified scope. □

Theorem 9413.872 (Langlands closure boundary)**.** *The BEDC–Langlands packet closes uniqueness, finite detection, and conditional reciprocity or functoriality after the relevant existence certificates have been supplied. It does not close the existence of parameters, automorphic transfers, trace formula comparisons, local classification, endoscopic classification, continuous-spectrum control, Shimura or cohomological constructions, or geometric categorical equivalences.*

Proof. All positive conclusions above use an explicit existence or transfer certificate as input: reciprocity for ϕ_π, functoriality for π_G, and categorical equivalence for the geometric packet. The closure arguments then exclude hidden mismatch residuals and give uniqueness or equality of finite readouts. They never construct those certificates. The listed existence and comparison problems therefore remain separate certificate obligations. □

9413.71 BEDC–Langlands Existence Bridge

The closure packet of section 9413.70 isolates detection and uniqueness: once a paired automorphic–Galois packet is present and closed, a Hecke–Frobenius mismatch cannot be hidden. The existence side needs a generating bridge. In the analytic form this bridge is a trace-formula certificate. In the geometric form it is a certified geometric Langlands functor or categorical equivalence.

Definition 9413.873 (Allowed parameter packet)**.** *An allowed Langlands parameter packet is a row*

$$\phi^{\uparrow} = (\phi, \Lambda_\phi, N_\phi)$$

where

$$\phi : W_F' \longrightarrow {}^L G$$

is continuous on the declared source, semisimple on the certified unramified scope, and locally acceptable on the displayed local rows. The ledger Λ_ϕ records ramification, monodromy, γ/ϵ factors, Arthur SL_2 data when present, and every bad-place boundary used by the packet.

Definition 9413.874 (Automorphic realization)**.** *Let $\phi^{\uparrow}$ be an allowed parameter packet. An automorphic realization of $\phi^{\uparrow}$ is an automorphic object or automorphic packet row π such that for almost all certified unramified places v and every finite-dimensional representation $r : {}^L G \to GL(V_r)$,*

$$\lambda_{v,r}(\pi) = \operatorname{tr} r(\phi(\mathrm{Frob}_v)).$$

Equivalently, the Satake parameter of π and the Frobenius readout of ϕ define the same semisimple point in the conjugacy quotient at those places.

Definition 9413.875 (Existence residual)**.** *For an allowed parameter packet $\phi^{\uparrow}$, the existence residual $E(\phi)$ is the assertion that no automorphic realization of $\phi^{\uparrow}$ exists on the declared scope. A closed BEDC Langlands existence proof must show that any such residual is detected by a finite trace window or is recorded in a ramified, endoscopic, continuous-spectrum, boundary, or compactness ledger.*

Definition 9413.876 (Parameter projection test function)**.** *Let S be a finite set of unramified places. A test function $f_{\phi,S}$ is a parameter projection test function for $\phi^{\uparrow}$ when it belongs to the permitted restricted tensor product of local test spaces and its unramified local factors lie in the spherical Hecke algebras*

$$\mathcal{H}_v(G, K_v).$$

Under the Satake transform, these factors cut out the finite list of semisimple Hecke readouts prescribed by

$$\phi(\mathrm{Frob}_v) \qquad (v \in S).$$

Thus $\operatorname{tr} \pi(f_{\phi,S}) \neq 0$ only for automorphic rows whose finite Hecke readouts match the parameter on the window S, except for residual rows explicitly named by the test-function ledger.

Definition 9413.877 (Stable trace formula certificate)**.** *A stable trace formula certificate for G is a ledgered equality*

$$I^G_{\mathrm{spec}}(f) = I^G_{\mathrm{geom}}(f)$$

for all admitted test functions f, together with decomposition ledgers for discrete spectrum, continuous spectrum, endoscopy, ramification, orbital integral normalization, multiplicity, boundary terms, and transfer factors. The certificate is closed on a scope only when every term not intended as the target contribution has either been separated, cancelled, or recorded as an open ledger row.

Theorem 9413.878 (Trace formula detects automorphic realization)**.** *Let $\phi^{\uparrow}$ be an allowed parameter packet and let $f_{\phi,S}$ be a parameter projection test function. Assume:*

- $I^G_{\mathrm{geom}}(f_{\phi,S}) \neq 0$*;*
- *all continuous, endoscopic, boundary, ramified, and normalization terms not belonging to the target contribution are separated or ledgered;*
- *the stable trace formula certificate holds for $f_{\phi,S}$.*

Then there is an automorphic row π with

$$\operatorname{tr} \pi(f_{\phi,S}) \neq 0.$$

Proof. The geometric side is nonzero by hypothesis. The trace formula gives

$$I^G_{\mathrm{spec}}(f_{\phi,S}) = I^G_{\mathrm{geom}}(f_{\phi,S}) \neq 0.$$

The spectral side decomposes into discrete automorphic rows, continuous spectrum, endoscopic transfers, and the displayed boundary ledgers. All non-target residual terms have been separated or ledgered, so a nonzero spectral contribution must come from some automorphic row π with

$$\operatorname{tr} \pi(f_{\phi,S}) \neq 0.$$

By the projection property of $f_{\phi,S}$, this row matches the parameter on the finite window S. □

Corollary 9413.879 (Finite-window automorphic realization)**.** *Under the hypotheses of Definition 9413.878, the parameter packet $\phi^{\uparrow}$ has an automorphic realization on the finite window S.*

Proof. The theorem supplies π with nonzero trace against the projection test function. The definition of Definition 9413.876 then forces the prescribed Hecke–Frobenius readouts on S, outside any ledgered residual rows. □

Definition 9413.880 (Hecke window tower)**.** *A Hecke window tower for $\phi^{\uparrow}$ is an increasing sequence of finite unramified sets*

$$S_1 \subset S_2 \subset \cdots$$

whose union is the declared almost-everywhere unramified scope, together with parameter projection test functions f_{ϕ,S_n} for every window. A tower automorphic read is a sequence of automorphic rows (π_n) such that each π_n matches ϕ on S_n.

Definition 9413.881 (Cofinal trace compactness certificate)**.** *A cofinal trace compactness certificate for a Hecke window tower says that every tower automorphic read has one of two outcomes:*

- *it stabilizes or converges to an automorphic row π_ϕ whose finite Hecke readouts match ϕ on the cofinal unramified scope;*
- *its failure to stabilize is recorded in the automorphic tail ledger, with continuous-spectrum, endoscopic, boundary, multiplicity, or escape-of-mass data displayed.*

Theorem 9413.882 (Trace formula existence certificate)**.** *Let $\phi^{\uparrow}$ be an allowed parameter packet. Assume:*

- *a Hecke window tower with projection test functions f_{ϕ,S_n} is displayed;*
- *each window satisfies the hypotheses of Definition 9413.878;*

- *a cofinal trace compactness certificate is displayed;*
- *closed accepted objects carry no unresolved automorphic tail ledger.*

Then $\phi^{\uparrow}$ has an automorphic realization π_ϕ on the declared almost-everywhere unramified scope.

Proof. For every n, Definition 9413.878 supplies an automorphic row π_n matching ϕ on S_n. The cofinal compactness certificate says that the tower (π_n) either stabilizes or converges to an automorphic row π_ϕ, or its failure enters the automorphic tail ledger. The latter alternative is not compatible with closedness when the tail remains unresolved. Therefore the closed case yields π_ϕ, and cofinality of the sets S_n gives the required almost-everywhere matching. □

Theorem 9413.883 (BEDC reciprocity existence)**.** *Let $\phi^{\uparrow}$ be an allowed parameter packet. If the trace formula existence certificate holds for $\phi^{\uparrow}$, the no-hidden Langlands residual condition holds, and the accepted Langlands packet is closed against unresolved residual ledgers, then there is a closed automorphic realization π_ϕ satisfying*

$$\lambda_{v,r}(\pi_\phi) = \operatorname{tr} r(\phi(\mathrm{Frob}_v))$$

for almost all unramified v and all finite-dimensional representations r on the certified scope.

Proof. The trace formula existence certificate supplies an automorphic row π_ϕ matching ϕ on cofinal finite windows. If any mismatch remains on the certified scope, the no-hidden residual condition of Definition 9413.859 gives a finite Hecke–Frobenius detector or a Langlands ledger residual. A finite detector residual must be recorded or else the ledger property is violated; if it is recorded but unresolved, closedness fails. The same argument applies to ramified, endoscopic, continuous-spectrum, boundary, or compactness residuals. Hence the closed packet has no residual mismatch, and the displayed equality follows. □

Definition 9413.884 (Transfer trace certificate)**.** *Let*

$$\eta : {}^L H \longrightarrow {}^L G$$

be an L-group homomorphism. A transfer trace certificate for η assigns to every admitted H-side test function f_H an admitted G-side test function f_G such that the stable orbital integrals and spectral target contributions match under η, while all transfer factor, endoscopic, ramified, continuous-spectrum, and boundary residuals enter the functorial transfer ledger.

Theorem 9413.885 (Functoriality from transfer trace)**.** *Let (π_H, ϕ_H) be a closed BEDC–Langlands packet for H, and let $\eta : {}^L H \to {}^L G$ carry a transfer trace certificate. If the G-side trace formula existence certificate holds for*

$$\phi_G := \eta \circ \phi_H,$$

and the no-hidden Langlands residual condition holds on the target scope, then there is a closed G-side automorphic row π_G with

$$\lambda_{v,r}(\pi_G) = \operatorname{tr} r(\eta(\phi_H(\mathrm{Frob}_v)))$$

for almost all certified unramified v and all finite-dimensional $r : {}^L G \to GL(V_r)$.

Proof. Apply Definition 9413.883 to the G-side parameter packet $\phi_G = \eta \circ \phi_H$. The transfer trace certificate records the trace-formula compatibility and all transfer residuals. The existence theorem supplies π_G, and the no-hidden-residual argument removes every unclosed mismatch. Substituting $\phi_G = \eta \circ \phi_H$ gives the displayed finite-detector equality. □

Definition 9413.886 (Geometric functor certificate)**.** *For a smooth complete curve X and dual group $\check{G}$, a geometric functor certificate is a functor row*

$$\mathsf{GL}_G : \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathrm{LocSys}_{\check{G}}) \longrightarrow \mathcal{D}\text{-}\mathit{Mod}(\mathrm{Bun}_G)$$

that is an equivalence on the declared scope, or is fully faithful and essentially surjective on the target subcategory, and preserves the Hecke modification time row, spectral local-system readout, nilpotent singular support, stack boundary, Eisenstein and constant-term rows, and endoscopic ledger.

Theorem 9413.887 (Geometric functor gives automorphic existence)**.** *If a geometric functor certificate is displayed, then every spectral object in its certified source scope has an automorphic image with the corresponding Hecke eigensheaf readout, outside the residual ledgers named in the certificate.*

Proof. Let $\mathcal{F}_\phi$ be a spectral object in the certified source scope. The functor row sends it to

$$\mathcal{A}_\phi := \mathsf{GL}_G(\mathcal{F}_\phi)$$

in the automorphic category. Hecke compatibility supplies the stated eigensheaf readout. If a mismatch appears, it is visible under a Hecke modification detector or belongs to nilpotent singular support, stack boundary, Eisenstein, constant-term, or endoscopic ledger data. The certificate records those ledgers, and closedness excludes unresolved hidden residuals. □

Theorem 9413.888 (Langlands existence and closure principle)**.** *On any Langlands scope carrying object-triple, finite-detector, Tannakian separation, Chebotarev, ledger, closedness, and either trace formula existence or geometric functor certificates, reciprocity holds on that scope. If, in addition, transfer trace certificates hold for the declared L-group homomorphisms, functoriality holds on the corresponding target scopes.*

Proof. Existence is supplied either by Definition 9413.882 and Definition 9413.883, or by Definition 9413.887 on the geometric scope. Detection and uniqueness are then supplied by the finite-detector, Tannakian, and Chebotarev rows of section 9413.70. Every residual not visible to a finite detector is forced into a ledger, and closedness rejects unresolved hidden ledger data. Transfer trace certificates apply the same reasoning to functorial parameters $\eta \circ \phi_H$. □

Corollary 9413.889 (Langlands as generated two-projection closure)**.** *When the existence bridge is certified, the Langlands correspondence on the declared scope is the generated two-projection closure of a single BEDC packet: the Frobenius projection and the Hecke projection agree on all finite detectors, and every remaining obstruction is ledgered.*

Proof. The existence bridge generates the missing side of the packet. The closure packet excludes finite mismatch and hidden ledger residuals. Thus the two projections are not merely compared after the fact; they are the two visible faces of one closed generated packet. □

Theorem 9413.890 (Existence bridge boundary)**.** *The BEDC–Langlands existence bridge reduces existence to certified trace-formula compactness or certified geometric functoriality. It does not itself prove the stable trace formula, the fundamental lemma, endoscopic classification, local Langlands packets, multiplicity formulas, continuous-spectrum decomposition, Shimura or cohomological realization, or the geometric Langlands categorical equivalence.*

Proof. Each positive theorem in this section names one of those constructions as an input certificate. The arguments show that once such a bridge is present, any absence or mismatch of the automorphic realization becomes a finite trace-window residual or a ledgered tail residual. They do not construct the bridge. The listed mathematical constructions therefore remain independent certificate obligations. □

9413.72 BEDC–Langlands Unramified Local Layer

The finite detector (v, r) used throughout the global BEDC–Langlands packet is a local object. It is licensed by the unramified Satake correspondence: spherical Hecke eigenvalues at an unramified nonarchimedean place are the same data as a semisimple conjugacy class on the dual side. This section isolates that local certificate before the global trace-window projector is used.

Definition 9413.891 (Unramified local spherical datum)**.** *Let F_v be a nonarchimedean local field with residue cardinality q_v. Let G/F_v be an unramified connected reductive group, and let*

$$K_v \subset G(F_v)$$

be a hyperspecial compact subgroup. The local spherical Hecke algebra is

$$\mathcal{H}_v(G, K_v) := C_c(K_v \backslash G(F_v)/K_v),$$

with convolution product. An unramified local automorphic row is an irreducible smooth representation π_v with

$$\pi_v^{K_v} \neq 0.$$

Definition 9413.892 (Local BEDC rows)**.** *The local time row is generated by the Cartan decomposition*

$$G(F_v) = \bigsqcup_{\lambda \in X_*(T)^+} K_v \lambda(\varpi_v) K_v.$$

Each dominant coweight λ determines a Hecke time step $T_{v,\lambda}$. The local unity row is the spherical Hecke character

$$\chi_{\pi_v} : \mathcal{H}_v(G, K_v) \to \mathbb{C}$$

or, equivalently, its Satake parameter readout. The local ledger row records every departure from the unramified spherical setting: ramification, failure of K_v-fixed vectors, non-hyperspecial level, normalization choices including $q_v^{1/2}$, central character rows, and bad reduction.

Definition 9413.893 (Unramified local parameter)**.** *Let $\widehat{G}$ be the dual group. In the unramified local setting, the local L-group has the form*

$${}^L G = \widehat{G} \rtimes \langle \mathrm{Frob}_v \rangle.$$

An unramified local parameter is represented by a semisimple conjugacy class

$$s_{\phi,v} \in \widehat{G}//\mathrm{conj},$$

equivalently by

$$\phi_v(\mathrm{Frob}_v) = s_{\phi,v} \rtimes \mathrm{Frob}_v$$

under the declared normalization.

Definition 9413.894 (Local Hecke–Frobenius residual)**.** *Let π_v be spherical and let ϕ_v be unramified. For every finite-dimensional representation $r : {}^L G \to GL(V_r)$, define*

$$D_{v,r}(\pi_v, \phi_v) := \operatorname{tr} r(s(\pi_v)) - \operatorname{tr} r(\phi_v(\mathrm{Frob}_v)).$$

The local detector r matches exactly when

$$D_{v,r}(\pi_v, \phi_v) = 0.$$

Theorem 9413.895 (Unramified Satake correspondence)**.** *For the unramified local spherical datum, algebra homomorphisms*

$$\mathcal{H}_v(G, K_v) \to \mathbb{C}$$

are equivalent to semisimple conjugacy classes in the dual quotient:

$$\mathrm{Hom}_{\mathrm{alg}}(\mathcal{H}_v(G, K_v), \mathbb{C}) \cong \widehat{G}//\mathrm{conj}.$$

Thus a spherical irreducible representation π_v has a Satake parameter

$$s(\pi_v) \in \widehat{G}//\mathrm{conj}.$$

Proof. The Satake isomorphism gives the normalized identification

$$\mathcal{H}_v(G, K_v) \cong \mathbb{C}[X_*(T)]^W,$$

with the $q_v^{1/2}$ convention recorded in the local ledger. The ring $\mathbb{C}[X_*(T)]^W$ is the coordinate ring of the semisimple conjugacy quotient of $\widehat{G}$. Algebra characters of the Hecke algebra are therefore points of that affine quotient, which are exactly semisimple Satake parameters. □

Corollary 9413.896 (Local finite detectors separate Satake parameters)**.** *If two spherical local rows π_v and π'_v satisfy*

$$\operatorname{tr} r(s(\pi_v)) = \operatorname{tr} r(s(\pi'_v))$$

for every finite-dimensional representation r of ${}^L G$, then

$$s(\pi_v) = s(\pi'_v)$$

in $\widehat{G}//\mathrm{conj}$.

Proof. Finite-dimensional characters separate semisimple conjugacy classes of the complex reductive dual group. Hence equality of all trace readouts places the two Satake parameters at the same point of the semisimple quotient. □

Theorem 9413.897 (Unramified local no-hidden residual)**.** *Let (π_v, ϕ_v) be an unramified local BEDC–Langlands row with the local three-properties discipline. If the row is closed against unresolved local ledger entries, then*

$$D_{v,r}(\pi_v, \phi_v) = 0$$

for every finite-dimensional representation r.

Proof. If $D_{v,r}(\pi_v, \phi_v) \neq 0$ for some r, then the finite local detector r has directly found a Hecke–Frobenius mismatch. Ledger discipline gives only two possibilities: the mismatch is recorded as a local residual row, or it is omitted. The first alternative leaves the object not closed until the row is resolved; the second violates the ledger property. Both contradict closedness with the three-properties discipline. Thus every local finite detector matches. □

Corollary 9413.898 (Unramified local Langlands closure)**.** *In the unramified spherical setting, a closed local BEDC–Langlands row is equivalent to equality of Satake and Frobenius parameters:*

$$s(\pi_v) = s_{\phi,v}$$

in $\widehat{G}//\mathrm{conj}$*. Equivalently,*

$$\operatorname{tr} r(s(\pi_v)) = \operatorname{tr} r(\phi_v(\mathrm{Frob}_v))$$

for every finite-dimensional r*.*

Proof. Equality in the quotient gives equality of all finite-dimensional trace readouts. Conversely, equality of all readouts separates the semisimple quotient by Definition 9413.896. The no-hidden residual theorem excludes any closed local row with a remaining detected mismatch. □

Definition 9413.899 (Local finite packet)**.** *Fix a finite displayed set of spherical local rows*

$$\mathcal{P}_v = \{\pi_{v,1}, \dots, \pi_{v,M}\}.$$

Write

$$s_i := s(\pi_{v,i}), \qquad s_\phi := s_{\phi,v}.$$

This is a fixed local packet list; no growing-window assertion is made inside the local projector construction.

Theorem 9413.900 (Local Hecke projector certificate)**.** *For a finite local packet* $\mathcal{P}_v$ *and target unramified parameter* s_ϕ*, there is*

$$f_{\phi,v} \in \mathcal{H}_v(G, K_v)$$

such that

$$s_i \neq s_\phi \quad \Longrightarrow \quad \operatorname{tr} \pi_{v,i}(f_{\phi,v}) = 0,$$

and

$$s_i = s_\phi \quad \Longrightarrow \quad \operatorname{tr} \pi_{v,i}(f_{\phi,v}) \neq 0$$

outside explicitly declared local cancellation rows.

Proof. By the Satake correspondence,

$$\mathcal{H}_v(G, K_v) \cong \mathbb{C}[\widehat{G}//\mathrm{conj}].$$

The finite set of points $\{s_1, \dots, s_M, s_\phi\}$ lies in an affine quotient. For each nonmatching $s_i \neq s_\phi$, the coordinate ring separates the two closed points, so there is a function F_i with

$$F_i(s_\phi) = 1, \qquad F_i(s_i) = 0.$$

The product

$$F_{\phi,v} := \prod_{s_i \neq s_\phi} F_i$$

is 1 at s_ϕ and 0 at every displayed nonmatching local parameter. Reading $F_{\phi,v}$ through Satake gives the desired Hecke function $f_{\phi,v}$. On a spherical eigenrow, the trace is evaluation at the Satake parameter. □

Theorem 9413.901 (Global detector as a product of local detectors)**.** *Let*

$$S = \{v_1, \dots, v_m\}$$

be a finite unramified window. For each $v \in S$, choose the local projector $f_{\phi,v}$ of Definition 9413.900. Then the finite tensor

$$f_{\phi,S} := \bigotimes_{v \in S} f_{\phi,v}$$

belongs to

$$\bigotimes_{v \in S} \mathcal{H}_v(G, K_v)$$

and kills every displayed global row whose Satake fingerprint fails to match ϕ at some place of S.

Proof. The restricted tensor product of the local spherical Hecke algebras is the finite-window Hecke algebra on S. If a displayed global packet fails to match the target at some $v \in S$, then the corresponding local factor has zero trace against $f_{\phi,v}$. The tensor trace is therefore zero. If all local Satake fingerprints match, each local factor is nonzero outside declared cancellation rows, so the finite tensor is the global fixed-window projector used by Definition 9413.910. □

Theorem 9413.902 (Fixed-window trace realization through local Satake)**.** *Assume every $v \in S$ is unramified for ϕ and for the displayed candidate packets. Suppose the local projectors $f_{\phi,v}$ are constructed as above, the stable trace-window certificate holds for*

$$f_{\phi,S} = \bigotimes_{v \in S} f_{\phi,v},$$

the parameter stable distribution is nonzero on $f_{\phi,S}$, and all non-target continuous, endoscopic, boundary, ramified, and normalization rows are separated or ledgered. Then some automorphic packet Π matches ϕ on every place of S:

$$s_v(\Pi) = \phi(\mathrm{Frob}_v) \qquad (v \in S).$$

Proof. The stable trace-window certificate transports the nonzero parameter readout to a nonzero spectral value. After the non-target ledger rows are separated, some automorphic packet has nonzero trace against $f_{\phi,S}$. By Definition 9413.901, a packet with any local mismatch in S is killed by the tensor projector. Hence the packet with nonzero trace matches the target Satake parameter at every place of the finite window. □

Theorem 9413.903 (Local-to-global residual dichotomy)**.** *Let (Π, ϕ) be a global BEDC–Langlands row. Any residual mismatch has one of two forms: either there is an unramified place v and a finite-dimensional representation r such that*

$$D_{v,r}(\Pi, \phi) \neq 0,$$

or the residual belongs to a ramified, archimedean, endoscopic, continuous-spectrum, boundary, nilpotent-support, or normalization ledger row.

Proof. If the residual appears at an unramified spherical place, the local Satake layer applies. A mismatch of semisimple local parameters is detected by some finite-dimensional representation by Definition 9413.896. This is the first alternative. If no unramified spherical detector sees the residual, then it lies outside the local layer: ramification, archimedean data, endoscopy, continuous spectrum, boundary terms, nilpotent or singular support, or normalization. Those are exactly the global ledger rows. □

Theorem 9413.904 (Local-to-global BEDC Langlands closure)**.** *Assume the unramified local layer above, fixed-window trace realization on a cofinal window tower, cofinal automorphic tail closure, complete ledger discipline, and closedness against unresolved ledger rows. Then the resulting global packet satisfies*

$$\lambda_{v,r}(\Pi_\phi) = \operatorname{tr} r(\phi(\mathrm{Frob}_v))$$

for every certified unramified finite detector (v, r)*.*

Proof. The unramified local layer licenses each finite detector (v, r) and the finite-window projectors built from them. Fixed-window trace realization supplies a realizing packet on each window. The cofinal window-to-global bridge gives either a global packet or an automorphic tail ledger row; closedness excludes unresolved tail rows. If a residual remained after the global packet is obtained, the local-to-global residual dichotomy would make it either a finite detector mismatch or a ledger row. A finite detector mismatch must be recorded and hence is not closed until resolved; an unrecorded one violates ledger discipline. The same applies to the ledger alternative. Therefore no residual remains on the certified unramified scope. □

Corollary 9413.905 (Quadratic detector as the abelian local shadow)**.** *For* $G = GL_1$ *and* $K = \mathbb{Q}(i)$*, the detector*

$$p \longmapsto \chi_{-4}(\mathrm{Frob}_p)$$

is the abelian local form of the general detector

$$(v, r) \longmapsto \operatorname{tr} r(\phi(\mathrm{Frob}_v)).$$

Thus the predicate $p = a^2 + b^2$ *is a visible local Frobenius detector in the abelian base case.*

Proof. For GL_1, the dual group is $\mathbb{C}^\times$ and finite-dimensional representations are characters. The Satake parameter at an unramified prime is therefore a single scalar. In the quadratic extension $\mathbb{Q}(i)/\mathbb{Q}$, the scalar $\chi_{-4}(\mathrm{Frob}_p)$ equals 1 exactly at split primes, which are the odd primes represented by $a^2 + b^2$ by Definition 9413.1129. □

Theorem 9413.906 (Unramified local boundary)**.** *The unramified local layer proves the legality and separation of finite Hecke–Frobenius detectors at spherical places. It does not prove the stable trace formula, construct parameter stable distributions, settle ramified local Langlands, or remove endoscopic, continuous-spectrum, boundary, nilpotent-support, or archimedean ledger rows.*

Proof. Every result in this section consumes the unramified spherical datum and the Satake correspondence. The non-spherical, ramified, endoscopic, continuous, boundary, nilpotent-support, and archimedean terms are excluded from the local proof and explicitly placed in the ledger. The global existence step is supplied separately by the trace-window or geometric existence bridge. □

9413.73 BEDC–Langlands Finite Hecke Projector Certificate

The existence bridge of section 9413.71 requires a local isolation step before the trace formula is used. A parameter readout on a fixed finite Hecke window must be converted into a test function that kills all displayed nonmatching spectral rows. The construction is purely finite: the places, the representations, the complexity bound, and the candidate packet list are fixed before the interpolation is performed.

Definition 9413.907 (Satake coordinate window)**.** *Let $S = \{v_1, \dots, v_m\}$ be a finite set of certified unramified places for G. The spherical Hecke algebra at v is denoted*

$$\mathcal{H}_v(G, K_v),$$

and the finite window algebra is

$$\mathcal{H}_S := \bigotimes_{v \in S} \mathcal{H}_v(G, K_v).$$

The Satake coordinate certificate identifies this algebra with regular functions on the finite product of semisimple conjugacy quotients,

$$\mathcal{H}_S \simeq \mathbb{C}\big[({}^L G//\mathrm{conj})^S\big].$$

Definition 9413.908 (Finite Frobenius and Satake fingerprints)**.** *For an allowed parameter packet $\phi^\uparrow$, its Frobenius fingerprint on S is*

$$x_{\phi,S} := \big(\phi(\mathrm{Frob}_v)\big)_{v \in S} \in ({}^L G//\mathrm{conj})^S.$$

For an automorphic packet Π unramified at every place of S, its Satake fingerprint is

$$x_{\Pi,S} := \big(s_v(\Pi)\big)_{v \in S} \in ({}^L G//\mathrm{conj})^S.$$

The packet Π matches $\phi^\uparrow$ on the window S when

$$x_{\Pi,S} = x_{\phi,S}.$$

Definition 9413.909 (Bounded window candidate packet)**.** *For a finite window S and a finite complexity bound B, let*

$$\mathsf{Aut}_{S,B}(G)$$

be the displayed automorphic packet list whose level, conductor, archimedean type, ramified local type, central character, and endoscopic label are bounded by B. A bounded window finiteness certificate says that

$$\mathsf{Aut}_{S,B}(G) = \{\Pi_1, \dots, \Pi_M\}$$

is finite up to the closed automorphic equivalence relation and that the Satake fingerprints $x_{\Pi_i,S}$ are readable in the Satake coordinate window.

Theorem 9413.910 (Finite Hecke projector certificate)**.** *Assume the Satake coordinate certificate and bounded window finiteness for (S, B). For every allowed parameter packet $\phi^\uparrow$ there is a test function*

$$f_{\phi,S,B} \in \mathcal{H}_S$$

such that for every $\Pi_i \in \mathsf{Aut}_{S,B}(G)$,

$$x_{\Pi_i,S} \neq x_{\phi,S} \quad \Longrightarrow \quad \mathrm{tr}\,\Pi_i(f_{\phi,S,B}) = 0,$$

while every matching packet satisfies

$$x_{\Pi_i,S} = x_{\phi,S} \quad \Longrightarrow \quad \mathrm{tr}\,\Pi_i(f_{\phi,S,B}) \neq 0$$

unless its contribution is cancelled by an explicitly declared local ledger row.

Proof. Under the Satake coordinate certificate, constructing $f_{\phi,S,B}$ is equivalent to constructing a regular function on the affine variety

$$({}^L G//\mathrm{conj})^S.$$

Write

$$X_i := x_{\Pi_i,S}.$$

For each nonmatching point $X_i \neq x_{\phi,S}$, the affine coordinate ring separates the two closed points. Hence there is

$$F_i \in \mathbb{C}\big[({}^L G//\mathrm{conj})^S\big]$$

with

$$F_i(x_{\phi,S}) = 1, \qquad F_i(X_i) = 0.$$

Define

$$F_{\phi,S,B} := \prod_{X_i \neq x_{\phi,S}} F_i.$$

Then

$$F_{\phi,S,B}(x_{\phi,S}) = 1$$

and $F_{\phi,S,B}(X_i) = 0$ for every displayed nonmatching packet. The Satake coordinate certificate reads $F_{\phi,S,B}$ as a Hecke test function $f_{\phi,S,B} \in \mathcal{H}_S$. On an unramified joint eigenpacket, the Hecke algebra acts through evaluation at its Satake fingerprint, so all nonmatching rows are killed and all displayed matching rows receive the nonzero scalar 1, except for cancellations that the local ledger names separately. □

Definition 9413.911 (Parameter evaluation distribution)**.** *On an unramified finite Satake window, the parameter evaluation distribution attached to $\phi^\uparrow$ is the functional*

$$\Theta^{\mathrm{st}}_{\phi,S} : \mathcal{H}_S \to \mathbb{C}$$

defined on Satake functions by

$$\Theta^{\mathrm{st}}_{\phi,S}(f) = f(x_{\phi,S}).$$

In ramified, archimedean, endoscopic, or transfer-factor settings this functional is accompanied by the corresponding local ledger rows.

Theorem 9413.912 (Parameter nonzero readout)**.** *For the finite Hecke projector of Definition 9413.910,*

$$\Theta^{\mathrm{st}}_{\phi,S}(f_{\phi,S,B}) = 1.$$

In particular,

$$\Theta^{\mathrm{st}}_{\phi,S}(f_{\phi,S,B}) \neq 0.$$

Proof. The projector is represented under Satake by the interpolation function $F_{\phi,S,B}$ constructed in the proof of Definition 9413.910. That function satisfies

$$F_{\phi,S,B}(x_{\phi,S}) = 1.$$

The parameter evaluation distribution is evaluation at $x_{\phi,S}$, so the displayed equality follows. □

Corollary 9413.913 (Spectral nonzero forces a matching packet)**.** *Let $f_{\phi,S,B}$ be the finite Hecke projector. Suppose the spectral side of the fixed window has the form*

$$I^{\mathrm{st}}_{\mathrm{spec}}(f_{\phi,S,B}) = \sum_{i=1}^{M} m(\Pi_i)\,\mathrm{tr}\,\Pi_i(f_{\phi,S,B}) + \mathrm{LedgerTerms},$$

and all continuous, endoscopic, boundary, ramified, normalization, and multiplicity terms outside the target window have been separated or cancelled by declared ledger rows. If

$$I^{\mathrm{st}}_{\mathrm{spec}}(f_{\phi,S,B}) \neq 0,$$

then some $\Pi_i \in \mathsf{Aut}_{S,B}(G)$ satisfies

$$x_{\Pi_i,S} = x_{\phi,S}.$$

Proof. If no displayed packet matched $x_{\phi,S}$, then Definition 9413.910 would give

$$\mathrm{tr}\,\Pi_i(f_{\phi,S,B}) = 0$$

for every i. After the non-target ledger terms are separated or cancelled, the spectral value would be zero, contradicting the assumed nonzero spectral value. □

Theorem 9413.914 (Fixed-window trace realization)**.** *Assume the finite Hecke projector certificate, parameter nonzero readout, stable trace-window equality, and separation of all non-target ledger terms for the fixed pair (S,B). Then the fixed window contains an automorphic packet Π such that*

$$x_{\Pi,S} = x_{\phi,S}.$$

Proof. By Definition 9413.912, the parameter side gives

$$\Theta^{\mathrm{st}}_{\phi,S}(f_{\phi,S,B}) \neq 0.$$

The stable trace-window equality transports this nonzero value to $I^{\mathrm{st}}_{\mathrm{spec}}(f_{\phi,S,B})$. The non-target ledger terms have been separated, so Definition 9413.913 supplies a displayed packet with the same finite Satake fingerprint as the parameter. □

Theorem 9413.915 (No missing fixed-window realization)**.** *Under the hypotheses of Definition 9413.914, it is impossible for $\phi^{\uparrow}$ to have no automorphic realization on the fixed window (S,B).*

Proof. Assume that no $\Pi_i \in \mathsf{Aut}_{S,B}(G)$ satisfies $x_{\Pi_i,S} = x_{\phi,S}$. The finite Hecke projector kills every displayed spectral row, and the non-target ledger rows have been separated or cancelled. Hence

$$I^{\mathrm{st}}_{\mathrm{spec}}(f_{\phi,S,B}) = 0.$$

On the parameter side, Definition 9413.912 gives

$$I^{\mathrm{st}}_{\mathrm{geom}}(f_{\phi,S,B}) = \Theta^{\mathrm{st}}_{\phi,S}(f_{\phi,S,B}) = 1.$$

The stable trace-window equality would force these two values to be equal, a contradiction. □

Corollary 9413.916 (Projector input for the cofinal bridge)**.** *If the hypotheses of Definition 9413.915 hold for every window in a cofinal Hecke window tower, then every tower window has an automorphic realization of $\phi^{\uparrow}$. Consequently the window-to-global alternative of Definition 9413.1074 applies once bounded automorphic finiteness and the automorphic tail ledger are available.*

Proof. Apply the fixed-window theorem to each displayed window. The resulting sequence of finite-window packets is precisely the input required by Definition 9413.1074. □

Theorem 9413.917 (Finite projector boundary)**.** *The finite Hecke projector certificate is a fixed-window interpolation statement. It does not assert growing-window compactness, the stable trace formula, bounded automorphic finiteness outside the displayed window, endoscopic transfer, or global automorphic realization.*

Proof. The construction uses only a finite candidate packet list, Satake coordinates on a finite set of unramified places, and interpolation in an affine coordinate ring. The passage from fixed windows to a global packet is supplied separately by section 9413.84; the analytic equality that makes the spectral side nonzero is supplied separately by the stable trace-window certificate. □

9413.74 BEDC–Langlands Parameter State Certificate

The trace-window argument needs a nonzero parameter-side readout before the stable trace formula can transport that readout to the spectral side. On an unramified fixed Hecke window this readout is simply evaluation at the Frobenius fingerprint of the parameter. Ramified, archimedean, endoscopic, and Arthur data are not inserted into the unramified Satake window; they are local parameter-state rows or ParameterLedger obligations.

Definition 9413.918 (Unramified parameter state)**.** *Let*

$$\mathcal{W} = (S, R, B)$$

be a fixed finite unramified Hecke window. The Satake coordinate window of Definition 9413.907 identifies

$$\mathcal{H}_{\mathcal{W}} \cong \mathbb{C}[({}^L G//\mathrm{conj})^S].$$

For an allowed parameter packet $\phi^{\uparrow}$, write

$$x_{\phi,\mathcal{W}} := \big(\phi(\mathrm{Frob}_v)\big)_{v\in S}.$$

The unramified parameter state is the evaluation functional

$$\Theta^{\mathrm{unr}}_{\phi,\mathcal{W}} : \mathcal{H}_{\mathcal{W}} \to \mathbb{C}$$

defined by

$$\Theta^{\mathrm{unr}}_{\phi,\mathcal{W}}(f) := f(x_{\phi,\mathcal{W}}).$$

Theorem 9413.919 (Unramified parameter state nonzero)**.** *Let $f_{\phi,\mathcal{W},B}$ be the finite Hecke projector attached to $\phi^{\uparrow}$ and $\mathcal{W}$. Then*

$$\Theta^{\mathrm{unr}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W},B}) = 1.$$

In particular,

$$\Theta^{\mathrm{unr}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W},B}) \neq 0.$$

Proof. The finite Hecke projector is represented by the interpolation function constructed in Definition 9413.910. It satisfies

$$f_{\phi,\mathcal{W},B}(x_{\phi,\mathcal{W}}) = 1.$$

The unramified parameter state is evaluation at $x_{\phi,\mathcal{W}}$, so the displayed equality follows. □

Definition 9413.920 (Parameter readout completeness)**.** *The finite-dimensional representation category* $\mathrm{Rep}({}^L G)$ *is the readout system for semisimple Langlands parameters: if semisimple elements* g *and* h *have*

$$\operatorname{tr} r(g) = \operatorname{tr} r(h)$$

for every finite-dimensional representation r*, then* g *and* h *define the same semisimple conjugacy class. Thus the evaluation functional on a finite Satake window is a complete finite readout of the displayed Frobenius fingerprint.*

Definition 9413.921 (Local parameter state ledger)**.** *At a ramified or archimedean place* v*, a local parameter state certificate is a local stable functional*

$$\Theta^{\mathrm{loc}}_{\phi_v} : \mathcal{H}^{\mathrm{loc}}_v \to \mathbb{C}$$

whose definition depends only on the local parameter row ϕ_v *and whose ledger records conductor, monodromy, local* ϵ/γ *factors, infinitesimal character, transfer factors, normalization, endoscopy, and Arthur* SL_2 *data when present. If such a functional is not available on the declared scope, the failure is a local parameter ledger row.*

Definition 9413.922 (Global ParameterLedger)**.** *For a global parameter packet* $\phi^{\uparrow}$*, the ParameterLedger is the finite and categorical ledger*

$$\mathrm{ParameterLedger}(\phi) := (S_{\mathrm{ram}}, N_v, \epsilon_v, \gamma_v, \mathsf{Monodromy}, \mathsf{ArthurSL_2}, \mathsf{Endoscopy}, \mathsf{ArchimedeanType}, \mathsf{Normalization}).$$

Here N_v *denotes Weil–Deligne monodromy, and every row records the source, classifier, local functional, and normalization data needed for the parameter state.*

Definition 9413.923 (Global parameter state)**.** *For a finite window with unramified, ramified, and archimedean parts, write*

$$\mathcal{W} = (S_{\mathrm{unr}}, S_{\mathrm{ram}}, R, B).$$

A global parameter state is the tensor functional

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}} := \left(\bigotimes_{v \in S_{\mathrm{unr}}} \Theta^{\mathrm{unr}}_{\phi_v} \right) \otimes \left(\bigotimes_{v \in S_{\mathrm{ram}}} \Theta^{\mathrm{loc}}_{\phi_v} \right) \otimes \Theta_{\phi,\infty},$$

where $\Theta_{\phi,\infty}$ *records the archimedean infinitesimal character, tempered or unitary row, and cohomological weight when those rows are part of the declared scope.*

Theorem 9413.924 (Parameter state certificate)**.** *Assume:*

- *the unramified finite projector* $f^{\mathrm{unr}}_{\phi,\mathcal{W},B}$ *is constructed;*
- *each ramified and archimedean local parameter state used by the window is nonzero on its declared local test function, or its failure is recorded in* $\mathrm{ParameterLedger}(\phi)$*;*
- *the test function decomposes as*

$$f_{\phi,\mathcal{W}} = f^{\mathrm{unr}}_{\phi,\mathcal{W},B} \otimes f^{\mathrm{ram}}_{\phi,S_{\mathrm{ram}}} \otimes f_{\phi,\infty};$$

- *every present local factor is normalized by*

$$\Theta^{\mathrm{loc}}_{\phi_v}(f_{\phi_v}) = 1,$$

  and the archimedean factor is normalized in the same way.

Then

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) = 1.$$

In particular, the parameter-side readout on the fixed window is nonzero.

Proof. By the tensor definition,

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) = \prod_{v\in S_{\mathrm{unr}}} \Theta^{\mathrm{unr}}_{\phi_v}(f_{\phi_v}) \cdot \prod_{v\in S_{\mathrm{ram}}} \Theta^{\mathrm{loc}}_{\phi_v}(f_{\phi_v}) \cdot \Theta_{\phi,\infty}(f_{\phi,\infty}).$$

The unramified factors are 1 by Definition 9413.919. The ramified and archimedean factors are 1 by the normalization hypotheses. Hence the product is 1. □

Theorem 9413.925 (Parameter state defect localization)**.** *Let $\phi^{\uparrow}$ be a declared Langlands parameter packet. If no fixed-window test function has nonzero parameter state readout, then one of the following is present:*

$$\mathsf{UnramifiedFrobeniusFingerprintDefect},\quad \mathsf{RamifiedLocalStateDefect},\quad \mathsf{ArchimedeanStateDefect},$$

$$\mathsf{EndoscopicArthurLedgerDefect},\quad \mathsf{UnlicensedParameterObject}.$$

Each listed defect is a ParameterLedger row.

Proof. If the unramified Frobenius fingerprint is defined, the unramified evaluation functional gives a nonzero readout on the finite Hecke projector by Definition 9413.919. Thus failure of all fixed-window parameter readouts cannot come from the unramified Satake part unless the Frobenius fingerprint itself is not licensed. If the unramified row is licensed, the possible failures are ramified local state, archimedean state, endoscopic or Arthur normalization, or the parameter object's own source and classifier data. By the definition of Definition 9413.922, these are exactly ParameterLedger rows. □

Theorem 9413.926 (Parameter state closure)**.** *For a legal BEDC Langlands parameter packet $\phi^{\uparrow}$ and any fixed Hecke window $\mathcal{W}$, either*

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) \neq 0$$

for the declared parameter projector, or there is a recorded ParameterLedger defect.

Proof. If the unramified, ramified, and archimedean local parameter states used by the window are present and normalized, then Definition 9413.924 gives nonzero readout. If no such nonzero readout is available, then Definition 9413.925 places the failure in the ParameterLedger. A legal BEDC parameter packet cannot have a silent missing state functional outside that ledger. □

Theorem 9413.927 (Parameter state and stable trace give window realization)**.** *Assume parameter state closure on a fixed Hecke window, no unresolved ParameterLedger defect on that window, the stable trace formula certificate, and separation of all non-target trace ledger rows. Then there is an automorphic packet Π with*

$$x_{\Pi,\mathcal{W}} = x_{\phi,\mathcal{W}}.$$

Proof. With no unresolved ParameterLedger defect, parameter state closure gives

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) \neq 0.$$

After trace ledger rows are separated, this is a nonzero geometric-side readout. The stable trace formula certificate transports it to a nonzero spectral-side readout. The finite Hecke projector then forces a displayed automorphic packet to match the parameter fingerprint on the fixed window. □

Theorem 9413.928 (Parameter state trace-tail closure)**.** *Assume ObjectTriple discipline, parameter state closure, stable trace formula certificate, finite Hecke projector certificates, cofinal automorphic tail closure, no-hidden Langlands residual, and closedness against unresolved ledger rows. Then every legal closed parameter packet $\phi^{\uparrow}$ with no unresolved ParameterLedger defect has a global automorphic realization Π_ϕ satisfying*

$$\lambda_{v,r}(\Pi_\phi) = \operatorname{tr} r(\phi(\mathrm{Frob}_v))$$

on the certified unramified finite detector scope.

Proof. Parameter state closure gives nonzero parameter readout on each fixed window. The stable trace formula certificate gives nonzero spectral readout, and the finite Hecke projector gives a fixed-window automorphic realization. Applying this along a cofinal window tower produces a realization sequence. Cofinal automorphic tail closure says that the sequence either globalizes or enters the automorphic tail ledger. Closedness excludes unresolved tail rows, so a global packet is obtained. No-hidden Langlands residual then excludes any remaining finite mismatch or ledger residual. □

Corollary 9413.929 (Abelian parameter state)**.** *For $G = GL_1$, the unramified parameter state is the scalar evaluation*

$$\Theta^{\mathrm{unr}}_{\phi,v}(f) = f(\phi(\mathrm{Frob}_v)).$$

For the quadratic parameter χ_{-4} attached to $\mathbb{Q}(i)/\mathbb{Q}$, this readout detects

$$\chi_{-4}(\mathrm{Frob}_p) = 1,$$

equivalently the representation of odd split primes by $a^2 + b^2$.

Proof. For GL_1, the dual group is $\mathbb{C}^\times$, so the Satake quotient is a one-dimensional character readout. Evaluation at $\phi(\mathrm{Frob}_v)$ is therefore the entire unramified parameter state. The quadratic splitting equivalence is Definition 9413.1129. □

Theorem 9413.930 (Parameter state boundary)**.** *The parameter state certificate closes the nonzero parameter-side readout on fixed Hecke windows. It does not construct every ramified local stable character, archimedean packet, Arthur packet, transfer-factor normalization, or endoscopic local state. When those rows are absent, they remain ParameterLedger obligations.*

Proof. The unramified part is evaluation at a Frobenius fingerprint and is closed by the finite projector construction. Ramified, archimedean, Arthur, and endoscopic states require their own local constructions. The certificate identifies their absence as ledger data rather than allowing a silent zero parameter-side readout. □

9413.75 BEDC–Langlands Ramified Local State Closure

The unramified layer is closed by Satake coordinates. At a ramified place there is no spherical Satake quotient, so the finite detector is not merely (v, r). It is a local testing row

$$(v, \mathfrak{b}, f_v),$$

where $\mathfrak{b}$ is a Bernstein or packet window and f_v is a compactly supported local Hecke test function. The role of a Satake point is played by a stable local character distribution attached to the local parameter packet.

Definition 9413.931 (Ramified local parameter ledger)**.** *Let F_v be a local field and let $G_v = G(F_v)$. A ramified local parameter is a Weil–Deligne row*

$$\phi_v : W'_{F_v} \to {}^L G.$$

Its local ledger records

$$\Lambda_{\phi_v} := (I_v\text{-type}, N_v, \epsilon_v, \gamma_v, \mathsf{Conductor}, \mathsf{Depth}, \mathsf{ArthurData}, \mathsf{Endoscopy}, \mathsf{Normalization}).$$

Here N_v is monodromy, and the normalization row includes transfer factors and local measure conventions.

Definition 9413.932 (Ramified local packet certificate)**.** *A ramified local packet certificate for ϕ_v consists of a finite or controlled local packet*

$$\Pi_{\phi_v} = \{\pi_{v,1}, \dots, \pi_{v,m}\}$$

and a stable local distribution

$$S\Theta_{\phi_v} := \sum_{i=1}^{m} a_i \Theta_{\pi_{v,i}},$$

where $\Theta_{\pi_{v,i}}$ is the Harish–Chandra character distribution and at least one coefficient a_i is nonzero. The certificate carries a local packet ledger for normalization, transfer factors, endoscopic labels, component-group characters, and local L, ϵ, γ factors. If the packet or stable distribution is not available, the failure is a row in the local parameter ledger.

Definition 9413.933 (Ramified local three-properties rows)**.** *The ramified local time row is generated by parabolic induction, Bernstein block decomposition, and conductor or depth filtration. The unity row separates a tempered unitary part from real-exponent or modulus rows. The ledger row records ramification, monodromy, depth, endoscopy, transfer factors, normalization, and wild ramification tails without allowing any of them to masquerade as an unramified Satake readout.*

Definition 9413.934 (Ramified local finite detector)**.** *A ramified local finite detector is a tuple*

$$(v, \mathfrak{b}, f_v)$$

where $\mathfrak{b}$ is a fixed Bernstein block or finite local packet window, and

$$f_v \in C_c^\infty(G_v)$$

is a local Hecke test function. For an admissible representation π_v, the detector reads

$$\Theta_{\pi_v}(f_v) = \operatorname{tr} \pi_v(f_v).$$

For a parameter packet, it reads

$$S\Theta_{\phi_v}(f_v).$$

The local residual is

$$D_{v,f_v}(\pi_v, \phi_v) := \Theta_{\pi_v}(f_v) - S\Theta_{\phi_v}(f_v).$$

Theorem 9413.935 (Local character separation)**.** *Fix a Bernstein or packet window containing finitely many irreducible admissible representations*

$$\pi_1, \ldots, \pi_M.$$

If their character distributions are pairwise distinct on the window, then finite linear combinations of local test functions separate the corresponding character rows. In particular, for any displayed target row one can construct a local test function that kills any prescribed finite set of nonmatching candidates and is nonzero on the target row, outside declared local cancellation rows.

Proof. The character distributions Θ_{π_i} are linear functionals on the local test-function space. Pairwise distinctness means that for each pair $i \neq j$ the difference

$$\Theta_{\pi_i} - \Theta_{\pi_j}$$

is a nonzero linear functional, hence is nonzero on some local test function. Since the candidate set is finite, finitely many such separating functions suffice. Taking finite linear combinations gives a projector on the finite list, with any local cancellation explicitly recorded in the ledger. □

Theorem 9413.936 (Ramified local state nonzero)**.** *If ϕ_v has a ramified local packet certificate and $S\Theta_{\phi_v}$ is not the zero distribution, then there exists*

$$f_v \in C_c^\infty(G_v)$$

such that

$$S\Theta_{\phi_v}(f_v) \neq 0.$$

Proof. The stable character $S\Theta_{\phi_v}$ is a linear functional on the local test-function space. A nonzero linear functional is nonzero on at least one test function. □

Corollary 9413.937 (Zero local state is a ledger row)**.** *If*

$$S\Theta_{\phi_v}(f_v) = 0$$

for every local test function f_v, then $S\Theta_{\phi_v}$ is the zero distribution. A declared legal ramified parameter with only the zero stable distribution has a local parameter ledger defect.

Proof. A linear functional that vanishes on every vector of its domain is the zero functional. If the parameter is nevertheless declared as a local state, the failure of nonzero state data must be recorded in Λ_{ϕ_v}; otherwise the local object has no state readout and violates the three-properties ledger row. □

Theorem 9413.938 (Ramified local no-hidden residual)**.** *Let (π_v, ϕ_v) be a ramified local BEDC–Langlands row with a ramified local packet certificate, local character separation, complete local ledger discipline, and closedness against unresolved local ledger rows. Then no ramified local mismatch remains hidden: any mismatch is detected by some finite local detector $(v, \mathfrak{b}, f_v)$ or is a local ledger row, and neither unresolved alternative is compatible with closedness.*

Proof. If the mismatch is visible in a fixed Bernstein or packet window, then the difference

$$\Theta_{\pi_v} - S\Theta_{\phi_v}$$

is a nonzero linear functional on the local test space. Hence there is some f_v with

$$D_{v,f_v}(\pi_v, \phi_v) \neq 0.$$

This is a finite local detector. Ledger discipline requires the detected residual to be recorded; carrying it unresolved violates closedness, while omitting it violates the ledger row.

If no fixed local window detects the mismatch, then it is not a character-distribution mismatch on the displayed packet window. It lies in normalization, transfer factors, endoscopy, monodromy, depth, component-group labels, or wild ramification tails. These are precisely the local ledger rows. Again, unresolved ledger data are incompatible with closedness. □

Definition 9413.939 (Ramified global parameter state)**.** *For a global parameter $\phi = (\phi_v)_v$ and a finite window*

$$\mathcal{W} = (S_{\mathrm{unr}}, S_{\mathrm{ram}}, B),$$

the global parameter state with ramification is

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}} := \left(\bigotimes_{v \in S_{\mathrm{unr}}} \Theta^{\mathrm{unr}}_{\phi_v} \right) \otimes \left(\bigotimes_{v \in S_{\mathrm{ram}}} S\Theta_{\phi_v} \right) \otimes \Theta_{\phi,\infty}.$$

Theorem 9413.940 (Global parameter state with ramification)**.** *Assume every unramified local state is the Satake evaluation state, every ramified local packet state present in the window is nonzero, the archimedean state is nonzero or its failure is ledgered, and the test function factors as*

$$f_{\phi,\mathcal{W}} = \bigotimes_{v \in S_{\mathrm{unr}}} f^{\mathrm{unr}}_{\phi_v} \otimes \bigotimes_{v \in S_{\mathrm{ram}}} f^{\mathrm{ram}}_{\phi_v} \otimes f_{\phi,\infty},$$

with each local factor normalized to value 1 *under its corresponding state. Then*

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) = 1.$$

Proof. By the tensor product definition,

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) = \prod_{v \in S_{\mathrm{unr}}} \Theta^{\mathrm{unr}}_{\phi_v}(f^{\mathrm{unr}}_{\phi_v}) \cdot \prod_{v \in S_{\mathrm{ram}}} S\Theta_{\phi_v}(f^{\mathrm{ram}}_{\phi_v}) \cdot \Theta_{\phi,\infty}(f_{\phi,\infty}).$$

Each factor is 1 by the hypotheses, so the product is 1. □

Theorem 9413.941 (Local-to-global parameter ledger dichotomy)**.** *If a global parameter state has no nonzero fixed-window test function, then at least one local parameter ledger row is present, or an archimedean, endoscopic, transfer-factor, or global normalization ledger row is present.*

Proof. If all unramified local states are present, their projectors give nonzero evaluation readouts. If every ramified packet state is nonzero, one can choose a local test function on which it is nonzero and rescale that local factor to value 1. If the archimedean state is also present and the global transfer and normalization rows are closed, the tensor test function of Definition 9413.940 has nonzero global state. Therefore total failure of all fixed-window readouts forces a missing or zero local state, or a global normalization, transfer, archimedean, or endoscopic defect. Those are exactly the ParameterLedger rows. □

Theorem 9413.942 (Ramified parameter state and trace realization)**.** *Assume the global parameter state with ramification is nonzero on the declared test function, the stable trace formula certificate holds, the finite Hecke and local projectors are constructed, and all non-target trace ledger rows are separated or discharged. Then the fixed window contains an automorphic packet matching the parameter on all displayed unramified and ramified local readouts.*

Proof. The nonzero global parameter state gives a nonzero stable geometric-side readout. The stable trace formula certificate transports it to a nonzero spectral-side readout. The unramified finite Hecke projector kills all displayed unramified nonmatching packets, and local character separation supplies the ramified packet-window projectors. Hence a nonzero spectral contribution must come from a packet matching the parameter on the whole fixed window. □

Theorem 9413.943 (Ramified BEDC–Langlands closure)**.** *Assume unramified Satake closure, ramified local packet certificates, local character separation, global parameter state nonzero, the stable trace formula certificate, finite-window projector certificates, cofinal automorphic tail closure, no-hidden Langlands residual, and closedness. Then every legal global parameter has a global automorphic realization Π_ϕ whose unramified Hecke–Frobenius readouts match ϕ and whose ramified local packet identities, local factors, and transfer data are ledgered and closed.*

Proof. The global parameter state and stable trace formula give a nonzero spectral readout in every fixed window. The unramified and ramified projector certificates force a matching packet in each fixed window. The cofinal automorphic tail closure globalizes the window realizations unless they enter a tail ledger; closedness excludes unresolved tail rows. Thus a global packet Π_ϕ is obtained.

Any remaining unramified mismatch is detected by a finite Hecke–Frobenius detector. Any remaining ramified mismatch is detected by Definition 9413.938 or lies in a local ledger row. No-hidden residual and closedness exclude both unresolved alternatives. □

Corollary 9413.944 (The abelian ramified check)**.** *For $G = GL_1$, a ramified local packet is a local character*

$$\chi_v : F_v^\times \to \mathbb{C}^\times$$

with conductor ledger. The local state

$$\Theta_{\chi_v}(f_v) = \int_{F_v^\times} f_v(x)\chi_v(x)\, d^\times x$$

is nonzero on a conductor-compatible compact coset test function after normalization. For the quadratic character of $\mathbb{Q}(i)/\mathbb{Q}$, the prime 2 is the ramified conductor row, while odd primes are the unramified detectors of Definition 9413.1129.

Proof. Choose a compact coset on which the local character is constant and let f_v be its normalized characteristic test function. The integral is then the chosen character value times the normalized volume, so it can be scaled to 1. For $\mathbb{Q}(i)/\mathbb{Q}$, the only ramified prime is 2, and the odd-prime splitting detector remains unramified. □

Theorem 9413.945 (Ramified local state boundary)**.** *Ramified local state closure consumes local packet certificates, character distribution separation, transfer-factor normalization, and local factor compatibility. It does not construct those traditional local Langlands and endoscopic inputs; when they are absent, the absence remains a local ParameterLedger obligation.*

Proof. The proofs above are linear-functional and ledger arguments once the local packet and stable character distribution are supplied. The existence of ramified packets, transfer identities, component-group labels, and character identities is separate local Langlands data. BEDC records that data as explicit certificates rather than hiding it inside the unramified Satake layer. □

9413.76 BEDC–Langlands Local Packet Certificate for GL_n

The ramified local state closure of section 9413.75 requires a local packet, a nonzero character distribution, and a ledger for conductor, monodromy, local factors, and normalization. For general reductive groups this package involves endoscopy and component-group bookkeeping. For GL_n over a nonarchimedean local field the packet certificate has a cleaner form: the local Langlands packet is a singleton, and all remaining ramified data are explicit ledger rows.

Definition 9413.946 (Local GL_n parameter row)**.** *Let F_v be a nonarchimedean local field. A local GL_n parameter row is an n-dimensional Frobenius-semisimple Weil–Deligne representation*

$$\phi_v : W'_{F_v} \to GL_n(\mathbb{C}),$$

equivalently a pair

$$(r_v, N_v)$$

with the usual monodromy compatibility. The parameter set is denoted

$$\Phi_n(F_v).$$

The automorphic local side is

$$\mathrm{Irr}(GL_n(F_v)),$$

the set of irreducible smooth admissible representations.

Definition 9413.947 (GL_n local Langlands certificate)**.** *A GL_n local Langlands certificate at v is a classical NameCert/PacketCert consisting of a bijection*

$$\mathrm{rec}_v : \mathrm{Irr}(GL_n(F_v)) \longrightarrow \Phi_n(F_v)$$

with the following ledgered compatibilities:

- *spherical representations have Satake parameter equal to the semisimple Frobenius class of $\mathrm{rec}_v(\pi_v)$;*
- *Rankin–Selberg local L, ϵ, and γ factors agree with the corresponding tensor-product factors on Weil–Deligne parameters;*
- *central characters satisfy*
$$\omega_{\pi_v} = \det(\mathrm{rec}_v(\pi_v)) \circ \mathrm{Art}_{F_v};$$
- *contragredients and character twists commute with the correspondence;*
- *conductor, depth, inertia type, monodromy N_v, additive character, Haar measure, and normalization conventions are recorded in the local ledger.*

The certificate is used here as a traditional mathematical input. The BEDC claim is the closure consequence obtained after this certificate is present.

Definition 9413.948 (GL_n local ledger)**.** *For a GL_n local parameter ϕ_v, the local ledger is*

$$\Lambda_{\phi_v}^{GL_n} := (I_v\text{-type}, N_v, \mathfrak{f}(\phi_v), \mathsf{Depth}, L_v, \epsilon_v, \gamma_v, \mathsf{CentralCharacter}, \mathsf{Normalization}).$$

It records every datum that is invisible to the unramified spherical Satake detector.

Theorem 9413.949 (GL_n packets are singleton packets)**.** *Under the GL_n local Langlands certificate, every parameter*

$$\phi_v \in \Phi_n(F_v)$$

has a unique corresponding irreducible admissible representation

$$\pi_{\phi_v} := \mathrm{rec}_v^{-1}(\phi_v).$$

Therefore its local packet is

$$\Pi_{\phi_v} = \{\pi_{\phi_v}\}.$$

Proof. The correspondence rec_v is a bijection. Thus the inverse image of ϕ_v exists and has exactly one element. The packet attached to ϕ_v is consequently the displayed singleton. □

Theorem 9413.950 (GL_n local three-properties certificate)**.** *The local row*

$$\mathcal{O}_v^{GL_n} := (\pi_{\phi_v}, \phi_v, \Lambda_{\phi_v}^{GL_n})$$

satisfies the BEDC time, unity, and ledger properties.

Proof. Time is supplied on the representation side by Bernstein decomposition, parabolic induction, depth filtration, and conductor filtration. On the parameter side it is supplied by Frobenius, inertia, and monodromy in

$$\phi_v = (r_v, N_v).$$

Unity is supplied by the tempered/unitary part of the local Langlands classification. For a general irreducible admissible representation, the Langlands classification expresses the row through tempered data and real exponent data; the tempered part is the unitary readout, while the real exponents are recorded as scale ledger rows.

The ledger property is exactly Definition 9413.948: conductor, depth, monodromy, local factors, central character, and normalization conventions are named rather than hidden in the unramified detector. □

Definition 9413.951 (GL_n stable local state)**.** *For a GL_n parameter ϕ_v, define its local stable state by*

$$S\Theta_{\phi_v} := \Theta_{\pi_{\phi_v}},$$

where $\Theta_{\pi_{\phi_v}}$ is the Harish–Chandra character distribution

$$\Theta_{\pi_{\phi_v}}(f_v) := \mathrm{tr}\, \pi_{\phi_v}(f_v), \qquad f_v \in C_c^\infty(GL_n(F_v)).$$

Because the packet is a singleton, no component-group sum is required.

Theorem 9413.952 (GL_n local state nonzero)**.** *For every GL_n local parameter ϕ_v, there exists*

$$f_v \in C_c^\infty(GL_n(F_v))$$

such that

$$S\Theta_{\phi_v}(f_v) \neq 0.$$

Proof. The representation π_{ϕ_v} is smooth and nonzero. Hence some nonzero vector is fixed by a compact open subgroup

$$K \subset GL_n(F_v).$$

Let

$$e_K = \frac{1_K}{\mathrm{vol}(K)}$$

be the normalized idempotent in the local Hecke algebra. The operator $\pi_{\phi_v}(e_K)$ is the projection onto the finite-dimensional space $\pi_{\phi_v}^K$. Since $\pi_{\phi_v}^K \neq 0$,

$$\Theta_{\pi_{\phi_v}}(e_K) = \mathrm{tr}\, \pi_{\phi_v}(e_K) = \dim \pi_{\phi_v}^K \neq 0.$$

By the definition of $S\Theta_{\phi_v}$, the same test function gives the required nonzero local state. □

Definition 9413.953 (GL_n local test residual)**.** *For a candidate representation π_v and a parameter ϕ_v, define the local test residual by*

$$D_{v,f_v}^{GL_n}(\pi_v, \phi_v) := \Theta_{\pi_v}(f_v) - \Theta_{\pi_{\phi_v}}(f_v).$$

The ramified finite detector is the row

$$(v, \mathfrak{b}, f_v),$$

where $\mathfrak{b}$ is a displayed Bernstein or packet window containing the candidates under comparison.

Theorem 9413.954 (GL_n character separation)**.** *Let*

$$\pi_1, \ldots, \pi_M$$

be pairwise non-isomorphic irreducible admissible representations of $GL_n(F_v)$ in a displayed finite local window. Then their Harish–Chandra character distributions are linearly independent as functionals on $C_c^\infty(GL_n(F_v))$. Consequently, for each target index i there is a test function

$$f_i^* \in C_c^\infty(GL_n(F_v))$$

such that

$$\Theta_{\pi_\ell}(f_i^*) = \delta_{\ell i}$$

for all displayed candidates π_ℓ.

Proof. Harish–Chandra character theory gives linear independence of the characters of pairwise non-isomorphic irreducible admissible representations. For the finite family

$$\Theta_{\pi_1}, \ldots, \Theta_{\pi_M},$$

linear independence in the dual space implies that there are test functions

$$f_1, \ldots, f_M$$

for which the matrix

$$A_{\ell j} := \Theta_{\pi_\ell}(f_j)$$

is invertible. Solving

$$\sum_j c_j A_{\ell j} = \delta_{\ell i}$$

and setting

$$f_i^* := \sum_j c_j f_j$$

gives the displayed isolating function. □

Theorem 9413.955 (GL_n ramified local no-hidden residual)**.** *Let (π_v, ϕ_v) be a local GL_n BEDC–Langlands row equipped with the local Langlands certificate and the three-properties ledger. If the row is closed against unresolved local residuals, then*

$$\pi_v \simeq \pi_{\phi_v}.$$

Equivalently,

$$D^{GL_n}_{v,f_v}(\pi_v, \phi_v) = 0$$

for every local test function f_v.

Proof. Assume $\pi_v \not\simeq \pi_{\phi_v}$. By Definition 9413.954, there is a local test function f_v with

$$\Theta_{\pi_v}(f_v) \neq \Theta_{\pi_{\phi_v}}(f_v).$$

Thus

$$D^{GL_n}_{v,f_v}(\pi_v, \phi_v) \neq 0.$$

This is a finite local detector. If the detected residual is entered in the ledger, the row is not closed until the residual is discharged. If it is not entered in the ledger, the ledger property fails. Both alternatives contradict closedness with the three-properties discipline. Hence $\pi_v \simeq \pi_{\phi_v}$, and all residuals vanish. □

Corollary 9413.956 (GL_n ramified local state closure)**.** *For $GL_n(F_v)$, every legal local parameter with a local Langlands certificate has a nonzero local state. Every ramified local mismatch is detected by a finite local test row $(v, \mathfrak{b}, f_v)$ or is an explicit local ledger row.*

Proof. Nonzero state follows from Definition 9413.952. Finite detection of representation mismatch follows from Definition 9413.955. The remaining ramified data are exactly the rows listed in Definition 9413.948. □

Definition 9413.957 (GL_n fixed-window parameter state)**.** *For a finite local-global window*

$$\mathcal{W} = (S_{\mathrm{unr}}, S_{\mathrm{ram}}, B),$$

the GL_n parameter state is

$$\Theta^{GL_n}_{\phi,\mathcal{W}} := \left(\bigotimes_{v \in S_{\mathrm{unr}}} \Theta^{\mathrm{unr}}_{\phi_v} \right) \otimes \left(\bigotimes_{v \in S_{\mathrm{ram}}} \Theta_{\pi_{\phi_v}} \right) \otimes \Theta_{\phi,\infty},$$

with archimedean factors present only on the declared scope.

Theorem 9413.958 (GL_n fixed-window parameter nonzero)**.** *Assume every archimedean factor in the declared window has a nonzero local state or a ledgered failure. Then every GL_n parameter with local Langlands certificates at the displayed nonarchimedean places has a fixed-window test function*

$$f_{\phi,\mathcal{W}}$$

such that

$$\Theta^{GL_n}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) \neq 0.$$

Proof. At unramified places, use the Satake projector from Definition 9413.919 and normalize its value to 1. At ramified nonarchimedean places, use Definition 9413.952 and rescale the chosen local test function so that

$$\Theta_{\pi_{\phi_v}}(f_{\phi_v}) = 1.$$

Normalize every present archimedean factor in the same way. The tensor product of these local functions satisfies

$$\Theta^{GL_n}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) = \prod_v \Theta_{\phi_v}(f_{\phi_v}) = 1.$$

□

Theorem 9413.959 (GL_n local-global residual dichotomy)**.** *Let (Π, ϕ) be a global GL_n BEDC–Langlands row on a fixed window. Any residual is either detected by an unramified Hecke–Frobenius detector, detected by a ramified local test row $(v, \mathfrak{b}, f_v)$, or belongs to an archimedean, continuous-spectrum, level-escape, conductor, normalization, or automorphic-tail ledger row.*

Proof. An unramified mismatch is detected by the finite representation readout (v, r) of Definition 9413.897. A ramified nonarchimedean mismatch is detected by Definition 9413.955. If no local detector sees the residual, it is not a displayed local character or Satake mismatch. It must therefore lie in archimedean module data, continuous spectrum, Eisenstein contribution, level or conductor escape, normalization, or automorphic tail behavior. These are global ledger rows by the trace-window and tail-closure certificates. □

Theorem 9413.960 (GL_n BEDC–Langlands conditional closure)**.** *Assume the GL_n local Langlands certificates at all displayed nonarchimedean places, the fixed-window parameter state certificate, the trace or existence bridge certificate, cofinal automorphic tail closure, no-hidden Langlands residual, and closedness. Then every legal global GL_n parameter in the declared scope has a global automorphic realization whose unramified Hecke–Frobenius readouts match the parameter and whose ramified local data are matched by the local Langlands ledger.*

Proof. The local packet certificate gives singleton ramified packets and nonzero local states. Hence Definition 9413.958 supplies a nonzero fixed-window parameter readout. The trace or existence bridge transports this readout to a nonzero automorphic spectral contribution on the same fixed window. Cofinal automorphic tail closure promotes compatible fixed-window realizations to a global automorphic row unless a tail ledger row is present; closedness excludes an unresolved tail.

If a residual remains, then Definition 9413.959 places it either in a finite detector or in a ledger row. No-hidden residual and closedness exclude unresolved instances of both alternatives. □

Theorem 9413.961 (GL_n local certificate boundary)**.** *The GL_n local packet certificate closes the local ramified BEDC module: singleton packet, nonzero local state, finite character detection, and local ledger discipline. It does not by itself construct the global automorphic realization; that construction is supplied by the separate trace or existence bridge.*

Proof. All preceding local statements use only the local Langlands certificate, Harish–Chandra character separation, admissibility, and the local ledger. Global existence requires a mechanism that turns a nonzero parameter-side fixed-window state into a spectral automorphic row. That mechanism is outside the local certificate and is exactly the role of the trace or existence bridge. □

9413.77 BEDC–Langlands Global Converse Bridge for GL_n

The local packet certificate of section 9413.76 turns every certified local GL_n parameter into a singleton local packet. The global existence problem is not solved by merely tensoring these local packets. The restricted tensor product is a legitimate adelic candidate only after the global compatibility ledger is present, and it becomes automorphic only after an existence bridge is supplied. For GL_n, the natural bridge is the Rankin–Selberg converse theorem.

Definition 9413.962 (GL_n global parameter row)**.** *Let F be a global field. A GL_n global parameter row is a parameter*

$$\phi : W'_F \to GL_n(\mathbb{C})$$

with local components

$$\phi_v : W'_{F_v} \to GL_n(\mathbb{C}).$$

At each nonarchimedean place where the local GL_n Langlands certificate is in scope, write

$$\pi_{\phi_v} := \mathrm{rec}_v^{-1}(\phi_v)$$

for the corresponding singleton packet representative.

Definition 9413.963 (Global compatibility certificate)**.** *A global compatibility certificate for ϕ consists of the following ledgered data:*

- *ϕ_v is unramified for almost all places v;*
- *π_{ϕ_v} is spherical for almost all nonarchimedean places;*
- *the central character row is global and satisfies*

$$\omega_\phi = \det(\phi) \circ \mathrm{Art}_F;$$

- *all ramified places, conductor exponents, monodromy rows, archimedean types, local L-factors, ϵ-factors, γ-factors, and normalization choices enter the global parameter ledger*

$$\Lambda_\phi^{GL_n} := (S_{\mathrm{ram}}, N_v, \mathfrak{f}_v, \epsilon_v, \gamma_v, \mathsf{ArchType}, \mathsf{CentralCharacter}, \mathsf{Normalization}).$$

Failure of any row is a global compatibility defect rather than an automorphic realization.

Definition 9413.964 (Local tensor product candidate)**.** *Under the global compatibility certificate, the local GL_n packets define the restricted tensor product candidate*

$$\Pi_\phi^{\mathrm{loc}} := \bigotimes_v{}' \pi_{\phi_v}.$$

This is an irreducible admissible adelic representation candidate of $GL_n(\mathbb{A}_F)$ on the declared scope. It is not, by definition, an automorphic representation.

Theorem 9413.965 (Local tensor candidate readout)**.** *If ϕ has a global compatibility certificate, then Π_ϕ^{loc} is defined as a restricted tensor product. For almost all unramified places v,*

$$s_v(\Pi_\phi^{\mathrm{loc}}) = \phi(\mathrm{Frob}_v).$$

Proof. Almost all local rows are unramified by the global compatibility certificate, so the corresponding representations are spherical and carry normalized spherical vectors. The restricted tensor product is therefore defined. At an unramified place, the local GL_n Langlands certificate is compatible with the Satake parameter, giving the displayed equality. □

Definition 9413.966 (Rankin–Selberg twist detector)**.** *Let $1 \le m \le n-1$, and let τ be a cuspidal automorphic representation of $GL_m(\mathbb{A}_F)$ in the admitted detector class. The Rankin–Selberg twist detector attached to (m, τ) reads the Euler product*

$$L(s, \Pi_\phi^{\mathrm{loc}} \times \tau) := \prod_v L(s, \pi_{\phi_v} \times \tau_v).$$

When τ has a parameter row ϕ_τ, the parameter-side expected readout is

$$L(s, \phi \otimes \phi_\tau).$$

The analytic residual is the ledger row recording failure of any of the following:

$$L(s, \Pi_\phi^{\mathrm{loc}} \times \tau) = L(s, \phi \otimes \phi_\tau),$$

meromorphic continuation, the prescribed functional equation, boundedness in vertical strips, and local $L/\epsilon/\gamma$ factor compatibility.

Definition 9413.967 (Finite twist window)**.** *For a complexity bound B, the finite twist window is*

$$\mathcal{T}_B(n) := \{(m, \tau) : 1 \le m \le n-1,\ \kappa(\tau) \le B\},$$

where $\kappa(\tau)$ records conductor, level, ramified type, central character, archimedean parameter, and normalization complexity. A residual visible for some $(m, \tau) \in \mathcal{T}_B(n)$ is a finite Rankin residual. A residual invisible in every fixed $\mathcal{T}_B(n)$ but present along unbounded conductor, level, ramified type, or archimedean parameter is a twist tail residual, recorded in

$$\mathsf{TwistTailLedger} := (\mathsf{ConductorEscape}, \mathsf{ArchimedeanEscape}, \mathsf{RamificationEscape}, \mathsf{NonuniformBoundedness}, \mathsf{GammaFact}$$

Theorem 9413.968 (Rankin residual dichotomy)**.** *Let Π_ϕ^{loc} be a global GL_n local tensor product candidate whose local packet and compatibility ledgers are closed. If the converse-theorem analytic hypotheses fail, then the failure is either a finite Rankin residual in some fixed twist window or a twist tail residual.*

Proof. The analytic hypotheses are tested by Rankin–Selberg twists (m, τ) with $1 \le m \le n-1$. If a hypothesis fails for a twist of bounded detector complexity, it is visible in a finite window $\mathcal{T}_B(n)$ and is a finite Rankin residual. If every bounded window is clean but failure occurs only along twists with unbounded conductor, level, ramified type, archimedean parameter, or normalization complexity, then the failure is not a fixed-window datum. It is precisely a twist tail residual. □

Definition 9413.969 (GL_n converse theorem certificate)**.** *A GL_n converse theorem certificate is a traditional analytic bridge which applies to an irreducible admissible generic representation candidate Π of $GL_n(\mathbb{A}_F)$ with the declared central character and asserts: if for all $1 \le m \le n-1$ and all admitted cuspidal automorphic τ on $GL_m(\mathbb{A}_F)$ the Rankin–Selberg twists*

$$L(s, \Pi \times \tau)$$

have the required meromorphic continuation, functional equation, boundedness in vertical strips, and local factor compatibility, then

$$\Pi$$

is automorphic. Non-generic, residual-spectrum, and boundary cases are not hidden inside this certificate; they enter the residual-spectrum ledger.

Definition 9413.970 (No hidden Rankin residual)**.** *The no-hidden Rankin residual condition says that every failure of a Rankin–Selberg analytic hypothesis is either detected in a fixed twist window $\mathcal{T}_B(n)$ or is recorded in* TwistTailLedger*, and that closed accepted rows carry no unresolved entry in either ledger.*

Theorem 9413.971 (Converse bridge closure)**.** *Assume ϕ has a global compatibility certificate, the local GL_n packet certificates are present, Π_ϕ^{loc} lies in the generic scope of the GL_n converse theorem certificate, no finite Rankin residual is present, no twist tail residual remains unresolved, and the row is closed. Then*

$$\Pi_\phi^{\mathrm{loc}}$$

is automorphic.

Proof. If Π_ϕ^{loc} were not automorphic while the converse certificate applied, at least one converse-theorem hypothesis would fail. By Definition 9413.968, that failure is either a finite Rankin residual or a twist tail residual. A finite residual contradicts the hypothesis that no finite Rankin residual is present. A tail residual contradicts the hypothesis that no twist tail residual remains unresolved. Hence all converse-theorem analytic hypotheses are closed. The GL_n converse theorem certificate therefore gives automorphy of Π_ϕ^{loc}. □

Theorem 9413.972 (GL_n global reciprocity from converse bridge)**.** *Assume:*

- *ϕ has a global compatibility certificate;*
- *local GL_n Langlands packet certificates hold at the displayed places;*
- *Π_ϕ^{loc} is in the generic scope of the GL_n converse theorem certificate;*
- *all Rankin–Selberg analytic detector residuals are finite-clean or discharged in the twist tail ledger;*
- *the no-hidden Langlands residual condition and closedness hold.*

Then there is an automorphic representation

$$\Pi_\phi$$

of $GL_n(\mathbb{A}_F)$ such that, for almost all unramified places v,

$$s_v(\Pi_\phi) = \phi(\mathrm{Frob}_v).$$

Equivalently, for every finite-dimensional representation r of the dual group in the certified readout class,

$$\lambda_{v,r}(\Pi_\phi) = \operatorname{tr} r(\phi(\mathrm{Frob}_v)).$$

Proof. The local packet certificates and the global compatibility certificate construct the restricted tensor product

$$\Pi_\phi^{\mathrm{loc}}.$$

The Rankin–Selberg detector hypotheses and Definition 9413.971 make this candidate automorphic. Set

$$\Pi_\phi := \Pi_\phi^{\mathrm{loc}}.$$

The almost-everywhere Satake equality follows from Definition 9413.965. Applying finite-dimensional representation readouts gives the displayed Hecke–Frobenius equality. Any remaining mismatch is a finite Hecke–Frobenius detector, a ramified local ledger row, an archimedean row, a residual-spectrum row, or an automorphic tail row; no-hidden residual and closedness exclude unresolved instances. □

Theorem 9413.973 (GL_N functorial transfer through the converse bridge)**.** *Let*

$$\eta : {}^L H \to GL_N(\mathbb{C})$$

be an N-dimensional L-group representation and let

$$\phi_H : W_F' \to {}^L H$$

be an H-side parameter. Put

$$\phi_\eta := \eta \circ \phi_H.$$

If ϕ_η satisfies the hypotheses of Definition 9413.972 for GL_N, then there is an automorphic representation Π_η of $GL_N(\mathbb{A}_F)$ with

$$s_v(\Pi_\eta) = \eta(\phi_H(\mathrm{Frob}_v))$$

for almost all certified unramified places v.

Proof. The composed parameter ϕ_η is a GL_N parameter row. Applying Definition 9413.972 to ϕ_η gives an automorphic representation Π_η with

$$s_v(\Pi_\eta) = \phi_\eta(\mathrm{Frob}_v).$$

The definition of ϕ_η identifies the right side with $\eta(\phi_H(\mathrm{Frob}_v))$. □

Theorem 9413.974 (Nonautomorphy is a Rankin residual)**.** *Within the scope of the GL_n converse theorem certificate, a legal local tensor product candidate that is not automorphic carries a Rankin–Selberg analytic residual.*

Proof. The contrapositive form of the converse theorem certificate says that a candidate in its scope which is not automorphic must fail at least one of the hypotheses: meromorphic continuation, functional equation, vertical-strip boundedness, or local factor compatibility for some Rankin–Selberg twist. Each failure is exactly a Rankin analytic residual. □

Corollary 9413.975 (Closed GL_n candidates are automorphic)**.** *In the declared generic scope, a GL_n local tensor product candidate with global compatibility, local packet closure, no hidden Rankin residual, and closedness cannot be both legal and nonautomorphic.*

Proof. If it were nonautomorphic, then Definition 9413.974 would produce a Rankin analytic residual. By Definition 9413.968, that residual is finite-visible or a twist tail row. The first alternative contradicts finite-clean Rankin closure; the second contradicts closedness against unresolved twist tail rows. □

Theorem 9413.976 (GL_n converse bridge boundary)**.** *The GL_n global converse bridge closes the passage from local packet data to automorphic realization only under the stated analytic certificate: global compatibility, generic scope, Rankin–Selberg twist closure, tail-ledger discipline, and closedness. It does not replace the converse theorem, nor does it assert automorphy for parameters outside the certificate's scope.*

Proof. The construction up to Π_ϕ^{loc} is local and ledgered. The step from a legal adelic candidate to an automorphic representation is precisely the converse theorem certificate. Outside its hypotheses, the failure is not erased; it is recorded as global-compatibility, non-generic, residual-spectrum, analytic, or tail ledger data. □

9413.78 BEDC–Langlands Tannakian Functorial Closure

The GL_n converse bridge constructs automorphic realizations for linear representations of an L-parameter. For a general reductive group G, the finite readouts are the finite-dimensional representations of ${}^LG$. The question is not whether each composed parameter

$$r \circ \phi : W_F' \to GL(V_r)$$

has a $GL(V_r)$-realization, but whether the resulting family of GL-objects is tensor-compatible and therefore comes from one ${}^LG$-valued packet.

Definition 9413.977 (Tannakian detector)**.** *A Tannakian detector for G is a pair*

$$(v, r)$$

where v is an unramified place in the certified scope and

$$r : {}^LG \to GL(V_r)$$

is a finite-dimensional representation. For a parameter ϕ, the parameter-side readout is

$$a_{v,r}(\phi) := \operatorname{tr} r(\phi(\mathrm{Frob}_v)).$$

For a G-side automorphic packet Π_G with Satake parameter $s_v(\Pi_G)$, the automorphic readout is

$$\lambda_{v,r}(\Pi_G) := \operatorname{tr} r(s_v(\Pi_G)).$$

The finite detector residual is

$$D_{v,r}(\Pi_G, \phi) := \lambda_{v,r}(\Pi_G) - a_{v,r}(\phi).$$

Definition 9413.978 (Representation compatibility rows)**.** *Let*

$$\{\Pi_r\}_{r \in \mathrm{Rep}({}^LG)}$$

be a family of $GL(V_r)$-side automorphic objects obtained from the composed parameters $r \circ \phi$. Its Tannakian compatibility rows are the finite relations generated by direct sum, tensor product, and dual:

$$\Pi_{r_1 \oplus r_2} \simeq \Pi_{r_1} \boxplus \Pi_{r_2},$$
$$L(s, \Pi_{r_1 \otimes r_2}) = L(s, \Pi_{r_1} \times \Pi_{r_2}),$$

and

$$\Pi_{r^\vee} \simeq \Pi_r^\vee.$$

Failures of these rows are denoted

$$R_\oplus(r_1, r_2), \qquad R_\otimes(r_1, r_2), \qquad R_\vee(r),$$

and form the Tannakian compatibility ledger.

Theorem 9413.979 (Tannakian separation)**.** *Let $g, h \in {}^LG$ be semisimple. If*

$$\operatorname{tr} r(g) = \operatorname{tr} r(h)$$

for every finite-dimensional representation r of ${}^LG$, then g and h have the same semisimple conjugacy class.

Proof. This is the detector separation theorem of Definition 9413.860. Characters of finite-dimensional representations generate the coordinate algebra of the semisimple conjugacy quotient

$${}^LG /\!/ \operatorname{conj}.$$

Equality of all character values therefore puts g and h at the same point of that quotient. Since both elements are semisimple, this point determines the semisimple conjugacy class. □

Definition 9413.980 (Tannakian generator)**.** *A finite set*

$$\mathcal{R}_0 = \{r_1, \ldots, r_m\}$$

of finite-dimensional representations of ${}^LG$ is a Tannakian generator when the representation ring is generated by $\mathcal{R}_0$ under $\oplus$, $\otimes$, and ${}^\vee$, and tensor-word characters in these generators separate semisimple conjugacy classes.

Theorem 9413.981 (Generator detection)**.** *Let $\mathcal{R}_0$ be a Tannakian generator. If two semisimple elements $g, h \in {}^LG$ have equal trace under every tensor word in $\mathcal{R}_0$, then they have the same semisimple conjugacy class.*

Proof. Every finite-dimensional character is an integral linear combination of characters of tensor words built from $\mathcal{R}_0$, because $\mathcal{R}_0$ generates the representation ring. Equality on all tensor words therefore implies equality of $\operatorname{tr} r(g)$ and $\operatorname{tr} r(h)$ for every finite-dimensional representation r. The result follows from Definition 9413.979. □

Definition 9413.982 (Tannakian residual dichotomy data)**.** *A finite Tannakian residual is a failure of one displayed finite representation relation, such as*

$$R_\otimes(r_1, r_2) \neq 0,$$

inside a fixed finite representation window. A representation-tail residual is a compatibility failure invisible in every fixed finite representation window but present along unbounded highest weight, tensor depth, multiplicity, local factor complexity, or functorial compatibility complexity. Its ledger is

$$\mathsf{RepTailLedger} := (\mathsf{HighestWeightEscape}, \mathsf{TensorDepthEscape}, \mathsf{MultiplicityEscape}, \mathsf{NonuniformLFactorBound}, \mathsf{Functorial}$$

Theorem 9413.983 (Tannakian residual dichotomy)**.** *If a family $\{\Pi_r\}_{r\in\mathrm{Rep}({}^LG)}$ of GL-transfers does not come from one tensor-compatible ${}^LG$-readout system, then there is a finite Tannakian residual or a representation-tail residual.*

Proof. Failure to come from one tensor-compatible readout means that some relation in the tensor category $\mathrm{Rep}({}^LG)$ is not respected by the family $\{\Pi_r\}$. If the failing relation uses a fixed finite expression in $\oplus$, $\otimes$, and ${}^\vee$, it is a finite Tannakian residual. If every fixed finite expression is compatible but no global tensor-compatible readout exists, the defect is not located in any finite representation window. It can only appear along unbounded representation complexity, which is exactly the representation-tail residual. □

Definition 9413.984 (No hidden Tannakian residual)**.** *The no-hidden Tannakian residual condition says that every failure of representation compatibility is either detected by a finite representation relation or is recorded in* RepTailLedger*, and that a closed accepted system carries no unresolved entry in either place.*

Theorem 9413.985 (Tannakian closure)**.** *Let $\{\Pi_r\}$ be a family of GL-transfers with the BEDC three-properties ledger, no-hidden Tannakian residual, and closedness. Then the family determines a unique semisimple ${}^LG$-readout system on the certified unramified scope.*

Proof. If the family did not determine one tensor-compatible readout system, Definition 9413.983 would give a finite Tannakian residual or a representation-tail residual. A finite residual is detected by a finite representation relation. It must be entered in the ledger, leaving the system not closed, or omitted, violating the ledger property. A tail residual is handled in the same way by RepTailLedger. Both alternatives contradict the closed no-hidden hypotheses. Thus the family is tensor-compatible.

For each certified unramified place v, the compatible character system on $\mathrm{Rep}({}^LG)$ defines a point of ${}^LG//\mathrm{conj}$. Uniqueness follows from Definition 9413.979. □

Theorem 9413.986 (Reconstruction from GL_N transfers)**.** *Let $\mathcal{R}_0$ be a Tannakian generator. Assume that for every tensor word w in $\mathcal{R}_0$, the composed parameter*

$$w \circ \phi$$

has a $GL(V_w)$-automorphic realization Π_w supplied by the GL_N local and global closure bridges. If these transfers satisfy no-hidden Tannakian residual and closedness, then for every certified unramified place v there is a unique semisimple class

$$s_v \in {}^LG//\mathrm{conj}$$

such that

$$\mathrm{tr}\, r(s_v) = \lambda_{v,r}(\Pi_r)$$

for every finite-dimensional representation r in the generated readout scope.

Proof. The GL_N closure bridges give the automorphic readouts for the generators and their tensor words. By Definition 9413.985, no closed compatible system can have a finite or tail Tannakian residual. Therefore the readouts form a tensor-compatible character system on $\mathrm{Rep}({}^LG)$. Tannakian separation gives a unique semisimple class s_v realizing those character values. □

Theorem 9413.987 (General G finite-readout closure)**.** *In the setting of Definition 9413.986, the reconstructed semisimple class agrees with the original parameter readout:*

$$s_v = \phi(\mathrm{Frob}_v)$$

in ${}^L G//\,\mathrm{conj}$ *for every certified unramified place* v*. Hence for every finite-dimensional representation* r *in the readout scope,*

$$\lambda_{v,r}(\Pi_r) = \mathrm{tr}\, r(\phi(\mathrm{Frob}_v)).$$

Proof. Each Π_r was constructed from the composed $GL(V_r)$-parameter $r \circ \phi$, so its unramified readout is

$$\lambda_{v,r}(\Pi_r) = \mathrm{tr}\, r(\phi(\mathrm{Frob}_v)).$$

Thus the reconstructed class s_v and the class $\phi(\mathrm{Frob}_v)$ have the same trace under every generated finite-dimensional representation. By generator detection, they are the same semisimple class. □

Definition 9413.988 (General G existence bridge certificate)**.** *A general* G *existence bridge certificate says that a tensor-compatible system of* GL_N *transfers attached to a parameter* ϕ *either descends to a* G*-side automorphic packet*

$$\Pi_\phi^G$$

or enters the existence ledger

$$\mathsf{ExistenceLedger}_G := (\mathsf{MissingGPacket}, \mathsf{EndoscopicPacketDefect}, \mathsf{ArthurPacketDefect}, \mathsf{ContinuousSpectrumDefect}, \mathsf{Bou}$$

The certificate may be supplied by stable trace formula data, endoscopic classification, Arthur packet construction, a geometric Langlands functor, or a cohomological realization on the declared scope.

Theorem 9413.989 (General G BEDC reciprocity)**.** *Assume:*

- GL_N *transfers exist for a Tannakian generator and its tensor words;*
- *the family satisfies no-hidden Tannakian residual and closedness;*
- *the general* G *existence bridge certificate is present;*
- *no-hidden Langlands residual and closedness hold for the resulting* G*-packet.*

Then there is a closed G*-side automorphic packet* Π_ϕ^G *such that, for almost all certified unramified* v *and all finite-dimensional* $r : {}^L G \to GL(V_r)$ *in the readout scope,*

$$\lambda_{v,r}(\Pi_\phi^G) = \mathrm{tr}\, r(\phi(\mathrm{Frob}_v)).$$

Proof. By Definition 9413.987, the GL_N transfers are compatible with the single parameter readout ϕ. The general G existence bridge certificate says that the compatible system descends to a G-side packet or enters $\mathsf{ExistenceLedger}_G$. An unresolved existence-ledger entry is not compatible with closedness; omitting it violates the ledger property. Hence the packet Π_ϕ^G exists in the closed case.

If a Hecke–Frobenius mismatch remains, the no-hidden Langlands residual condition makes it a finite detector residual or a ledger row. The first contradicts the finite readout closure; the second contradicts closedness while unresolved. The displayed equality follows. □

Theorem 9413.990 (Tannakian functoriality closure)**.** *Let*

$$\eta : {}^L H \to {}^L G$$

be an L-group homomorphism and let (Π_H, ϕ_H) be a closed H-side packet. Put

$$\phi_G := \eta \circ \phi_H.$$

If ϕ_G satisfies the hypotheses of Definition 9413.989, then there is a closed G-side packet Π_G satisfying

$$\lambda_{v,r}(\Pi_G) = \operatorname{tr} r(\eta(\phi_H(\mathrm{Frob}_v)))$$

for almost all certified unramified v and all finite-dimensional $r : {}^L G \to GL(V_r)$ in the readout scope.

Proof. Apply Definition 9413.989 to the parameter $\phi_G = \eta \circ \phi_H$. The resulting G-packet has readouts

$$\lambda_{v,r}(\Pi_G) = \operatorname{tr} r(\phi_G(\mathrm{Frob}_v)).$$

Substituting the definition of ϕ_G gives the displayed formula. □

Corollary 9413.991 (GL_1 as the minimal Tannakian model)**.** *For ${}^L G = \mathbb{C}^\times$, the representation category is generated by the characters*

$$z \mapsto z^k.$$

Tannakian compatibility is the identity

$$z^{k+\ell} = z^k z^\ell.$$

For the quadratic character attached to $\mathbb{Q}(i)/\mathbb{Q}$, the visible unramified detector

$$\chi_{-4}(\mathrm{Frob}_p) = 1$$

is equivalent to $p = a^2 + b^2$ for odd primes. Thus the two-square readout is the minimal abelian shadow of the general Tannakian detector system.

Proof. For $\mathbb{C}^\times$, every finite-dimensional semisimple representation is a finite direct sum of characters z^k, and tensor product adds exponents. The quadratic character χ_{-4} is the class-field detector for the extension $\mathbb{Q}(i)/\mathbb{Q}$; its unramified value 1 is exactly the splitting condition for odd primes, equivalently $p = a^2 + b^2$. □

Theorem 9413.992 (Tannakian closure boundary)**.** *Tannakian functorial closure proves that compatible GL_N readouts determine the finite detector system of a general G-parameter, and that incompatibility is finite-visible or ledgered as representation tail. It does not by itself construct the missing G-automorphic packet; that is exactly the role of the general G existence bridge.*

Proof. The arguments above are representation-category and ledger arguments: they use GL_N transfers, tensor compatibility, Tannakian separation, and no-hidden residual discipline. The descent from compatible GL_N readouts to an actual G-side automorphic packet is a separate existence statement, represented by Definition 9413.988. □

9413.79 BEDC–Langlands Stable Multiplicity Formula Certificate

The general G existence bridge of section 9413.80 uses a stable multiplicity formula as the step from a nonzero stable parameter distribution to a nonempty automorphic packet. This section isolates that step. The additional datum, absent from the singleton GL_n setting, is the finite component group attached to an Arthur or Langlands parameter. Its finite Fourier theory is the packet-internal detector for multiplicity and labeling residuals.

Definition 9413.993 (Arthur component group)**.** *Let*

$$\psi : L_F \times SL_2(\mathbb{C}) \to {}^L G$$

be a discrete Arthur parameter. Its component group is the finite row

$$\mathcal{S}_\psi := \pi_0 \left(Z_{\widehat{G}}(\operatorname{im}\psi)/Z(\widehat{G})^{\Gamma_F} \right).$$

It records the finite internal symmetry of the packet attached to ψ.

Definition 9413.994 (Packet Fourier ledger)**.** *A packet labeling certificate for ψ consists of a packet candidate*

$$\Pi_\psi(G)$$

and a finite packet character datum, written in the basic case as a map

$$\ell : \Pi_\psi(G) \to \widehat{\mathcal{S}_\psi}.$$

For $\pi \in \Pi_\psi(G)$ write $\chi_\pi := \ell(\pi)$. Failure of packet labeling, component-character normalization, sign convention, or packet membership is recorded in

$$\mathsf{PacketLabelLedger}(\psi).$$

Definition 9413.995 (Packet Fourier distributions)**.** *For a test function f and $s \in \mathcal{S}_\psi$, define the Fourier-twisted packet distribution*

$$\Theta_{\psi,s}(f) := \sum_{\pi \in \Pi_\psi(G)} \chi_\pi(s)\Theta_\pi(f),$$

where

$$\Theta_\pi(f) := \operatorname{tr}\pi(f).$$

The stable packet distribution is a declared finite linear combination

$$S\Theta^G_\psi(f) := \sum_{\pi \in \Pi_\psi(G)} m_\psi(\pi)\Theta_\pi(f),$$

with $m_\psi(\pi)$ determined by the multiplicity formula and recorded in the multiplicity ledger.

Definition 9413.996 (Component group three-properties rows)**.** *The time row of $\mathcal{S}_\psi$ is generated by the chain*

$$\operatorname{im}\psi \longrightarrow Z_{\widehat{G}}(\operatorname{im}\psi) \longrightarrow \pi_0.$$

The unity row is finite Fourier orthogonality on $\mathcal{S}_\psi$:

$$\frac{1}{|\mathcal{S}_\psi|} \sum_{s \in \mathcal{S}_\psi} \chi(s)\overline{\chi'(s)} = \delta_{\chi,\chi'}.$$

The ledger row records packet labels, multiplicities, global signs, transfer factors, endoscopic labels, and normalization choices.

Theorem 9413.997 (Component-group Fourier detection)**.** *Let $\mathcal{S}$ be a finite group. If two coefficient functions*

$$a, b : \widehat{\mathcal{S}} \to \mathbb{C}$$

are distinct, then there exists $s \in \mathcal{S}$ such that

$$\sum_{\chi \in \widehat{\mathcal{S}}} a(\chi)\chi(s) \neq \sum_{\chi \in \widehat{\mathcal{S}}} b(\chi)\chi(s).$$

Proof. Let $c = a - b$. Since $a \neq b$, the function c is nonzero. The finite Fourier transform

$$\widehat{c}(s) := \sum_{\chi \in \widehat{\mathcal{S}}} c(\chi)\chi(s)$$

is invertible on the finite character group. If $\widehat{c}(s) = 0$ for all $s \in \mathcal{S}$, then Fourier inversion gives $c = 0$, a contradiction. Hence some s has $\widehat{c}(s) \neq 0$. □

Corollary 9413.998 (Packet multiplicity mismatch is finite-detected)**.** *If the actual spectral multiplicity function on a packet differs from the multiplicity function predicted by the stable multiplicity formula, then a component-group Fourier detector*

$$s \in \mathcal{S}_\psi$$

detects the mismatch, or the mismatch is a packet ledger row.

Proof. Group packet members by their component character labels. The actual multiplicities and predicted multiplicities give two coefficient functions on $\widehat{\mathcal{S}_\psi}$. If these functions differ, Definition 9413.997 gives an element s whose Fourier-twisted packet distribution distinguishes them. If the packet labels or the grouping needed for this comparison are unavailable, the failure is exactly a packet ledger row. □

Definition 9413.999 (Stable multiplicity formula certificate)**.** *A stable multiplicity formula certificate for ψ consists of:*

- *a packet candidate $\Pi_\psi(G)$;*
- *a packet labeling certificate over $\mathcal{S}_\psi$;*
- *a multiplicity function*
$$m_\psi : \Pi_\psi(G) \to \mathbb{Z}_{\geq 0};$$
- *an identity on the discrete stable scope*
$$S\Theta_\psi^G(f) = \sum_{\pi \in \Pi_\psi(G)} m_\psi(\pi)\Theta_\pi(f) + \mathsf{MultiplicityLedger}_\psi(f),$$
  where the ledger contains component-group data, signs, transfer factors, endoscopy, continuous spectrum, boundary, and normalization rows.

Failure to supply any listed row is a MultiplicityDefectLedger *entry.*

Definition 9413.1000 (No hidden multiplicity residual)**.** *The no-hidden multiplicity residual condition says that every failure of packet membership, packet labeling, component-group Fourier compatibility, multiplicity, stable character identity, or packet normalization is finite-detected by a packet Fourier detector or is recorded in* MultiplicityDefectLedger*, and closed packets carry no unresolved such row.*

Theorem 9413.1001 (Stable distribution nonzero forces packet nonempty)**.** *Assume:*

- $S\Theta_\psi^G(f_0) \neq 0$ *for some fixed test function* f_0*;*
- *the stable multiplicity formula certificate holds;*
- *continuous, boundary, endoscopic, and normalization ledger terms are separated or explicitly ledgered;*
- *the object is closed against unresolved ledger rows.*

Then

$$\Pi_\psi(G) \neq \varnothing.$$

Proof. By the stable multiplicity formula,

$$S\Theta_\psi^G(f_0) = \sum_{\pi \in \Pi_\psi(G)} m_\psi(\pi)\Theta_\pi(f_0) + \mathsf{MultiplicityLedger}_\psi(f_0).$$

The ledger terms are separated or explicitly recorded. If $\Pi_\psi(G)$ were empty, the packet sum would be zero. The nonzero value of $S\Theta_\psi^G(f_0)$ would then have to come entirely from a ledger term: continuous spectrum, boundary, endoscopy, normalization, or multiplicity defect. Carrying such a row unresolved contradicts closedness, while omitting it violates the ledger property. Therefore a closed nonzero stable distribution has a nonempty packet. □

Theorem 9413.1002 (Missing packet forces ledger contradiction)**.** *Let* ψ *be a closed three-properties parameter with*

$$S\Theta_\psi^G(f_0) \neq 0.$$

If $\Pi_\psi(G) = \varnothing$*, then an unresolved ledger residual is present.*

Proof. With an empty packet, the nonzero stable distribution cannot be accounted for by packet characters. The source of the nonzero readout must be endoscopic transfer, continuous spectrum, Eisenstein boundary, packet-label failure, multiplicity formula defect, or normalization data. These are precisely ledger rows. If the row is carried, the object is not closed; if it is omitted, the ledger property fails. □

Definition 9413.1003 (Endoscopic packet transfer residual)**.** *Let* $\xi : {}^LH \to {}^LG$ *be an endoscopic embedding and suppose*

$$\psi = \xi \circ \psi_H.$$

For matching test functions $f^H \leftrightarrow f^G$*, the endoscopic packet transfer residual is*

$$R_{\mathrm{endo}}(f^G, f^H) := S\Theta_\psi^G(f^G) - S\Theta_{\psi_H}^H(f^H).$$

Theorem 9413.1004 (Endoscopic transfer residual detection)**.** *If* R_{endo} *is nonzero, then it is detected on a fixed matching test window or enters the endoscopic tail ledger.*

Proof. If some fixed matching pair $f^H \leftrightarrow f^G$ has

$$R_{\mathrm{endo}}(f^G, f^H) \neq 0,$$

then the residual is finite-visible. If all fixed matching windows are clean but transfer still fails globally, the failure lies in singular orbital limits, ramification escape, transfer-factor normalization, boundary, or continuous spectrum. These are exactly endoscopic tail ledger rows. □

Theorem 9413.1005 (Endoscopic induction with multiplicity)**.** *Assume proper endoscopic groups have the existence bridge, endoscopic transfer residuals are no-hidden, and the relevant stable multiplicity formulae are closed. If*

$$\psi = \xi \circ \psi_H$$

comes from a proper endoscopic group H, then the G-side packet $\Pi_\psi(G)$ exists in the closed scope.

Proof. The induction hypothesis gives a nonempty H-side packet $\Pi_{\psi_H}(H)$. Endoscopic transfer carries its stable distribution to the G-side unless a transfer residual occurs. By Definition 9413.1004, such a residual is finite-visible or ledgered as endoscopic tail; both alternatives contradict closedness when unresolved. Hence transfer succeeds. The stable multiplicity formula on the G-side then records the transferred packet with its packet labels and multiplicities. □

Theorem 9413.1006 (General G existence bridge, multiplicity form)**.** *Assume:*

- *a parameter state certificate gives*

$$S\Theta^G_\psi(f_0) \neq 0$$

  on a fixed window;
- *the stable multiplicity formula certificate holds;*
- *endoscopic transfer and endoscopic induction certificates hold;*
- *trace tail ledger rows are complete;*
- *no-hidden multiplicity residual and closedness hold.*

Then the closed parameter ψ has

$$\Pi_\psi(G) \neq \varnothing.$$

Proof. If the primitive discrete contribution of $S\Theta^G_\psi(f_0)$ is nonzero, then Definition 9413.1001 gives a nonempty G-packet. If the nonzero contribution is a proper endoscopic contribution, then Definition 9413.1005 gives the G-packet. If neither alternative holds, the nonzero readout belongs to continuous spectrum, Eisenstein boundary, singular orbit, normalization, or multiplicity-defect data. These are trace or multiplicity ledger rows, and closedness excludes unresolved such rows. □

Theorem 9413.1007 (Stable multiplicity reciprocity)**.** *Under the hypotheses of Definition 9413.1006, plus Tannakian separation, Chebotarev, and no-hidden Langlands residual, there is $\pi \in \Pi_\psi(G)$ such that*

$$\lambda_{v,r}(\pi) = \operatorname{tr} r(\psi(\mathrm{Frob}_v))$$

for almost all certified unramified places v and all finite-dimensional readouts $r : {}^LG \to GL(V_r)$ in scope.

Proof. The multiplicity-form bridge gives a nonempty packet. Choose $\pi \in \Pi_\psi(G)$. Any unramified mismatch is detected by the finite Tannakian detector (v, r). If no such detector sees a mismatch, Tannakian separation and Chebotarev fix the semisimple unramified readout; any remaining discrepancy is ramified, endoscopic, continuous, boundary, multiplicity, or normalization ledger data. No-hidden residual and closedness exclude unresolved residuals. □

Theorem 9413.1008 (Stable multiplicity certificate boundary)**.** *The stable multiplicity formula certificate closes packet nonemptiness from a nonzero stable distribution once packet labels, component-group Fourier data, multiplicities, endoscopic transfer, and ledger rows are supplied. It does not construct Arthur packets, prove the stable multiplicity formula, or prove endoscopic transfer.*

Proof. The arguments are finite Fourier, linear distribution, and ledger arguments after the traditional packet and multiplicity data are present. The construction of those data remains the independent mathematical input. □

9413.80 BEDC–Langlands General G Existence Bridge

The Tannakian functorial closure of section 9413.78 reduces the finite readout problem for a general reductive group G to compatible GL_N transfers. It does not by itself construct the G-side automorphic packet. The existence bridge for general G is the stable-trace and endoscopic part of the Langlands machine: a nonzero stable parameter readout must appear as a primitive G-packet, as a proper endoscopic transfer, or as a declared trace tail ledger row.

Definition 9413.1009 (General G parameter object)**.** *Let F be a global field and let G/F be a connected reductive group. A general G parameter object is an Arthur-type row*

$$\psi : L_F \times SL_2(\mathbb{C}) \to {}^L G,$$

with ordinary Langlands parameters

$$\phi : W_F' \to {}^L G$$

included by taking the SL_2 factor to be trivial. Its BEDC ledger is

$$\Lambda_\psi := (S_{\mathrm{ram}}, N_v, \epsilon_v, \gamma_v, \mathcal{S}_\psi, \mathsf{Endoscopy}, \mathsf{ContinuousSpectrum}, \mathsf{Boundary}, \mathsf{Normalization}),$$

where

$$\mathcal{S}_\psi := \pi_0(Z_{\widehat{G}}(\operatorname{im}\psi)).$$

The time row is generated by Frobenius, local parameters, Arthur SL_2, and trace-window inclusions; the unity row is the stable semisimple or tempered readout; the ledger row is Λ_ψ.

Definition 9413.1010 (G-side automorphic realization residual)**.** *A G-side automorphic packet $\Pi_\psi(G)$ realizes ψ when, for almost all unramified places v, some $\pi \in \Pi_\psi(G)$ has*

$$\lambda_{v,r}(\pi) = \operatorname{tr} r(\psi(\mathrm{Frob}_v))$$

for every finite-dimensional representation $r : {}^L G \to GL(V_r)$ in the certified readout scope. If no such G-packet is present, the missing realization residual is

$$E_G(\psi) := \mathsf{MissingGAutomorphicPacket}(\psi).$$

Definition 9413.1011 (Stable parameter distribution certificate)**.** *A stable parameter distribution certificate for ψ assigns to every fixed Hecke window $\mathcal{W}$ a stable functional*

$$S\Theta_\psi^G : \mathcal{H}_{\mathcal{W}}(G) \to \mathbb{C}$$

and a parameter projector $f_{\psi,\mathcal{W}}^G$ such that

$$S\Theta_\psi^G(f_{\psi,\mathcal{W}}^G) \neq 0$$

on the declared nonzero scope. At unramified places this is Satake evaluation at $\psi(\mathrm{Frob}_v)$; at ramified places it uses the local packet stable character and its local ledger.

Definition 9413.1012 (Stable multiplicity formula certificate)**.** *A stable multiplicity formula certificate for a discrete parameter ψ gives a packet candidate $\Pi_\psi(G)$ and a component-group pairing so that the target stable distribution has the form*

$$S\Theta_\psi^G(f) = \sum_{\pi\in\Pi_\psi(G)} m(\pi)\Theta_\pi(f) + \mathsf{LedgerTerms}_\psi(f),$$

where $\mathsf{LedgerTerms}_\psi$ *consists only of continuous spectrum, Eisenstein residual, endoscopic transfer, boundary, multiplicity normalization, and transfer-factor rows.*

Definition 9413.1013 (Endoscopic transfer certificate)**.** *An endoscopic datum is a row*

$$\mathfrak{e} = (H, \xi, s, \Delta)$$

with an L-embedding

$$\xi : {}^LH \to {}^LG.$$

An endoscopic transfer certificate assigns matching test functions

$$f^H \longleftrightarrow f^G$$

such that stable orbital integrals match after the declared transfer factor and the spectral stable distributions satisfy

$$S\Theta_{\psi_H}^H(f^H) = S\Theta_{\xi\circ\psi_H}^G(f^G) + \mathsf{EndoscopicLedger}(f).$$

Transfer-factor, normalization, nonregular, ramified, and matching failures are rows of $\mathsf{EndoscopicLedger}$*.*

Definition 9413.1014 (Stabilized trace formula certificate)**.** *A stabilized trace formula certificate for G records, for admitted test functions f^G, an identity*

$$I_{\mathrm{disc}}^G(f^G) = \sum_{\mathfrak{e}=(H,\xi)} \iota(G,H) SI_{\mathrm{disc}}^H(f^H) + \mathsf{TraceLedger}(f^G),$$

where $\mathsf{TraceLedger}$ *contains continuous spectrum, Eisenstein terms, boundary, singular orbital integrals, ramification, normalization, and transfer-factor data. Its finite/tail residual discipline is the trace defect dichotomy of Definition 9413.1045.*

Definition 9413.1015 (Endoscopic induction certificate)**.** *Endoscopic complexity is ordered by a well-founded tuple such as*

$$\mathrm{ec}(G) := (\mathrm{ssrank}\, G, \dim G, \#\pi_0(Z(\widehat{G}))).$$

An endoscopic induction certificate says that every proper elliptic endoscopic group H appearing in the stabilized trace formula has smaller complexity than G, and that the general existence bridge is already available for H on the declared scope.

Definition 9413.1016 (General trace tail ledger)**.** *The general G trace tail ledger is*

$$\mathsf{GeneralTraceTailLedger}_G := (\mathsf{ContinuousSpectrum}, \mathsf{EisensteinResidual}, \mathsf{Boundary}, \mathsf{SingularOrbitalIntegral}, \mathsf{TransferNorm}$$

A trace-tail ledger certificate says that any nonzero stable readout not accounted for by a primitive packet or a proper endoscopic packet enters this ledger.

Theorem 9413.1017 (Endoscopic residual dichotomy)**.** *If an endoscopic transfer certificate fails for an admitted transfer row, then the failure is either a finite transfer defect on a fixed test window or an endoscopic tail defect.*

Proof. If the mismatch is visible for a fixed pair of matching test functions $f^H \leftrightarrow f^G$, then the stable orbital-integral or spectral transfer equality fails on a finite window. That is a finite transfer defect. If every fixed window transfer matches but the transfer fails along singular orbit limits, ramification growth, transfer-factor normalization limits, or cofinal window growth, the defect is not finite-window data. It is an endoscopic tail defect and belongs to the endoscopic tail ledger. □

Corollary 9413.1018 (Closed objects have no endoscopic transfer failure)**.** *A closed BEDC trace object with complete endoscopic ledger discipline cannot carry an unresolved endoscopic transfer failure.*

Proof. By Definition 9413.1017, any failure is finite-visible or a tail row. A finite failure must be entered in the ledger or omitted; the first leaves the object not closed, and the second violates the ledger property. The same argument applies to a tail row. □

Theorem 9413.1019 (Stabilized trace residual dichotomy)**.** *If the stabilized trace formula identity for G fails on the declared scope, then the residual is visible on a fixed trace window or belongs to* $\mathsf{GeneralTraceTailLedger}_G$.

Proof. This is the stable form of Definition 9413.1045. A nonzero restricted residual on some finite trace window is finite-visible. If every finite window is clean but the stabilized identity fails globally, the defect can only lie in continuous spectrum, Eisenstein boundary, singular orbital integrals, ramification escape, transfer normalization, or endoscopic tail behavior, all of which are entries of $\mathsf{GeneralTraceTailLedger}_G$. □

Theorem 9413.1020 (General G existence bridge certificate)**.** *Let $\psi^\uparrow$ be a legal discrete G-parameter object. Assume:*

- *local packet and local state certificates hold at every displayed place;*
- *a stable parameter distribution certificate gives a nonzero fixed-window readout;*
- *the stabilized trace formula certificate holds;*
- *endoscopic transfer certificates hold for all proper endoscopic data in the trace identity;*
- *the stable multiplicity formula certificate holds for primitive G-discrete contributions;*
- *the endoscopic induction certificate holds;*
- *the general trace tail ledger is complete;*
- *closed accepted objects carry no unresolved trace, endoscopic, or existence ledger rows.*

Then $\psi^\uparrow$ has a G-side automorphic packet realization, or its absence is an explicit ledger row. In the closed case, the packet exists.

Proof. Choose a fixed window and a test function

$$f^G_{\psi,\mathcal{W}}$$

with

$$S\Theta^G_\psi(f^G_{\psi,\mathcal{W}}) \neq 0.$$

The stabilized trace formula and endoscopic transfer certificates place this nonzero stable readout into exactly three classes.

First, the primitive G-discrete part may be nonzero. The stable multiplicity formula then expresses that primitive stable distribution as a sum over $\Pi_\psi(G)$ plus declared ledger terms. If $\Pi_\psi(G)$ were empty and the primitive readout were nonzero, the nonzero contribution would have to be a ledger term. A closed object cannot carry it unresolved, and omission violates the ledger property. Thus the primitive nonzero case gives a nonempty G-packet.

Second, the stable readout may come from a proper endoscopic group H. By the endoscopic induction certificate, the existence bridge for H supplies an H-side packet for the corresponding parameter ψ_H. The endoscopic transfer certificate carries that packet to the G-side unless a transfer residual occurs. By Definition 9413.1018, an unresolved transfer residual is incompatible with closedness. Thus the endoscopic case gives a G-side packet in the closed scope.

Third, the readout may be neither primitive discrete nor proper endoscopic discrete. Then it lies in continuous spectrum, Eisenstein residual, boundary, singular orbital-integral, normalization, ramification, or endoscopic-tail data. These are exactly the rows of $\mathsf{GeneralTraceTailLedger}_G$. A closed object cannot carry them unresolved.

The three alternatives exhaust the stabilized spectral decomposition. Therefore a closed legal parameter has a G-side automorphic packet. Without closedness, failure is precisely a ledger row. □

Corollary 9413.1021 (General G reciprocity from the existence bridge)**.** *Under the hypotheses of Definition 9413.1020, if no-hidden Langlands residual holds, then there is a closed packet* $\Pi_\psi(G)$ *such that for almost all certified unramified places* v *and all finite-dimensional* $r : {}^LG \to GL(V_r)$ *in the readout scope,*

$$\lambda_{v,r}(\pi) = \operatorname{tr} r(\psi(\mathrm{Frob}_v))$$

for some $\pi \in \Pi_\psi(G)$*.*

Proof. The existence bridge gives a nonempty G-packet in the closed case. If a finite Hecke–Frobenius mismatch remains, it is detected by the Tannakian detector (v, r) of Definition 9413.977. If no finite detector sees it, then by Tannakian separation and Chebotarev the unramified semisimple readout is already fixed; any remaining obstruction is a ramified, endoscopic, continuous-spectrum, boundary, multiplicity, or normalization ledger row. No-hidden residual and closedness exclude both unresolved alternatives. □

Corollary 9413.1022 (General G functoriality from the existence bridge)**.** *Let*

$$\eta : {}^LH \to {}^LG$$

be an L*-group homomorphism and let* (Π_H, ψ_H) *be a closed* H*-side packet. Put*

$$\psi_G := \eta \circ \psi_H.$$

If ψ_G *satisfies the hypotheses of Definition 9413.1020, then there is a* G*-side packet* Π_G *such that*

$$\lambda_{v,r}(\Pi_G) = \operatorname{tr} r(\eta(\psi_H(\mathrm{Frob}_v)))$$

on the certified unramified finite detector scope.

Proof. The parameter $\psi_G = \eta \circ \psi_H$ is a legal G-parameter on the declared scope. The existence bridge gives a G-side packet, and the preceding reciprocity corollary gives its finite readout equality with ψ_G. Substituting the definition of ψ_G yields the displayed formula. □

Theorem 9413.1023 (General G BEDC–Langlands closure)**.** *On any reductive-group scope carrying local packets, parameter states, stabilized trace formula, endoscopic transfer, stable multiplicity, endoscopic induction, Tannakian separation, Chebotarev, no-hidden Langlands residual, trace-tail ledger discipline, and closedness, Langlands reciprocity and functoriality hold on the certified scope.*

Proof. Existence is supplied by Definition 9413.1020. Once the G-packet exists, the detector equality is forced by Definition 9413.1021. Functoriality is obtained by applying the same existence and no-hidden residual argument to $\eta \circ \psi_H$ as in Definition 9413.1022. Uniqueness of the semisimple parameter readout follows from the Tannakian and Chebotarev rows of Definition 9413.861. □

Theorem 9413.1024 (General G existence bridge boundary)**.** *The general G existence bridge is a conditional BEDC closure theorem. It consumes stable trace formula, endoscopic transfer, stable multiplicity, local packet, parameter-state, induction, and tail-ledger certificates. It does not construct those certificates or remove the traditional analytic and endoscopic obligations.*

Proof. Every positive implication above invokes one of the listed certificates. The argument proves that, once they are present, absence of a G-packet cannot remain hidden: it is primitive discrete, proper-endoscopic, or ledgered as trace tail. The construction of the certificates themselves is outside this bridge. □

9413.81 BEDC–Langlands Compact Discrete Spectrum Core

The cleanest analytic existence setting is the compact quotient, or more generally a scope where the automorphic spectrum under consideration is purely discrete with finite multiplicities. In that setting the spectral side of a fixed Hecke window is an honest Hilbert direct sum, and a nonzero value of the finite-window projector cannot be hidden in continuous spectrum, Eisenstein boundary, or endoscopic transfer terms.

Definition 9413.1025 (Compact discrete automorphic Hilbert row)**.** *Fix a global field F and a connected reductive group G. A compact discrete automorphic Hilbert row consists of a closed central-character scope for which*

$$G(F)\backslash G(\mathbb{A}_F)$$

is compact after the declared central reduction, or else a certified subscope whose relevant automorphic spectrum is purely discrete. The Hilbert object is

$$\mathcal{H}_{\mathrm{aut}} := L^2_{\mathrm{disc}}\big(G(F)\backslash G(\mathbb{A}_F)\big),$$

and, away from a finite bad set S_0, the unramified Hecke algebra is

$$\mathcal{H}^{S_0} := \bigotimes_{v \notin S_0}{}' \mathcal{H}_v(G, K_v).$$

The discrete spectral decomposition on the unramified fixed-vector scope has the form

$$\mathcal{H}_{\mathrm{aut}}^{K^{S_0}} \cong \widehat{\bigoplus}_{\Pi} m(\Pi)\Pi^{K^{S_0}},$$

with finite multiplicities $m(\Pi)$ on the displayed scope.

Definition 9413.1026 (Compact discrete ledger)**.** *The compact discrete ledger records every term excluded from the clean Hilbert row:*

$$\mathsf{ContinuousSpectrum},\quad \mathsf{EisensteinBoundary},\quad \mathsf{ResidualBoundary},\quad \mathsf{EndoscopicTransfer},$$

$$\mathsf{RamifiedLocalRow},\quad \mathsf{ArchimedeanRow},\quad \mathsf{NormalizationRow}.$$

The compact discrete core is closed only on scopes where these rows are absent, separated by the test function, or explicitly carried as ledger obligations outside the claim.

Definition 9413.1027 (Hecke spectral fingerprint)**.** *For a discrete automorphic packet Π unramified outside S_0, its unramified Hecke fingerprint is*

$$x_\Pi := \big(s_v(\Pi)\big)_{v\notin S_0}.$$

For an allowed parameter packet $\phi^\uparrow$, its Frobenius fingerprint is

$$x_\phi := \big(\phi(\mathrm{Frob}_v)\big)_{v\notin S_0}.$$

On a finite Hecke window $\mathcal{W} = (S, R, \mathcal{B})$, write $x_{\Pi,\mathcal{W}}$ and $x_{\phi,\mathcal{W}}$ for the corresponding finite restrictions.

Definition 9413.1028 (Compact finite spectral packet)**.** *For a finite Hecke window $\mathcal{W}$ and a finite complexity bound B, let*

$$\mathsf{Aut}^{\mathrm{disc}}_{\mathcal{W},B} = \{\Pi_1, \dots, \Pi_M\}$$

be the finite list of discrete automorphic packets admitted by the window and the bound. The bounded finiteness row records that this list is finite up to the closed automorphic equivalence relation.

The parameter state row used below is the certificate of section 9413.74, specialized to the compact discrete window. In the unramified part it is evaluation at $x_{\phi,\mathcal{W}}$; ramified and archimedean state choices remain ParameterLedger rows.

Theorem 9413.1029 (Fixed-window spectral realization)**.** *Let $f_{\phi,\mathcal{W},B}$ be the finite Hecke projector supplied by Definition 9413.910 on a compact finite spectral packet. If*

$$I_{\mathrm{spec}}(f_{\phi,\mathcal{W},B}) \neq 0$$

and the compact discrete ledger rows outside the target packet are absent or separated, then some

$$\Pi \in \mathsf{Aut}^{\mathrm{disc}}_{\mathcal{W},B}$$

satisfies

$$x_{\Pi,\mathcal{W}} = x_{\phi,\mathcal{W}}.$$

Proof. On the compact discrete scope the spectral side is the finite window sum

$$I_{\mathrm{spec}}(f_{\phi,\mathcal{W},B}) = \sum_{i=1}^{M} m(\Pi_i)\,\mathrm{tr}\,\Pi_i(f_{\phi,\mathcal{W},B}) + \mathrm{LedgerTerms}\,.$$

The non-target ledger terms are absent or separated by hypothesis. Hence the displayed discrete packet sum is nonzero. If no Π_i matched $x_{\phi,\mathcal{W}}$, then the projector property would give

$$\mathrm{tr}\,\Pi_i(f_{\phi,\mathcal{W},B}) = 0$$

for every i, forcing the spectral value to vanish. This contradicts the nonzero spectral readout. Therefore at least one packet matches the parameter on the fixed window. □

Theorem 9413.1030 (Parameter state and trace give fixed-window realization)**.** *Assume a parameter state certificate for $\phi^{\uparrow}$ on $\mathcal{W}$, the stable trace-window equality*

$$I^{\mathrm{st}}_{\mathrm{spec}}(f) = I^{\mathrm{st}}_{\mathrm{geom}}(f),$$

and the geometric-side identification

$$I^{\mathrm{st}}_{\mathrm{geom}}(f_{\phi,\mathcal{W},B}) = \Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W},B}).$$

If the compact discrete ledger rows outside the target packet are absent or separated, then $\phi^{\uparrow}$ has a fixed-window automorphic realization on $\mathcal{W}$.

Proof. The parameter state certificate gives

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W},B}) = 1,$$

so the geometric side is nonzero on the projector. The stable trace-window equality transfers this nonzero value to the spectral side. The fixed-window spectral realization theorem then supplies a discrete automorphic packet with

$$x_{\Pi,\mathcal{W}} = x_{\phi,\mathcal{W}}.$$

□

Definition 9413.1031 (Compact cofinal realization sequence)**.** *Let*

$$\mathcal{W}_1 \subset \mathcal{W}_2 \subset \cdots$$

be a cofinal Hecke window tower. A compact cofinal realization sequence is a sequence of discrete automorphic packets (Π_n) such that

$$x_{\Pi_n,\mathcal{W}_n} = x_{\phi,\mathcal{W}_n}$$

for every n.

Theorem 9413.1032 (Compact bounded subsequence globalization)**.** *Let (Π_n) be a compact cofinal realization sequence. If bounded automorphic finiteness holds and some infinite subsequence has bounded complexity, then there is a global automorphic packet Π_ϕ matching ϕ on every certified unramified finite detector.*

Proof. This is the compact discrete instance of Definition 9413.1072. Bounded finiteness gives only finitely many closed packet classes below the chosen complexity bound, so one class occurs infinitely often. Every fixed detector eventually lies in the cofinal tower, and a sufficiently late occurrence of the recurring packet matches the parameter on that detector. Thus the recurring packet matches all certified unramified finite detectors. □

Theorem 9413.1033 (Compact unbounded sequence is a tail row)**.** *If a compact cofinal realization sequence has no bounded-complexity infinite subsequence, then it enters the automorphic tail ledger.*

Proof. For every finite complexity bound B, only finitely many terms of the sequence lie below B. Hence complexity escapes along the cofinal tower. In the compact discrete scope, such escape can only appear as level or conductor growth, archimedean type growth, ramified local type growth, multiplicity bookkeeping growth, or departure from the compact discrete scope into a ledgered endoscopic, boundary, or continuous row. These are exactly the automorphic tail rows. □

Theorem 9413.1034 (Compact cofinal window closure)**.** *Assume every window of a cofinal tower has a compact fixed-window realization, bounded automorphic finiteness holds, the automorphic tail ledger is complete, and closed accepted packets cannot carry unresolved tail rows. Then $\phi^{\uparrow}$ has a global automorphic realization.*

Proof. Choose a compact cofinal realization sequence. If it has a bounded infinite subsequence, the compact bounded subsequence globalization theorem produces the global packet. If it has no such subsequence, the compact unbounded sequence theorem places it in the automorphic tail ledger. An unrecorded tail violates ledger discipline, and an unresolved recorded tail violates closedness. Hence the tail alternative is unavailable for a closed accepted packet, and the global realization alternative remains. □

Theorem 9413.1035 (Compact discrete BEDC–Langlands existence core)**.** *On a compact discrete automorphic scope, assume:*

- *parameter state certificates on a cofinal Hecke window tower;*
- *stable trace-window equality on each window;*
- *finite Hecke projector certificates;*
- *bounded automorphic finiteness;*
- *a complete automorphic tail ledger;*
- *no-hidden Langlands residual and closedness against unresolved ledger rows.*

Then there is a closed automorphic packet Π_ϕ such that

$$\lambda_{v,r}(\Pi_\phi) = \operatorname{tr} r(\phi(\mathrm{Frob}_v))$$

for every certified unramified finite detector (v, r).

Proof. The parameter state and trace theorem gives a fixed-window realization on every window of the cofinal tower. The compact cofinal window closure theorem globalizes these realizations to a packet Π_ϕ. If a Hecke–Frobenius mismatch remains, the no-hidden residual condition makes it either a finite detector residual or a ledger residual. A finite detector residual contradicts the cofinal matching unless it is an unresolved row; carrying such a row violates closedness, while omitting it violates ledger discipline. The same argument applies to ramified, endoscopic, continuous, boundary, archimedean, and normalization ledger residuals. Hence the closed packet has no remaining mismatch. □

Theorem 9413.1036 (Compact discrete functorial core)**.** *Let*

$$\eta : {}^L H \to {}^L G$$

be an L-group homomorphism. If the target parameter

$$\phi_G := \eta \circ \phi_H$$

satisfies the compact discrete existence core on the G-side, then there is a G-side automorphic packet Π_G with

$$\lambda_{v,r}(\Pi_G) = \operatorname{tr} r(\eta(\phi_H(\mathrm{Frob}_v)))$$

for every certified unramified finite detector on the target scope.

Proof. Apply Definition 9413.1035 to ϕ_G. The resulting packet satisfies

$$\lambda_{v,r}(\Pi_G) = \operatorname{tr} r(\phi_G(\mathrm{Frob}_v)).$$

Substituting $\phi_G = \eta \circ \phi_H$ gives the displayed formula. □

Theorem 9413.1037 (Compact discrete boundary)**.** *The compact discrete core closes the passage from nonzero fixed-window spectral readout to global automorphic realization only on scopes where the spectral side is purely discrete or where all non-discrete terms are separated into ledger rows. It does not prove the stable trace formula, construct parameter state certificates, or settle the general continuous, Eisenstein, endoscopic, ramified, archimedean, or boundary case.*

Proof. The argument uses the Hilbert direct-sum spectral decomposition and the finite Hecke projector. If continuous spectrum, Eisenstein series, endoscopy, ramification, or boundary terms are present, they are outside the compact discrete row and must be handled by the ledger mechanisms of the general trace-window bridge. The compact result therefore supplies a closed core case, not the full analytic trace formula. □

9413.82 BEDC–Langlands Stable Trace Formula Certificate

The stable trace formula is treated here as a BEDC closure certificate. The claim is not that the analytic technology is avoided. The claim is that, once the trace object is presented with its finite windows and tail ledgers, a failure of the trace identity has only two possible forms: it is visible on a fixed finite trace window, or it is a trace tail row. A closed trace object can carry neither unresolved form.

Definition 9413.1038 (Trace object)**.** *Let G be a reductive group over a global field F, and let*

$$f \in C_c^\infty(G(\mathbb{A}_F))$$

be an admitted test function. A trace object is the row

$$\mathrm{TF}^\uparrow(G,F) := (I_{\mathrm{spec}}, I_{\mathrm{geom}}, \Lambda_{\mathrm{TF}}),$$

where

$$I_{\mathrm{spec}}(f) = \sum_{\Pi} m(\Pi) \operatorname{tr} \Pi(f) + I_{\mathrm{cont}}(f)$$

and

$$I_{\mathrm{geom}}(f) = \sum_{\gamma} a(\gamma) O_\gamma(f) + I_{\mathrm{sing}}(f).$$

The trace ledger Λ_{TF} records ramification, normalization, orbital singularities, endoscopy, continuous spectrum, boundary terms, transfer factors, and multiplicity rows.

Definition 9413.1039 (Trace three-properties rows)**.** *The time row of the trace object is generated by convolution, Hecke-time operators, and trace-window inclusions*

$$\mathcal{W}_1 \subset \mathcal{W}_2 \subset \cdots .$$

The unity row says that spectral and geometric expansions are two readouts of the same trace pairing. The ledger row says that every continuous, endoscopic, boundary, singular, ramified, multiplicity, or normalization residual is recorded before any closed trace identity is claimed.

Definition 9413.1040 (Trace residual)**.** *The trace residual is the linear functional*

$$R_{\mathrm{TF}}(f) := I_{\mathrm{spec}}(f) - I_{\mathrm{geom}}(f).$$

A stable trace formula certificate is closed on a scope only if

$$R_{\mathrm{TF}}(f) = 0$$

for every admitted test function on that scope, after all ledger rows have been separated, cancelled, or discharged.

Definition 9413.1041 (Finite trace window)**.** *A finite trace window is a tuple*

$$\mathcal{W} = (S, B, C),$$

where S is a finite place set, B is a spectral complexity bound, and C is a geometric orbital complexity bound. Its admitted test space is

$$\mathcal{T}_{\mathcal{W}} \subset C_c^\infty(G(\mathbb{A}_F)).$$

The window carries a finite spectral list

$$\mathsf{Spec}_{\mathcal{W}} = \{\Pi_1, \dots, \Pi_M\}$$

and a finite geometric list

$$\mathsf{Geom}_{\mathcal{W}} = \{\gamma_1, \dots, \gamma_N\},$$

after all terms outside the window have been placed in the trace ledger.

Theorem 9413.1042 (Finite trace residual detection)**.** *If the restricted residual*

$$R_{\mathrm{TF}}|_{\mathcal{T}_{\mathcal{W}}}$$

is nonzero on a fixed finite trace window, then there is

$$f \in \mathcal{T}_{\mathcal{W}}$$

with

$$R_{\mathrm{TF}}(f) \neq 0.$$

Proof. The restriction of R_{TF} to $\mathcal{T}_{\mathcal{W}}$ is a linear functional. A nonzero linear functional is nonzero on at least one vector of its domain. That vector is the required test function. □

Definition 9413.1043 (Finite trace matrix residual)**.** *On a finite trace window, the spectral and geometric sides have the finite forms*

$$I_{\mathrm{spec}}(f) = \sum_{i=1}^{M} m_i \Theta_i(f), \qquad \Theta_i(f) := \operatorname{tr} \Pi_i(f),$$

and

$$I_{\mathrm{geom}}(f) = \sum_{j=1}^{N} a_j O_j(f).$$

Thus the finite trace residual is

$$R_{\mathrm{TF}}(f) = \sum_{i=1}^{M} m_i \Theta_i(f) - \sum_{j=1}^{N} a_j O_j(f).$$

Definition 9413.1044 (Trace defect dichotomy rows)**.** *A finite trace defect is a window $\mathcal{W}$ such that*

$$R_{\mathrm{TF}}|_{\mathcal{T}_{\mathcal{W}}} \neq 0.$$

A trace tail defect is a residual that vanishes on every fixed finite trace window but remains nonzero in a growing-window or limiting operation. Tail rows include continuous spectrum, Eisenstein boundary, endoscopic transfer, singular orbital integrals, ramification escape, and measure or transfer-factor normalization.

Theorem 9413.1045 (Trace defect dichotomy)**.** *If*

$$R_{\mathrm{TF}} \neq 0,$$

then the trace object has either a finite trace defect or a trace tail defect.

Proof. If there is a finite trace window $\mathcal{W}$ with nonzero restricted residual, then the first alternative holds. Otherwise the residual vanishes on every fixed finite trace window. Since the total residual is assumed nonzero, it cannot be represented by any fixed finite window. It therefore lies in a growing-window or limiting row: continuous spectrum, Eisenstein boundary, endoscopy, singular orbits, ramification escape, or normalization. This is precisely the trace tail alternative. □

Definition 9413.1046 (Trace tail ledger certificate)**.** *A trace tail ledger certificate says that every trace tail defect is recorded in*

$$\mathrm{TraceTailLedger} = (\mathsf{ContinuousSpectrum}, \mathsf{EisensteinBoundary}, \mathsf{Endoscopy}, \mathsf{SingularOrbit}, \mathsf{Ramification}, \mathsf{MeasureNormal}$$

The row is closed only when the recorded defect is discharged or separated from the claimed stable identity.

Theorem 9413.1047 (No hidden trace defect)**.** *If a trace object carries the trace three-properties rows, a complete trace tail ledger certificate, and closedness against unresolved trace ledger rows, then*

$$R_{\mathrm{TF}} = 0.$$

Proof. Assume $R_{\mathrm{TF}} \neq 0$. By Definition 9413.1045, there is a finite trace defect or a trace tail defect.

In the finite case, Definition 9413.1042 supplies a fixed test function f with $R_{\mathrm{TF}}(f) \neq 0$. This is a detected trace residual. Ledger discipline requires it to be recorded; carrying it unresolved violates closedness, and omitting it violates the ledger row.

In the tail case, the trace tail ledger certificate requires the defect to be recorded in TraceTailLedger. Again, carrying it unresolved violates closedness, while omitting it violates the ledger row. Both alternatives contradict the closed trace object. Hence the residual is zero. □

Theorem 9413.1048 (Compact trace identity)**.** *Let $X = \Gamma\backslash G$ be a compact quotient of a locally compact group by a discrete cocompact subgroup, and let*

$$f \in C_c^\infty(G).$$

For the right regular operator

$$R(f)\varphi(x) = \int_G f(g)\varphi(xg)\,dg,$$

one has

$$\operatorname{Tr} R(f) = \sum_\pi m(\pi)\operatorname{tr}\pi(f) = \sum_{[\gamma]} \operatorname{vol}(\Gamma_\gamma\backslash G_\gamma) O_\gamma(f).$$

Proof. The kernel of $R(f)$ is

$$K_f(x,y) = \sum_{\gamma\in\Gamma} f(x^{-1}\gamma y).$$

Since X is compact and f is compactly supported, $R(f)$ is trace class. The spectral decomposition of $L^2(X)$ gives

$$\operatorname{Tr} R(f) = \sum_{\pi} m(\pi) \operatorname{tr} \pi(f).$$

The same trace is the diagonal integral of the kernel:

$$\operatorname{Tr} R(f) = \int_{\Gamma\backslash G} K_f(x,x)\, dx.$$

Substituting the kernel, exchanging the finite-on-support sum with the integral, and grouping by conjugacy classes gives

$$\int_{\Gamma\backslash G} \sum_{\gamma\in\Gamma} f(x^{-1}\gamma x)\, dx = \sum_{[\gamma]} \operatorname{vol}(\Gamma_\gamma\backslash G_\gamma) O_\gamma(f).$$

Thus the spectral and geometric readouts are equal to the same operator trace. □

Corollary 9413.1049 (Compact trace object closure)**.** *In the compact quotient setting of Definition 9413.1048,*

$$R_{\mathrm{TF}}(f) = 0$$

for every admitted test function f.

Proof. Both the spectral and geometric sides are equal to $\operatorname{Tr} R(f)$, so their difference is zero. □

Definition 9413.1050 (Stable trace formula certificate)**.** *A stable trace formula certificate is the package consisting of:*

- *a compact trace identity base or a justified truncated kernel identity;*
- *a complete ledger for continuous spectrum, Eisenstein boundary, endoscopy, singular orbital integrals, ramification, transfer factors, and normalization;*
- *stable orbital integral matching on the declared scope;*
- *no unresolved trace residual after the ledger rows are discharged or separated.*

Theorem 9413.1051 (Stable trace formula as no-hidden trace defect)**.** *Within the BEDC trace object interface, the stable trace formula certificate is equivalent to the compact trace identity base together with no hidden trace defect and complete trace-tail ledger discipline on the declared scope.*

Proof. If the stable trace formula certificate holds, then every continuous, Eisenstein, endoscopic, singular, ramified, transfer-factor, and normalization residual has been recorded and discharged or separated. Thus no hidden trace defect remains.

Conversely, assume the compact trace identity base, no hidden trace defect, and complete trace-tail ledger discipline on the declared scope. Any nonzero trace residual would be finite visible or tail visible by Definition 9413.1045. The finite case is excluded by no hidden trace defect, and the tail case is excluded by the complete ledger and closedness. Hence the residual vanishes on the declared stable scope, which is the stable trace formula certificate. □

Theorem 9413.1052 (Trace closure implies Langlands existence)**.** *Assume a parameter state certificate, finite Hecke projectors, the stable trace formula certificate, cofinal automorphic tail closure, no-hidden Langlands residual, and closedness against unresolved ledger rows. Then the parameter packet $\phi^{\uparrow}$ has a global automorphic realization on the certified unramified finite detector scope.*

Proof. Fix a finite Hecke window $\mathcal{W}$. The parameter state certificate gives a projector $f_{\phi,\mathcal{W}}$ with nonzero parameter-side readout. The stable trace formula certificate transports this nonzero readout to the spectral side. The finite Hecke projector then forces a matching automorphic packet in the fixed window. Applying this to a cofinal tower gives a cofinal realization sequence. By the automorphic tail closure theorem, the sequence either globalizes to an automorphic packet or enters the automorphic tail ledger. Closedness excludes an unresolved tail row, so a global packet remains. No-hidden Langlands residual then excludes any remaining Hecke–Frobenius mismatch. □

Theorem 9413.1053 (BEDC–Langlands trace closure theorem)**.** *On a Langlands scope carrying unramified local Satake closure, finite Hecke projectors, compact trace identity base, no hidden trace defect, complete trace-tail ledger discipline, parameter state certificates, cofinal automorphic tail closure, no-hidden Langlands residual, and closedness, Langlands reciprocity holds on the certified unramified finite detector scope.*

Proof. The compact trace identity base and no-hidden trace defect give the stable trace formula certificate by Definition 9413.1051. Unramified local Satake closure licenses the finite detectors, and the finite Hecke projector supplies fixed-window isolation. Parameter state certificates provide nonzero parameter-side readouts. Therefore Definition 9413.1052 gives a global automorphic packet. No-hidden Langlands residual removes all remaining mismatch, giving

$$\lambda_{v,r}(\Pi_\phi) = \operatorname{tr} r(\phi(\mathrm{Frob}_v))$$

for every certified unramified finite detector (v, r). □

Theorem 9413.1054 (Stable trace certificate boundary)**.** *The stable trace formula certificate described here is a BEDC closure form of the trace formula. It identifies every possible failure as finite visible or ledgered tail visible, and it proves the compact kernel trace identity base. It does not replace the analytic work needed to discharge continuous spectrum, Eisenstein series, endoscopy, singular orbital integrals, transfer factors, ramification, or normalization in a specific noncompact case.*

Proof. The compact quotient proof uses only the ordinary trace-class kernel identity. All noncompact and unstable terms are explicitly named as ledger rows. The certificate is closed only when those rows are discharged or separated on the declared scope; otherwise they remain obligations rather than hidden equalities. □

9413.83 BEDC–Langlands Trace-Window Closure

The trace-formula bridge of section 9413.71 can be read as a fixed-window contradiction. If an allowed parameter has no automorphic realization, then every trace-window projector should have zero spectral target contribution. A stable parameter distribution gives a nonzero finite readout, and the stable trace formula transports that readout to the spectral side. The absence of an automorphic packet must therefore become a finite trace-window residual or an automorphic tail ledger. The fixed-window projector used below is supplied by section 9413.73.

Definition 9413.1055 (Finite Hecke window)**.** *A finite Hecke window is a tuple*

$$\mathcal{W} = (S, R, \mathcal{B})$$

where S is a finite set of places containing the displayed bad places, $R = \{r_1, \dots, r_m\}$ is a finite list of finite-dimensional representations of ${}^L G$, and $\mathcal{B}$ is a finite complexity bound for conductor, level, central character, archimedean type, and other window data. The admitted automorphic rows in the window form the truncated packet

$$\mathsf{Aut}_{G,\mathcal{W}}(F).$$

Definition 9413.1056 (Window readout and window residual)**.** *For $\pi \in \mathsf{Aut}_{G,\mathcal{W}}(F)$ define*

$$\lambda_{\mathcal{W}}(\pi) := \big(\lambda_{v,r}(\pi)\big)_{v\in S,\ r\in R}.$$

For an allowed parameter packet $\phi^{\uparrow}$ define

$$a_{\mathcal{W}}(\phi) := \big(\operatorname{tr} r(\phi(\mathrm{Frob}_v))\big)_{v\in S,\ r\in R}.$$

The window residual is

$$D_{\mathcal{W}}(\pi, \phi) := \lambda_{\mathcal{W}}(\pi) - a_{\mathcal{W}}(\phi).$$

It is a finite mismatch address inside the fixed window $\mathcal{W}$.

Theorem 9413.1057 (Finite Hecke window separation)**.** *Assume that the truncated packet*

$$\mathsf{Aut}_{G,\mathcal{W}}(F) = \{\pi_1, \dots, \pi_M\}$$

has pairwise distinct window readouts. Then there is a Hecke test function $f_{\phi,\mathcal{W}}$ such that

$$\operatorname{tr} \pi_i(f_{\phi,\mathcal{W}}) = 0$$

whenever $\lambda_{\mathcal{W}}(\pi_i) \neq a_{\mathcal{W}}(\phi)$, and

$$\operatorname{tr} \pi_i(f_{\phi,\mathcal{W}}) \neq 0$$

whenever $\lambda_{\mathcal{W}}(\pi_i) = a_{\mathcal{W}}(\phi)$ and the matching summand is not cancelled by a declared ledger row.

Proof. This is the finite-window form of Definition 9413.910. The joint Hecke operators of the finite window act on a finite truncated packet with finitely many joint eigenvalue rows

$$\lambda_{\mathcal{W}}(\pi_i).$$

On this finite set, polynomial interpolation gives a function $P_{\phi,\mathcal{W}}$ that is zero on all eigenvalue rows distinct from $a_{\mathcal{W}}(\phi)$ and nonzero on the matching row. The Satake identification reads this polynomial as a Hecke test function in the window algebra. Applying it to the joint eigenpacket gives the stated trace values, with any declared cancellation placed in the test-function ledger. □

Definition 9413.1058 (Parameter stable distribution certificate)**.** *A parameter stable distribution certificate for $\phi^{\uparrow}$ assigns to each finite Hecke window $\mathcal{W}$ a stable functional*

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}} : \mathcal{H}_{\mathcal{W}} \to \mathbb{C}$$

such that its value on unramified Hecke readout functions depends only on $a_{\mathcal{W}}(\phi)$, and all ramified, endoscopic, continuous, boundary, normalization, and transfer-factor terms have ledger rows. It is nonzero on a window when there is a test function $f_{\phi,\mathcal{W}}$ with

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) \neq 0.$$

Definition 9413.1059 (Stable trace-window certificate)**.** *A stable trace-window certificate for a finite Hecke window records*

$$I^{\mathrm{st}}_{\mathrm{geom}}(f) = I^{\mathrm{st}}_{\mathrm{spec}}(f)$$

for all admitted window test functions f, together with the spectral decomposition

$$I^{\mathrm{st}}_{\mathrm{spec}}(f) = \sum_{\Pi} m(\Pi)\Theta_{\Pi}(f) + I_{\mathrm{cont}}(f) + I_{\mathrm{endo}}(f) + I_{\mathrm{bdry}}(f),$$

where every continuous, endoscopic, boundary, ramified, multiplicity, and normalization term is either separated from the target packet or recorded in the trace ledger.

Theorem 9413.1060 (Stable trace detects the target packet)**.** *Let $\phi^{\uparrow}$ have a parameter stable distribution certificate. Assume there is a finite Hecke window $\mathcal{W}$ and a projector $f_{\phi,\mathcal{W}}$ such that*

$$\Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) \neq 0.$$

If the stable trace-window certificate holds and all non-target terms are separated or ledgered, then some automorphic packet Π satisfies

$$\Theta_{\Pi}(f_{\phi,\mathcal{W}}) \neq 0.$$

Proof. The parameter stable distribution supplies the nonzero geometric or parameter-side readout

$$I^{\mathrm{st}}_{\mathrm{geom}}(f_{\phi,\mathcal{W}}) = \Theta^{\mathrm{st}}_{\phi,\mathcal{W}}(f_{\phi,\mathcal{W}}) \neq 0.$$

The stable trace-window certificate gives the same nonzero value on the spectral side. In the spectral decomposition, all non-target residual terms have been separated or ledgered. Hence the remaining discrete automorphic packet sum is nonzero, so some packet Π has nonzero stable character on $f_{\phi,\mathcal{W}}$. □

Corollary 9413.1061 (Fixed-window automorphic realization)**.** *Under the hypotheses of Definition 9413.1060, the parameter $\phi^{\uparrow}$ has an automorphic realization on the fixed window $\mathcal{W}$.*

Proof. By the theorem, some packet Π has

$$\Theta_{\Pi}(f_{\phi,\mathcal{W}}) \neq 0.$$

The test function was constructed as a window projector in Definition 9413.1057. Therefore its nonzero value can occur only on packets whose window readout equals $a_{\mathcal{W}}(\phi)$, outside ledgered cancellation rows. □

Definition 9413.1062 (Cofinal Hecke window tower)**.** *A cofinal Hecke window tower is an increasing sequence*

$$\mathcal{W}_1 \subset \mathcal{W}_2 \subset \cdots$$

whose union contains every certified unramified finite Hecke–Frobenius detector. A tower realization of $\phi^{\uparrow}$ is a sequence of automorphic packets Π_n with

$$\lambda_{\mathcal{W}_n}(\Pi_n) = a_{\mathcal{W}_n}(\phi).$$

Definition 9413.1063 (Automorphic compactness ledger)**.** *The automorphic compactness ledger records every way a cofinal tower realization fails to stabilize to a global automorphic packet:*

$$\mathsf{LevelEscape},\quad \mathsf{ConductorEscape},\quad \mathsf{ArchimedeanEscape},\quad \mathsf{ContinuousSpectrumEscape},$$

$$\mathsf{EndoscopicSwitching},\quad \mathsf{BoundaryEscape},\quad \mathsf{MultiplicityEscape}.$$

A cofinal automorphic compactness certificate says that every tower realization either has a cofinally stable global packet Π_ϕ or enters this ledger.

Theorem 9413.1064 (Cofinal trace realization)**.** *Assume every window of a cofinal Hecke window tower has a fixed-window automorphic realization of $\phi^\uparrow$. If a cofinal automorphic compactness certificate holds and closed accepted objects carry no unresolved automorphic compactness ledger, then $\phi^\uparrow$ has a global automorphic packet Π_ϕ matching all certified unramified finite detectors.*

Proof. Choose a matching packet Π_n for each window $\mathcal{W}_n$. The cofinal compactness certificate says that the sequence either stabilizes cofinally to a global packet Π_ϕ or enters the automorphic compactness ledger. The ledger alternative is incompatible with a closed accepted object if the tail remains unresolved. Thus the closed case has a global packet. Since the windows are cofinal among the certified unramified finite detectors, Π_ϕ matches ϕ on all of them. □

Theorem 9413.1065 (No missing automorphic realization)**.** *Let $\phi^\uparrow$ be an allowed parameter packet. Suppose it carries a parameter stable distribution certificate, finite Hecke window projector certificates, stable trace-window certificates on a cofinal tower, a cofinal automorphic compactness certificate, no-hidden Langlands residual, and closedness against unresolved residual ledgers. Then $\phi^\uparrow$ has an automorphic realization.*

Proof. Assume that no automorphic realization exists. The parameter stable distribution certificate gives a fixed window $\mathcal{W}$ and a test function $f_{\phi,\mathcal{W}}$ with nonzero parameter-side stable readout. By Definition 9413.1060, the spectral side has a nonzero automorphic packet contribution unless all non-target spectral terms absorb the value. Such absorption is exactly a continuous-spectrum, endoscopic, ramified, boundary, multiplicity, or normalization ledger row. If that row is omitted, ledger discipline is violated; if it is carried unresolved, closedness fails.

If a target automorphic packet contribution exists, then Definition 9413.1061 gives a fixed-window realization. Applying this argument along the cofinal tower and then using Definition 9413.1064 gives a global automorphic realization, contradicting the assumption. Hence the assumption is impossible for a closed packet. □

Theorem 9413.1066 (Functorial existence by trace-window closure)**.** *Let (π_H, ϕ_H) be a closed packet for H, and let*

$$\eta : {}^L H \to {}^L G$$

preserve the parameter triple rows. If the target parameter

$$\phi_G := \eta \circ \phi_H$$

satisfies the hypotheses of Definition 9413.1065 on the G-side, then there is a G-side automorphic packet Π_G with

$$\lambda_{v,r}(\Pi_G) = \operatorname{tr} r(\eta(\phi_H(\mathrm{Frob}_v)))$$

on the certified unramified finite detectors.

Proof. Apply Definition 9413.1065 to ϕ_G. This gives a G-side automorphic packet matching ϕ_G on all certified unramified finite detectors. Substituting $\phi_G = \eta \circ \phi_H$ yields the displayed equality. Any remaining mismatch is handled by the no-hidden residual row exactly as in Definition 9413.883. □

Theorem 9413.1067 (Trace-window closure boundary)**.** *The trace-window closure argument proves existence only relative to parameter stable distributions, fixed-window projectors, stable trace-window formulae, and cofinal automorphic compactness. It does not construct those certificates.*

Proof. Every positive step above consumes one of those certificates: window separation consumes finite Hecke semisimplicity and Satake readout; nonzero spectral realization consumes parameter stable distributions and stable trace-window equality; global realization consumes cofinal automorphic compactness. The argument shows that, once those rows are present, a missing automorphic realization cannot be hidden in a closed packet. It does not replace the traditional construction of the rows. □

9413.84 BEDC–Langlands Window-to-Global Bridge

The trace-window closure of section 9413.83 uses a compactness row. This section separates that row into a finite complexity certificate and an explicit automorphic tail ledger. The point is to prevent a fixed-window realization theorem from being read as a growing-window theorem without an intervening stability witness.

Definition 9413.1068 (Automorphic complexity)**.** *An automorphic packet* Π *has automorphic complexity*

$$\kappa(\Pi) := \kappa_{\mathrm{level}}(\Pi) + \kappa_{\mathrm{cond}}(\Pi) + \kappa_{\infty}(\Pi) + \kappa_{\mathrm{ram}}(\Pi) + \kappa_{\mathrm{endo}}(\Pi) + \kappa_{\mathrm{mult}}(\Pi).$$

The six summands record, respectively, compact-open or level complexity, conductor complexity, archimedean infinitesimal-character or weight complexity, ramified local type complexity, endoscopic or Arthur packet label complexity, and multiplicity or packet bookkeeping complexity. The expression is a ledgered height: changing the automorphic category may change its implementation, but not the obligation that every escape mode represented by a hidden name be addressable.

Definition 9413.1069 (Bounded automorphic finiteness certificate)**.** *For* $B < \infty$ *set*

$$\mathsf{Aut}_{\leq B}(G) := \{\Pi : \kappa(\Pi) \leq B\}.$$

A bounded automorphic finiteness certificate says that $\mathsf{Aut}_{\leq B}(G)$ *is finite up to the declared closed automorphic equivalence relation for every finite* B*.*

Definition 9413.1070 (Cofinal window realization)**.** *Let*

$$\mathcal{W}_1 \subset \mathcal{W}_2 \subset \cdots$$

be a cofinal Hecke window tower in the sense of Definition 9413.1062. A cofinal window realization of an allowed parameter packet $\phi^{\uparrow}$ *is a sequence of automorphic packets* (Π_n) *such that*

$$\lambda_{\mathcal{W}_n}(\Pi_n) = a_{\mathcal{W}_n}(\phi)$$

for every n*. Equivalently, for every detector* (v, r) *lying in* $\mathcal{W}_n$*,*

$$\lambda_{v,r}(\Pi_n) = \operatorname{tr} r(\phi(\mathrm{Frob}_v)).$$

Definition 9413.1071 (Automorphic tail ledger)**.** *The automorphic tail ledger is the refinement of Definition 9413.1063 that names the concrete ways a cofinal window realization can fail to stabilize:*

$$\mathsf{LevelConductorEscape},\quad \mathsf{ArchimedeanParameterEscape},\quad \mathsf{RamifiedLocalTypeEscape},$$

$$\mathsf{ContinuousSpectrumEscape},\quad \mathsf{EndoscopicSwitching},\quad \mathsf{BoundaryEisensteinResidualEscape}.$$

A complete automorphic tail ledger says that every unbounded realization sequence has at least one of these rows, or a declared refinement of one of them, as its obstruction to global stabilization.

Theorem 9413.1072 (Bounded subsequence gives global realization)**.** *Let (Π_n) be a cofinal window realization of $\phi^{\uparrow}$. Assume the bounded automorphic finiteness certificate. If there are $B < \infty$ and an infinite subsequence $n_j \to \infty$ such that*

$$\kappa(\Pi_{n_j}) \leq B$$

for all j, then there is an automorphic packet Π_ϕ satisfying

$$\lambda_{v,r}(\Pi_\phi) = \operatorname{tr} r(\phi(\mathrm{Frob}_v))$$

for every certified unramified finite Hecke–Frobenius detector (v, r).

Proof. By bounded automorphic finiteness, the packets of complexity at most B represent only finitely many closed automorphic equivalence classes. Hence one class occurs for infinitely many terms of the subsequence. Choose a representative Π_ϕ of that recurring class.

Let (v, r) be any certified unramified finite detector. Cofinality of the tower gives $N(v, r)$ such that $(v, r) \in \mathcal{W}_n$ for all $n \geq N(v, r)$. Since the recurring class appears along infinitely many n_j, choose one with $n_j \geq N(v, r)$. The packet Π_{n_j} realizes ϕ on $\mathcal{W}_{n_j}$, so

$$\lambda_{v,r}(\Pi_{n_j}) = \operatorname{tr} r(\phi(\mathrm{Frob}_v)).$$

Closed automorphic equivalence preserves the declared Hecke readouts, so the same equality holds for Π_ϕ. Since (v, r) was arbitrary, Π_ϕ matches the parameter on the full cofinal detector scope. □

Theorem 9413.1073 (Unbounded realization sequence enters the tail ledger)**.** *Let (Π_n) be a cofinal window realization of $\phi^{\uparrow}$. If no infinite subsequence has bounded automorphic complexity, then the realization sequence enters the automorphic tail ledger.*

Proof. The absence of a bounded-complexity infinite subsequence means that for every finite B, only finitely many n satisfy

$$\kappa(\Pi_n) \leq B.$$

Thus the realization sequence escapes every finite complexity sublevel. By the definition of κ, this escape must occur through level or conductor growth, archimedean parameter growth, ramified local type growth, endoscopic or Arthur packet switching, multiplicity bookkeeping growth, or movement of mass into continuous, boundary, Eisenstein, or residual spectrum. These are exactly the rows named by Definition 9413.1071. Completeness of the ledger records the observed escape as an automorphic tail row. □

Theorem 9413.1074 (Window-to-global alternative)**.** *Assume that every window in a cofinal Hecke window tower has an automorphic realization of $\phi^{\uparrow}$, that bounded automorphic finiteness holds, and that the automorphic tail ledger is complete. Then either $\phi^{\uparrow}$ has a global automorphic realization on the certified unramified finite detector scope, or a cofinal realization sequence enters the automorphic tail ledger.*

Proof. Choose one realizing packet Π_n for each window $\mathcal{W}_n$. If some infinite subsequence of (Π_n) has bounded automorphic complexity, then Definition 9413.1072 produces a global automorphic packet Π_ϕ matching all certified unramified finite detectors. If no such subsequence exists, then Definition 9413.1073 places the sequence in the automorphic tail ledger. These two cases exhaust the sequence. □

Theorem 9413.1075 (Closed window-to-global realization)**.** *Assume the hypotheses of Definition 9413.1074. If closed accepted Langlands packets cannot carry unresolved automorphic tail ledger rows, then $\phi^\uparrow$ has a global automorphic realization on the certified unramified finite detector scope.*

Proof. By the window-to-global alternative, either the global realization is already present or the chosen cofinal realization sequence enters the automorphic tail ledger. In the second case, the tail row is either unrecorded, which violates ledger discipline, or recorded but unresolved, which violates closedness. Hence the tail alternative is not available for a closed accepted packet. The global realization alternative remains. □

Corollary 9413.1076 (Trace-window existence gives global realization)**.** *Let $\phi^\uparrow$ have parameter stable distribution certificates, finite-window projector certificates, and stable trace-window certificates on a cofinal Hecke window tower. Assume bounded automorphic finiteness, a complete automorphic tail ledger, and closedness against unresolved automorphic tail rows. Then $\phi^\uparrow$ has a global automorphic realization.*

Proof. The fixed-window certificates give an automorphic realization on every window by Definition 9413.1061. The closed window-to-global realization theorem applies to the resulting cofinal realization sequence. □

Corollary 9413.1077 (Global reciprocity after no-hidden residuals)**.** *Under the hypotheses of Definition 9413.1076, assume also the no-hidden Langlands residual condition of Definition 9413.859. Then the global automorphic packet Π_ϕ satisfies*

$$\lambda_{v,r}(\Pi_\phi) = \operatorname{tr} r(\phi(\mathrm{Frob}_v))$$

on the certified unramified finite detector scope, and every residual mismatch is either detected or rejected by closedness.

Proof. The preceding corollary supplies the global automorphic packet. If a Hecke–Frobenius mismatch remained on the certified scope, the no-hidden residual condition would make it a finite detector residual or a ramified, endoscopic, continuous-spectrum, boundary, or normalization ledger residual. A finite detector residual contradicts the cofinal matching; an unresolved ledger residual contradicts closedness. Hence no residual mismatch remains in a closed accepted packet. □

Theorem 9413.1078 (Functorial window-to-global transfer)**.** *Let (Π_H, ϕ_H) be a closed H-side packet, and let*

$$\eta : {}^L H \to {}^L G$$

preserve the declared Langlands packet rows. Put

$$\phi_G := \eta \circ \phi_H.$$

If ϕ_G satisfies the hypotheses of Definition 9413.1077 on the G-side, then there is a G-side automorphic packet Π_G with

$$\lambda_{v,r}(\Pi_G) = \operatorname{tr} r(\eta(\phi_H(\mathrm{Frob}_v)))$$

on the certified unramified finite detector scope.

Proof. Apply Definition 9413.1077 to ϕ_G. The resulting packet Π_G matches the Frobenius readout of ϕ_G on the certified detector scope. Substituting $\phi_G = \eta \circ \phi_H$ gives the displayed equality. Any remaining failure would be a no-hidden residual or an unresolved automorphic tail row, both incompatible with the closed hypotheses. □

Theorem 9413.1079 (Categorical analogue)**.** *In a geometric Langlands setting, the same bridge has the following categorical form. If a certified Langlands functor sends every finite Hecke modification window of a spectral object into the automorphic category, and if the functor is essentially surjective modulo a complete categorical boundary ledger, then the spectral object has an automorphic realization unless it enters that boundary ledger.*

Proof. Finite Hecke modification windows play the role of the tower $\mathcal{W}_n$. Essential surjectivity replaces bounded automorphic finiteness, and the categorical boundary ledger replaces the automorphic tail ledger. The same dichotomy applies: a cofinally stable image gives an automorphic realization, while failure of stability is a declared boundary row. Closedness excludes unresolved boundary rows. □

Theorem 9413.1080 (Window-to-global boundary)**.** *The window-to-global bridge proves only a conditional passage from finite Hecke windows to a global automorphic packet. It does not prove bounded automorphic finiteness, stable trace-window formulae, parameter stable distributions, or geometric essential surjectivity.*

Proof. Each step consumes one displayed certificate. Fixed-window existence comes from the trace-window machinery; repetition inside a finite complexity sublevel comes from bounded automorphic finiteness; exclusion of unbounded escape comes from the automorphic tail ledger and closedness. The bridge therefore identifies the precise obstruction to globalization: missing finite-window realization, missing bounded finiteness, or an unresolved automorphic tail row. □

9413.85 BEDC–Langlands No-Hidden Residual Master Lemma

The master no-hidden residual condition used by the Langlands closure theorem is not an independent oracle. It is the finite coproduct of the detector-completeness certificates already isolated for the unramified, ramified, component-group, endoscopic, continuous, and cofinal-tail faces of the Langlands object.

Definition 9413.1081 (Total Langlands residual decomposition)**.** *For a candidate Langlands row*

$$\mathcal{O}^{\uparrow} = (\pi, \psi),$$

the total residual is the formal sum

$$R_{\mathrm{Lan}}(\pi, \psi) = R_{\mathrm{unr}} \oplus R_{\mathrm{ram}} \oplus R_{\mathrm{mult}} \oplus R_{\mathrm{endo}} \oplus R_{\mathrm{cont}} \oplus R_{\mathrm{tail}}.$$

The summands denote, respectively, unramified Hecke–Frobenius mismatch, ramified local packet or character mismatch, packet multiplicity or component-label mismatch, endoscopic transfer mismatch, continuous/Eisenstein/boundary residual, and cofinal-window or representation-complexity tail.

Definition 9413.1082 (Completeness certificates for no-hidden residual)**.** *A no-hidden residual certificate for $\mathcal{O}^{\uparrow} = (\pi, \psi)$ consists of the following data on the declared Langlands scope:*

- *unramified Satake and Tannakian separation for finite Hecke–Frobenius detectors;*
- *ramified local character separation and complete local parameter ledger discipline;*
- *component-group Fourier completeness for packet labels and multiplicities;*
- *endoscopic transfer finite-window or tail-ledger dichotomy;*
- *continuous-spectrum and boundary ledger completeness;*
- *cofinal automorphic tail closure;*
- *a ledger policy requiring every finite-visible or tail-visible residual to be recorded, discharged, or declared outside the claim.*

Theorem 9413.1083 (Unramified residual is finite-detected)**.** *If*

$$R_{\mathrm{unr}} \neq 0,$$

then there is an unramified place v and a finite-dimensional representation

$$r : {}^L G \to GL(V_r)$$

such that

$$\lambda_{v,r}(\pi) \neq \operatorname{tr} r(\psi(\mathrm{Frob}_v)).$$

Proof. The unramified residual says that the Satake semisimple class attached to π at some unramified place differs from the Frobenius semisimple class attached to ψ. If every finite-dimensional representation r had equal trace on these two classes, then Definition 9413.860 would identify the two semisimple conjugacy classes. This contradicts the asserted residual. Hence some finite detector (v, r) has nonzero Hecke–Frobenius residual. □

Theorem 9413.1084 (Ramified residual is finite-detected or local-ledgered)**.** *If*

$$R_{\mathrm{ram}} \neq 0,$$

then some ramified finite local detector

$$(v, \mathfrak{b}, f_v)$$

has

$$\Theta_{\pi_v}(f_v) \neq S\Theta_{\psi_v}(f_v),$$

or the residual is a local parameter ledger row.

Proof. Inside a fixed Bernstein or packet window, a ramified mismatch is the nonzero distribution

$$\Theta_{\pi_v} - S\Theta_{\psi_v}.$$

A nonzero linear functional on the local test-function space is nonzero on some f_v, and Definition 9413.935 supplies the finite-window separation used to isolate the mismatch. If no fixed local window detects it, then Definition 9413.938 places the remaining alternatives in the local ledger: monodromy, normalization, wild ramification, transfer factors, depth, or local packet labels. □

Theorem 9413.1085 (Component residual is Fourier-detected)**.** *If $R_{\mathrm{mult}} \neq 0$, then a component-group Fourier detector detects it, or the obstruction is a packet ledger row.*

Proof. A multiplicity or packet-label residual is a difference between two finite coefficient functions on the character group

$$\widehat{\mathcal{S}_\psi}.$$

When both functions are defined and differ, Definition 9413.997 provides an element

$$s \in \mathcal{S}_\psi$$

whose Fourier readout distinguishes them. Equivalently, the Fourier-twisted packet distribution changes at s. If the packet labels, coefficients, or comparison scope needed for this finite Fourier transform are absent, then Definition 9413.998 classifies the failure as a packet ledger row. □

Theorem 9413.1086 (Endoscopic residual is fixed-window visible or tail-ledgered)**.** *If*

$$R_{\mathrm{endo}} \neq 0,$$

then some matching endoscopic test pair

$$f^H \leftrightarrow f^G$$

has nonzero transfer residual, or the residual belongs to the endoscopic tail ledger.

Proof. This is exactly the finite/tail dichotomy of Definition 9413.1004. If a fixed matching pair witnesses the mismatch, the residual is finite-visible. If all fixed matching windows agree while a transfer failure remains, the failure has left the finite transfer window and is therefore a transfer-factor, ramification, singular-orbital, normalization, boundary, or continuous-spectrum tail row. □

Theorem 9413.1087 (Continuous and boundary residuals are ledger rows)**.** *If $R_{\mathrm{cont}} \neq 0$, then the residual belongs to the continuous-spectrum, Eisenstein, residual-spectrum, truncation, intertwining, scattering, or boundary ledger.*

Proof. Continuous and boundary terms are not isolated discrete packet characters. They arise from parabolic induction, Eisenstein families, constant terms, truncation boundaries, scattering matrices, poles of intertwining operators, or limiting trace-formula rows. If one of these terms is already visible on a fixed trace window, then it is visible as a trace residual and is recorded by the trace ledger. If it appears only through a limiting window, it is a trace tail defect. The dichotomy is the one recorded in Definition 9413.1045, and the ledger requirement is the trace-tail certificate of Definition 9413.1046. □

Theorem 9413.1088 (Cofinal tail residual dichotomy)**.** *If every finite Hecke window has a realization but the cofinal tower does not stabilize to a global packet, then the residual belongs to the automorphic compactness ledger.*

Proof. Choose a realization on each window of a cofinal Hecke tower. The cofinal automorphic compactness certificate used in Definition 9413.1064 says that such a tower either has a cofinally stable global packet or enters the automorphic compactness ledger of Definition 9413.1063. The failure of stabilization is exactly the second alternative. □

Theorem 9413.1089 (NoHiddenLanglandsResidual master lemma)**.** *Assume a candidate Langlands row*

$$\mathcal{O}^{\uparrow} = (\pi, \psi)$$

carries the completeness certificates of Definition 9413.1082. If

$$R_{\mathrm{Lan}}(\pi, \psi) \neq 0,$$

then some residual summand is visible to a finite Langlands detector, or the residual is recorded in the ramified, packet, endoscopic, continuous, boundary, representation-tail, or automorphic-tail ledger.

Proof. By Definition 9413.1081, a nonzero total residual has a nonzero summand.

If $R_{\mathrm{unr}} \neq 0$, then Definition 9413.1083 gives a finite Hecke–Frobenius detector. If $R_{\mathrm{ram}} \neq 0$, then Definition 9413.1084 gives a ramified local detector or a local ledger row. If $R_{\mathrm{mult}} \neq 0$, then Definition 9413.1085 gives a component-group Fourier detector or a packet ledger row. If $R_{\mathrm{endo}} \neq 0$, then Definition 9413.1086 gives a fixed matching test pair or an endoscopic tail row. If $R_{\mathrm{cont}} \neq 0$, then Definition 9413.1087 places the residual in the continuous or boundary ledger. If $R_{\mathrm{tail}} \neq 0$, then Definition 9413.1088 places the residual in the automorphic compactness or representation tail ledger.

These cases exhaust the displayed decomposition. Therefore no nonzero Langlands residual is unaddressed: it is finite-visible or ledgered. □

Corollary 9413.1090 (Closed Langlands rows have zero total residual)**.** *Let $\mathcal{O}^{\uparrow} = (\pi, \psi)$ be a closed BEDC–Langlands row with the three-properties ledger and the no-hidden residual certificates above. Then*

$$R_{\mathrm{Lan}}(\pi, \psi) = 0.$$

Proof. If the total residual were nonzero, the master lemma would make it finite-visible or ledgered. A finite-visible residual must be recorded by ledger discipline; carrying it unresolved contradicts closedness, and omitting it violates the ledger property. A ledger residual is excluded by the same closedness requirement. Hence no total residual remains. □

Corollary 9413.1091 (Reciprocity from existence and no-hidden residual)**.** *Assume $\Pi_{\psi}(G) \neq \varnothing$ and let $\pi \in \Pi_{\psi}(G)$ be a closed packet member satisfying the certificates above. Then for every certified unramified finite detector (v, r),*

$$\lambda_{v,r}(\pi) = \operatorname{tr} r(\psi(\mathrm{Frob}_v)).$$

Proof. The displayed equality is the vanishing of the unramified summand R_{unr} at the detector (v, r). By Definition 9413.1090, the whole total residual vanishes, so the unramified component vanishes on the certified detector scope. □

Theorem 9413.1092 (Boundary of the master lemma)**.** *The master lemma is conditional on the named completeness certificates. It does not construct local Langlands packets, stable trace formulae, endoscopic transfer, component-group labels, automorphic compactness, or continuous-spectrum analysis. It proves that, once those certificates and the ledger policy are present, the phrase no-hidden Langlands residual has a finite decomposition proof.*

Proof. Each branch of the proof invokes one named completeness input: Tannakian separation for unramified readouts, local character separation for ramified readouts, finite Fourier inversion for component data, endoscopic finite/tail separation, trace-tail ledger discipline for continuous and boundary terms, and cofinal compactness for automorphic escape. The proof is therefore a composition theorem, not a construction of those inputs. □

9413.86 BEDC–Langlands Exact Globalization Contract

The Langlands closure chain can be compressed into a certificate DAG statement. Local packet rows, finite Hecke windows, parameter states, trace identities, multiplicity formulae, endoscopic transfers, Tannakian separation, Chebotarev uniqueness, cofinal tail closure, and no-hidden residual discipline are separate certificates. Exact globalization says that once they are connected by complete NameCert and ledger-pullback data, their composite has no unaddressed residual.

Definition 9413.1093 (Langlands certificate DAG)**.** *A Langlands certificate DAG is a finite acyclic graph*

$$\mathcal{D}_{\mathrm{Lan}}$$

whose nodes are drawn from the certificate interfaces

$$\mathsf{LocalPacketCert},\quad \mathsf{ParameterStateCert},\quad \mathsf{FiniteHeckeProjectorCert},$$

$$\mathsf{StabilizedTraceFormulaCert},\quad \mathsf{StableMultiplicityFormulaCert},\quad \mathsf{EndoscopicTransferCert},$$

$$\mathsf{TannakianSeparationCert},\quad \mathsf{ChebotarevCert},\quad \mathsf{CofinalAutomorphicTailClosure},\quad \mathsf{NoHiddenLanglandsResidual}.$$

Each node C carries a NameCert row

$$\mathrm{NameCert}(C) = (\mathrm{SourceSpec}_C, \mathrm{PatternSpec}_C, \mathrm{ClassifierSpec}_C, \mathrm{StabilityCert}_C, \mathrm{LedgerPolicy}_C).$$

The sink node is the closed global Langlands row

$$\mathsf{GlobalLanglandsObject}(\Pi_\psi, \psi).$$

Definition 9413.1094 (Ledger pullback edge)**.** *An edge*

$$C \longrightarrow C'$$

of $\mathcal{D}_{\mathrm{Lan}}$ consists of a readout map from the source interface to the target interface and a pullback ledger

$$\Lambda_{C\to C'}$$

with the following property. Any residual created by composing the two interfaces either projects to a residual already visible in $\mathrm{LedgerPolicy}_C$*, projects to a residual already visible in* $\mathrm{LedgerPolicy}_{C'}$*, or is recorded as an edge-compatibility row in $\Lambda_{C\to C'}$.*

Definition 9413.1095 (Node exactness)**.** *A node C of the certificate DAG is exact when every residual in the readout scope of C is finite-visible through a detector named by C, or is recorded by* $\mathrm{LedgerPolicy}_C$*. A closed exact node carries no unresolved ledger row.*

Definition 9413.1096 (Finite-window exactness)**.** *For a finite Hecke window*

$$\mathcal{W} = (S, R, \mathcal{B})$$

as in Definition 9413.1055, a packet Π is exact over $\mathcal{W}$ for ψ when

$$\lambda_{\mathcal{W}}(\Pi) = a_{\mathcal{W}}(\psi)$$

and every residual not measured inside $\mathcal{W}$ is recorded in the window-tail ledger attached to the bound $\mathcal{B}$.

Theorem 9413.1097 (Ledger pullback preserves exactness)**.** *Let $C \to C'$ be a ledger pullback edge. If C and C' are exact, then their composite interface is exact.*

Proof. Let ρ be a residual of the composite interface. If its projection to the source interface is nonzero, exactness of C makes it finite-visible or records it in $\mathrm{LedgerPolicy}_C$. If its projection to the target interface is nonzero, exactness of C' does the same using $\mathrm{LedgerPolicy}_{C'}$.

It remains to consider the case in which both projections vanish but the composite residual is still asserted to be nonzero. Such a residual is not a source residual and not a target residual; it is precisely a compatibility failure of the edge. By Definition 9413.1094, every edge-compatibility failure is recorded in $\Lambda_{C \to C'}$. Hence the composite is exact. □

Theorem 9413.1098 (Certificate DAG induction)**.** *Let $\mathcal{D}_{\mathrm{Lan}}$ be a Langlands certificate DAG. Suppose every source node is exact and every edge is a ledger pullback edge. Then every node obtained by composing certificates along $\mathcal{D}_{\mathrm{Lan}}$ is exact. If the sink is closed, the sink has no unresolved residual.*

Proof. Choose a topological ordering of the finite acyclic graph. Source nodes are exact by hypothesis. Assume all predecessors of a node C' are exact. Composing C' with each predecessor along its incoming ledger pullback edge preserves exactness by Definition 9413.1097. Since the incoming set is finite, repeated application gives exactness of the composite interface at C'. Induction over the topological ordering proves exactness for every node, including the sink.

At a closed sink, any finite-visible residual must be recorded by the sink ledger policy, and any ledger residual is incompatible with closedness if unresolved. Omitting it violates ledger discipline. Thus the closed sink carries no unresolved residual. □

Theorem 9413.1099 (Cofinal exactness dichotomy)**.** *Assume every window of a cofinal Hecke tower has an exact finite-window realization of ψ. If bounded automorphic finiteness and the complete automorphic tail ledger hold, then either there is a global packet Π_ψ matching every certified finite detector, or a cofinal realization sequence enters the automorphic tail ledger.*

Proof. Choose one exact realizing packet on each finite window. This gives a cofinal window realization in the sense of Definition 9413.1070. The window-to-global alternative of Definition 9413.1074 applies: bounded complexity along an infinite subsequence gives a global packet matching all certified unramified finite detectors, while absence of such a subsequence sends the realization sequence to the automorphic tail ledger. □

Corollary 9413.1100 (Closed cofinal exactness gives a global packet)**.** *Under the hypotheses of Definition 9413.1099, if closed accepted Langlands rows carry no unresolved automorphic tail ledger, then there is a global packet Π_ψ matching every certified finite detector.*

Proof. The dichotomy gives either a global packet or an automorphic tail row. The tail row is either unrecorded, contradicting ledger discipline, or recorded but unresolved, contradicting closedness. Hence the global packet alternative remains. □

Definition 9413.1101 (Exact globalization contract)**.** *The contract*

$$\mathsf{ExactGlobalizationContract}_{\mathrm{Lan}}$$

consists of:

- *a Langlands certificate DAG with NameCert data at every node;*

- *complete ledger pullback on every edge;*
- *exact finite-window realization on a cofinal Hecke tower;*
- *bounded automorphic finiteness and a complete automorphic tail ledger;*
- *the no-hidden residual certificate of Definition 9413.1082;*
- *closedness against unresolved residual ledgers.*

Theorem 9413.1102 (ExactGlobalizationContract for Langlands)**.** *Assume*

$$\mathsf{ExactGlobalizationContract}_{\mathrm{Lan}}.$$

Then there is a global packet Π_ψ *and*

$$R_{\mathrm{Lan}}(\Pi_\psi, \psi) = 0.$$

Proof. The certificate DAG induction of Definition 9413.1098 shows that the composed Langlands interface is exact: every residual is finite-visible or ledgered. Exact finite-window realization on the cofinal tower, together with Definition 9413.1100, produces a global packet Π_ψ matching every certified finite detector.

Assume that

$$R_{\mathrm{Lan}}(\Pi_\psi, \psi) \neq 0.$$

By Definition 9413.1089, the residual is finite-visible or ledgered. A finite-visible residual is already in the DAG readout scope and must be recorded by the relevant ledger policy. A ledger residual is recorded by construction. In both cases an unresolved row contradicts closedness, while omission contradicts ledger discipline. Therefore no residual remains. □

Theorem 9413.1103 (BEDC–Langlands exact closure)**.** *If the Langlands certificate DAG has NameCert data at every node, complete ledger pullbacks on every edge, exact finite-window realization on a cofinal tower, no-hidden residual completeness, and closedness, then Langlands reciprocity holds on the certified unramified finite detector scope:*

$$\lambda_{v,r}(\Pi_\psi) = \operatorname{tr} r(\psi(\mathrm{Frob}_v)).$$

Proof. The hypotheses are exactly the data of Definition 9413.1101. By Definition 9413.1102, there is a global packet and the total Langlands residual vanishes. Projecting the equality

$$R_{\mathrm{Lan}}(\Pi_\psi, \psi) = 0$$

to the unramified summand gives

$$R_{\mathrm{unr}} = 0.$$

For the detector (v, r), this is precisely

$$\lambda_{v,r}(\Pi_\psi) = \operatorname{tr} r(\psi(\mathrm{Frob}_v)).$$

□

Corollary 9413.1104 (Functorial exact closure)**.** *Let*

$$\eta : {}^L H \to {}^L G$$

be an L-group homomorphism. If a closed H-side packet (Π_H, ψ_H) *is given and the target parameter*

$$\psi_G := \eta \circ \psi_H$$

satisfies the exact globalization contract on the G-side, then there is a G-side packet Π_G *such that*

$$\lambda_{v,r}(\Pi_G) = \operatorname{tr} r(\eta(\psi_H(\mathrm{Frob}_v))).$$

Proof. Apply Definition 9413.1103 to the target parameter ψ_G. The resulting packet satisfies

$$\lambda_{v,r}(\Pi_G) = \operatorname{tr} r(\psi_G(\mathrm{Frob}_v)).$$

Substitute $\psi_G = \eta \circ \psi_H$. □

Corollary 9413.1105 (GL_n exact closure)**.** *For $G = GL_n$, assume the local GL_n packet certificate, the Rankin–Selberg detector closure used by the converse theorem, exact finite twist windows, the twist tail ledger, and closedness. Then the GL_n Langlands reciprocity readout holds on the certified unramified scope.*

Proof. For GL_n, local packets are singleton packets, and the component and endoscopic rows of the general certificate DAG reduce to the local packet, converse-theorem, and twist-ledger rows. The Definition 9413.971 supplies the global automorphic packet whenever all finite Rankin–Selberg detector conditions hold or sends the failure to the twist tail ledger. Closedness excludes unresolved twist-tail data. The exact globalization contract then removes the remaining Hecke–Frobenius residual. □

Corollary 9413.1106 (GL_1 two-square shadow)**.** *For $G = GL_1$, $F = \mathbb{Q}$, and $K = \mathbb{Q}(i)$, the exact closure readout specializes at odd primes to*

$$p = a^2 + b^2 \quad \Longleftrightarrow \quad \chi_{-4}(\mathrm{Frob}_p) = 1.$$

Proof. The GL_1 certificate DAG is class field theory with singleton packets and scalar Hecke–Frobenius detectors. The quadratic character of $\mathbb{Q}(i)/\mathbb{Q}$ has value 1 exactly at split odd primes. Splitting in $\mathbb{Q}(i)$ is equivalent to

$$p \equiv 1 \pmod 4,$$

and Fermat's two-square theorem identifies this condition with $p = a^2 + b^2$. □

Theorem 9413.1107 (Boundary of exact globalization)**.** *The exact globalization contract is a conditional composition theorem. It does not construct the local packet certificates, stable trace formula, stable multiplicity formula, endoscopic transfer, Chebotarev input, bounded automorphic finiteness, or cofinal tail certificate. It states that, once those nodes and their ledger pullbacks are supplied as NameCert data, their composite cannot hide a residual outside the finite-detector or ledger alternatives.*

Proof. The proof of the contract uses only DAG induction, edge ledger pullback, the cofinal window-to-global dichotomy, and the no-hidden residual master lemma. Each analytic or representation-theoretic ingredient is consumed as a certificate node. Thus the theorem records the exact BEDC globalization mechanism and leaves construction of the input certificates to their own modules. □

9413.87 BEDC–Langlands Main Closure Theorem

The preceding Langlands modules isolate the local packet rows, parameter-state rows, trace and multiplicity bridges, endoscopic transfer, Tannakian readouts, and no-hidden residual discipline. This section records the combined closure theorem. No additional analytic input is introduced here; the statement is a composition of the certificates already displayed.

Definition 9413.1108 (Certified Langlands parameter object)**.** *Let F be a global field and let G/F be a connected reductive group. A certified parameter object is a row*

$$\psi^{\uparrow} := (\psi, \mathsf{T}_{\psi}, \mathsf{U}_{\psi}, \mathsf{L}_{\psi})$$

where

$$\psi : L_F \times SL_2(\mathbb{C}) \to {}^L G$$

is an Arthur-type parameter, with ordinary Langlands parameters included by a trivial SL_2 factor. Its ledger contains

$$\Lambda_{\psi} := (S_{\mathrm{ram}}, N_v, \epsilon_v, \gamma_v, \mathcal{S}_{\psi}, \mathsf{Endoscopy}, \mathsf{ContinuousSpectrum}, \mathsf{Boundary}, \mathsf{Normalization}).$$

Definition 9413.1109 (Main detector system)**.** *The finite detector system for a certified G-parameter consists of four finite detector types.*

The unramified Hecke–Frobenius detector is

$$(v, r),$$

where v is unramified and $r : {}^L G \to GL(V_r)$ is finite-dimensional. Its residual is

$$D_{v,r}(\pi, \psi) := \lambda_{v,r}(\pi) - \operatorname{tr} r(\psi(\mathrm{Frob}_v)).$$

The ramified local detector is

$$(v, \mathfrak{b}, f_v),$$

where $\mathfrak{b}$ is a Bernstein or packet window and $f_v \in C_c^{\infty}(G(F_v))$. Its residual compares

$$\Theta_{\pi_v}(f_v) \qquad \text{and} \qquad S\Theta_{\psi_v}(f_v).$$

The component-group Fourier detector is an element

$$s \in \mathcal{S}_{\psi},$$

reading the Fourier-twisted packet distribution

$$\Theta_{\psi,s}(f) = \sum_{\pi \in \Pi_{\psi}(G)} \chi_{\pi}(s) \Theta_{\pi}(f).$$

The endoscopic transfer detector is a matching test pair

$$f^G \leftrightarrow f^H$$

for an endoscopic embedding $\xi : {}^L H \to {}^L G$, reading the difference between the H-stable distribution and its G-transfer.

Definition 9413.1110 (Main residual ledger)**.** *The total Langlands residual of a candidate pair* (π, ψ) *is classified into six rows:*

$$R_{\mathrm{unr}}, \quad R_{\mathrm{ram}}, \quad R_{\mathrm{mult}}, \quad R_{\mathrm{endo}}, \quad R_{\mathrm{cont}}, \quad R_{\mathrm{tail}}.$$

They denote, respectively, unramified Hecke–Frobenius mismatch, ramified local packet mismatch, component-group or multiplicity mismatch, endoscopic transfer mismatch, continuous/Eisenstein/boundary residual, and cofinal-window or representation-complexity tail.

Definition 9413.1111 (Master no-hidden residual)**.** *The master no-hidden Langlands residual condition says that every nonzero row of*

$$R_{\mathrm{Langlands}}(\pi, \psi)$$

is detected by one of the finite detectors of Definition 9413.1109, or is recorded in the corresponding ramified, endoscopic, continuous, boundary, multiplicity, representation-tail, or automorphic-tail ledger.

Theorem 9413.1112 (No hidden residual excludes wrong closed packets)**.** *Let* (π, ψ) *be a closed BEDC–Langlands object with the three-properties ledger and the master no-hidden residual condition. Then*

$$R_{\mathrm{Langlands}}(\pi, \psi) = 0.$$

Proof. Assume a nonzero residual remains. By the master no-hidden condition, it is finite-detected or ledgered. In the finite-detected case, one of the detectors

$$(v, r), \qquad (v, \mathfrak{b}, f_v), \qquad s \in \mathcal{S}_\psi, \qquad f^G \leftrightarrow f^H$$

has a nonzero readout residual. Ledger discipline then requires that residual to be recorded; carrying it unresolved contradicts closedness, and omitting it violates the ledger property. In the ledger case, the residual is ramified, endoscopic, continuous, boundary, automorphic tail, or representation tail data. The same closedness and ledger argument applies. Hence no residual remains. □

Theorem 9413.1113 (Main existence bridge)**.** *Assume a certified parameter* $\psi^\uparrow$ *carries local packet certificates, parameter state certificates, stabilized trace formula certificates, stable multiplicity formula certificates, endoscopic transfer certificates, endoscopic induction, trace-tail ledger discipline, and closedness. Then*

$$\Pi_\psi(G) \neq \varnothing.$$

Proof. The parameter state certificate gives a fixed-window test function $f_{\psi,\mathcal{W}}$ with nonzero stable parameter readout. By the stabilized trace formula certificate, the nonzero readout appears on the spectral side. The spectral contribution has three possible addresses.

If it is a primitive G-discrete contribution, the stable multiplicity formula certificate and Definition 9413.1001 force a nonempty packet. If it comes from a proper endoscopic group, endoscopic induction and Definition 9413.1005 carry the packet to the G-side unless a transfer residual occurs; such a residual is finite-detected or ledgered, hence incompatible with closedness while unresolved. If the contribution is neither primitive nor proper-endoscopic, it lies in continuous spectrum, Eisenstein boundary, singular orbital, normalization, or tail data, all of which are ledger rows and are excluded in the closed case. Therefore the G-packet is nonempty. □

Theorem 9413.1114 (BEDC–Langlands reciprocity)**.** *Assume the hypotheses of Definition 9413.1113, together with Tannakian separation, Chebotarev uniqueness, the master no-hidden residual condition, and closedness. Then every certified closed parameter $\psi^{\uparrow}$ has $\pi \in \Pi_{\psi}(G)$ such that, for almost all certified unramified places v and every finite-dimensional $r : {}^{L}G \to GL(V_r)$ in the readout scope,*

$$\lambda_{v,r}(\pi) = \operatorname{tr} r(\psi(\mathrm{Frob}_v)).$$

Proof. By Definition 9413.1113, the packet is nonempty. Choose $\pi \in \Pi_{\psi}(G)$. If any finite readout mismatch remains, it is part of $R_{\mathrm{Langlands}}(\pi, \psi)$ and is excluded by Definition 9413.1112. Thus all unramified finite detectors agree. Tannakian separation and Chebotarev uniqueness then identify the semisimplified parameter readout on the certified scope. Any remaining ramified, endoscopic, continuous, boundary, or tail discrepancy is a ledger row and is likewise excluded by closedness. □

Theorem 9413.1115 (BEDC–Langlands functoriality)**.** *Let*

$$\eta : {}^{L}H \to {}^{L}G$$

be an L-group homomorphism and let (π_H, ψ_H) be a closed H-side packet. Put

$$\psi_G := \eta \circ \psi_H.$$

If ψ_G satisfies the hypotheses of Definition 9413.1114, then there is a G-side packet $\Pi_{\psi_G}(G)$ with a member π_G such that

$$\lambda_{v,r}(\pi_G) = \operatorname{tr} r(\eta(\psi_H(\mathrm{Frob}_v)))$$

on the certified unramified readout scope.

Proof. Apply Definition 9413.1114 to the target parameter $\psi_G = \eta \circ \psi_H$. The resulting packet has readouts

$$\lambda_{v,r}(\pi_G) = \operatorname{tr} r(\psi_G(\mathrm{Frob}_v)).$$

Substituting $\psi_G = \eta \circ \psi_H$ gives the formula. □

Theorem 9413.1116 (BEDC–Langlands main closure theorem)**.** *On any reductive-group scope carrying local packet certificates, parameter state certificates, stabilized trace formula certificates, stable multiplicity formula certificates, endoscopic transfer certificates, endoscopic induction, Tannakian separation, Chebotarev uniqueness, the master no-hidden Langlands residual condition, complete ledger discipline, and closedness, Langlands reciprocity and functoriality hold on the certified scope.*

Proof. Reciprocity is exactly Definition 9413.1114. Functoriality is exactly Definition 9413.1115. The existence input used by reciprocity is supplied by Definition 9413.1113; the absence of wrong closed packets is supplied by Definition 9413.1112. □

Corollary 9413.1117 (GL_1 detector shadow)**.** *For $G = GL_1$ and the quadratic character attached to $\mathbb{Q}(i)/\mathbb{Q}$, the general finite readout condition reduces at odd primes to*

$$\chi_{-4}(\mathrm{Frob}_p) = 1,$$

equivalently

$$p = a^2 + b^2.$$

Proof. For GL_1, the L-group is $\mathbb{C}^\times$, packets are singletons, component groups and endoscopy disappear on this scope, and class field theory identifies the parameter with a Hecke character. The splitting condition for odd primes in $\mathbb{Q}(i)$ is $\chi_{-4}(\mathrm{Frob}_p) = 1$, which is equivalent to the two-square criterion. □

Theorem 9413.1118 (Main closure boundary)**.** *The main closure theorem is conditional on the named local, trace, multiplicity, endoscopic, Tannakian, Chebotarev, and ledger certificates. It does not construct the traditional analytic, endoscopic, or geometric Langlands inputs; it states that once those inputs are present as BEDC certificates, no residual can remain hidden in a closed object.*

Proof. Every step above invokes a named certificate established or isolated in the preceding modules. The argument is the BEDC composition principle: finite-visible residuals are detected, non-finite residuals are ledgered, and closedness rejects unresolved ledgers. It is not a substitute for constructing the input certificates. □

9413.88 BEDC–Langlands Base Case for GL_1

The abelian case makes the BEDC–Langlands proof chain completely explicit. For $G = GL_1$, Langlands reciprocity is global class field theory. The automorphic side is the group of Hecke characters of the idele class group, the Galois side is the group of continuous characters of the abelianized Weil group, and the finite Hecke–Frobenius detector is a single unramified place.

Definition 9413.1119 (GL_1 Langlands packet)**.** *Let F be a global field and set*

$$C_F := F^\times \backslash \mathbb{A}_F^\times.$$

A GL_1 automorphic object is a Hecke character

$$\chi : C_F \to \mathbb{C}^\times.$$

A GL_1 Galois parameter is a continuous character

$$\phi : W_F^{\mathrm{ab}} \to \mathbb{C}^\times.$$

A BEDC–GL_1 Langlands packet is a row

$$\mathcal{O}^\uparrow = (\chi, \phi, \Lambda_{\mathcal{O}}),$$

where $\Lambda_{\mathcal{O}}$ records ramified places, conductor, archimedean type, norm-scale factors, local ϵ/γ factors, and the Artin reciprocity normalization.

Definition 9413.1120 (GL_1 detector and residual)**.** *For an unramified place v, let ϖ_v be a uniformizer and let Frob_v be the corresponding Frobenius element under the chosen reciprocity convention. The GL_1 detector residual is*

$$D_v(\chi, \phi) := \chi(\varpi_v) - \phi(\mathrm{Frob}_v).$$

The packet matches on the detector v exactly when

$$D_v(\chi, \phi) = 0.$$

Definition 9413.1121 (GL_1 three-properties rows)**.** *The GL_1 time row sends an unramified place to the paired readout*

$$v \longmapsto (\mathrm{Frob}_v, \varpi_v).$$

The unity row says that a unitary finite-order character takes values in S^1, while a general Hecke character is decomposed as

$$\chi = \chi_{\mathrm{unit}} \cdot |\cdot|^s$$

with the norm-scale factor $|\cdot|^s$ recorded in the ledger. The ledger row is precisely the list of ramified, conductor, infinity-type, normalization, and local-factor data not seen by unramified finite detectors.

Theorem 9413.1122 (GL_1 finite detector uniqueness)**.** *Let*

$$\phi, \phi' : W_F^{\mathrm{ab}} \to \mathbb{C}^\times$$

be continuous characters. If

$$\phi(\mathrm{Frob}_v) = \phi'(\mathrm{Frob}_v)$$

for almost all unramified places v, then

$$\phi = \phi'.$$

Proof. Chebotarev density says that the unramified Frobenius classes are dense in the abelianized Galois or Weil quotient on the declared scope. The two characters are continuous and agree on a dense subset, hence agree on its closure. Therefore they are equal. □

Corollary 9413.1123 (GL_1 no-hidden residual)**.** *For a BEDC–GL_1 packet, any mismatch outside the unramified finite detectors must lie in the ramified, conductor, infinity-type, norm-scale, or local-factor ledger.*

Proof. The unramified detector values determine the continuous abelian parameter by Definition 9413.1122. A residual not seen there is therefore not an unramified Frobenius mismatch. The only remaining declared rows are the ledger rows listed in Definition 9413.1121. □

Definition 9413.1124 (Class field reciprocity certificate)**.** *The class field reciprocity certificate for F is the Artin reciprocity map*

$$\mathrm{Art}_F : C_F \to W_F^{\mathrm{ab}}$$

with the convention row fixed so that, at unramified places,

$$\mathrm{Art}_F(\varpi_v) = \mathrm{Frob}_v\,.$$

Changing the inverse convention changes only this normalization row; the detector equality is transported with it.

Theorem 9413.1125 (GL_1 reciprocity)**.** *Assume the class field reciprocity certificate. For every continuous character*

$$\phi : W_F^{\mathrm{ab}} \to \mathbb{C}^\times,$$

the character

$$\chi_\phi := \phi \circ \mathrm{Art}_F$$

is a Hecke character and satisfies

$$\chi_\phi(\varpi_v) = \phi(\mathrm{Frob}_v)$$

for almost all unramified places v. Conversely, every Hecke character $\chi : C_F \to \mathbb{C}^\times$ gives the abelian parameter

$$\phi_\chi := \chi \circ \mathrm{Art}_F^{-1}$$

with the same unramified detector equality.

Proof. The class field reciprocity certificate identifies the idele class group with the abelian Weil side under the declared normalization. Composing a continuous abelian Weil character with Art_F gives a continuous character of C_F, hence a Hecke character. At an unramified place,

$$\chi_\phi(\varpi_v) = \phi(\mathrm{Art}_F(\varpi_v)) = \phi(\mathrm{Frob}_v).$$

The converse is the same argument applied to the inverse reciprocity map. □

Theorem 9413.1126 (GL_1 finite projector)**.** *Let S be a fixed finite set of unramified places and let*

$$\mathsf{Aut}_{S,B}(GL_1) = \{\chi_1, \ldots, \chi_M\}$$

be a finite bounded candidate list. For every abelian parameter ϕ, there is a Laurent polynomial Hecke test function $f_{\phi,S,B}$ on $(\mathbb{C}^\times)^S$ such that

$$\chi_i(\varpi_v)_{v\in S} \neq \phi(\mathrm{Frob}_v)_{v\in S} \quad \Longrightarrow \quad \mathrm{tr}\, \chi_i(f_{\phi,S,B}) = 0,$$

while a matching character evaluates nontrivially.

Proof. For GL_1, the spherical Hecke algebra on S is the Laurent polynomial coordinate ring of $(\mathbb{C}^\times)^S$. The bounded candidate list gives finitely many points

$$X_i = (\chi_i(\varpi_v))_{v\in S},$$

and the parameter gives the point

$$X_\phi = (\phi(\mathrm{Frob}_v))_{v\in S}.$$

The Laurent coordinate ring separates finite closed point sets, so the same interpolation argument as Definition 9413.910 gives a function equal to 1 at X_ϕ and 0 at every displayed nonmatching X_i. □

Theorem 9413.1127 (GL_1 BEDC closure)**.** *For $G = GL_1$, the BEDC–Langlands existence, uniqueness, finite detection, and no-hidden-residual rows are closed by global class field theory.*

Proof. Existence is Definition 9413.1125: every abelian parameter ϕ produces the Hecke character χ_ϕ, and every Hecke character produces the abelian parameter ϕ_χ. Finite detection and uniqueness are Definition 9413.1122. Any remaining residual is forced by Definition 9413.1123 into the ramified, conductor, infinity-type, norm-scale, or local-factor ledger. A closed packet carries no unresolved ledger row. Hence the paired object has no hidden mismatch. □

Corollary 9413.1128 (GL_1 cofinal bridge)**.** *For $G = GL_1$, if each finite Hecke window is read through the character χ_ϕ of Definition 9413.1125, then the cofinal window-to-global bridge has the global alternative immediately: the same Hecke character realizes every unramified window.*

Proof. For every unramified place v, the equality

$$\chi_\phi(\varpi_v) = \phi(\mathrm{Frob}_v)$$

holds outside the declared ramified ledger. Therefore the same automorphic character realizes every finite window in the cofinal tower. The automorphic tail alternative of Definition 9413.1074 is not needed in this abelian base case, because a global realizing row is already present. □

Theorem 9413.1129 (Quadratic splitting detector)**.** *Let $K = \mathbb{Q}(i)$ and let χ_{-4} be the quadratic character attached to $K/\mathbb{Q}$. For every odd prime p, the following conditions are equivalent:*

$$p = a^2 + b^2,$$

$$p \equiv 1 \pmod 4,$$

$$p \text{ splits in } \mathbb{Q}(i),$$

$$\chi_{-4}(\mathrm{Frob}_p) = 1.$$

Under GL_1 reciprocity, these are also equivalent to the corresponding Hecke character ω_{-4} satisfying

$$\omega_{-4}(p) = 1.$$

Proof. Fermat's two-square theorem gives the equivalence between $p = a^2 + b^2$ and $p \equiv 1 \pmod 4$ for odd primes. In $\mathbb{Q}(i)$, a prime $p \neq 2$ splits exactly when -1 is a square modulo p, which is again equivalent to $p \equiv 1 \pmod 4$. Splitting means that the Frobenius element in $\mathrm{Gal}(\mathbb{Q}(i)/\mathbb{Q}) \cong \{\pm 1\}$ is the identity, so $\chi_{-4}(\mathrm{Frob}_p) = 1$. The last equivalence is the detector equality supplied by Definition 9413.1125. □

Corollary 9413.1130 (Two-square theorem as the minimal detector)**.** *The statement that an odd prime is represented by $a^2 + b^2$ is the minimal visible finite detector of GL_1 reciprocity for the quadratic extension $\mathbb{Q}(i)/\mathbb{Q}$.*

Proof. By Definition 9413.1129, the two-square condition is exactly the assertion that the quadratic Frobenius readout equals 1. Under class field reciprocity, the same readout is the Hecke character value $\omega_{-4}(p)$. Thus the classical arithmetic predicate is a single GL_1 Hecke–Frobenius detector. □

Theorem 9413.1131 (Nonabelian lift boundary)**.** *The GL_1 base case closes the abelian Langlands packet. For a general reductive group G, the detector v is replaced by (v, r) with $r : {}^LG \to GL(V_r)$, and the character value is replaced by*

$$\mathrm{tr}\, r(s_v(\pi)) \quad \textit{and} \quad \mathrm{tr}\, r(\phi(\mathrm{Frob}_v)).$$

The nonabelian existence problem is therefore not the GL_1 class field certificate, but the construction of the automorphic packet through the stable trace formula, geometric Langlands functor, or cohomological realization.

Proof. For GL_1, every finite-dimensional representation of the dual group is a character, and class field reciprocity supplies the global automorphic character directly. For general G, finite-dimensional characters of ${}^LG$ separate semisimple conjugacy classes by the Tannakian row, while Chebotarev controls Frobenius density. Those rows close uniqueness and residual detection once a packet exists. The existence of the packet is the separate certificate isolated in section 9413.71. □

9413.89 Unified Relation Atlas

The preceding sections give local worked examples of the same general discipline. A mathematical object is not treated as an isolated point. It is treated as a carriered packet whose visible appearances are reality projections. The atlas in this section is not a catalogue of all mathematics. It is the relation schema governing the examples already in view: common carrier, projection, generalized continuation, transport ledger, and boundary ledger.

Definition 9413.1132 (Unified relation packet)**.** *A* unified relation packet *is a tuple*

$$\mathcal{O} := (\mathsf{Carrier}, \mathsf{Classifier}, (\pi_i)_{i\in I}, \mathsf{Transport}, \mathsf{Ledger}, \mathsf{Boundary})$$

where the maps

$$\pi_i : \mathcal{O} \to R_i$$

read the same carrier in different realities. The reality targets may include algebraic, geometric, analytic, spectral, arithmetic, measure, and categorical interfaces:

$$R_{\text{alg}}, R_{\text{geom}}, R_{\text{analytic}}, R_{\text{spectral}}, R_{\text{arith}}, R_{\text{measure}}, R_{\text{cat}}.$$

The classifier records when two carrier rows are the same for the purpose of the packet. The transport rows record continuation between realities. The ledger records which scale, branch, convergence, prime, zero, or boundary data remain present after a projection.

Principle 9413.1133 (Carriered relation before object isolation)**.** *Within unified reality, a mature mathematical interface is read as a licensed name over displayed carrier data. It is not used as an uninspected primitive when a carrier, classifier, transport row, and boundary ledger are the relevant mathematical content.*

Definition 9413.1134 (Quadratic-norm atlas row)**.** *The* quadratic-norm row *begins with the Pythagorean carrier of section 9413.6:*

$$a^2 + b^2 \sim c^2.$$

After the nonzero scale row $c\#0$ is displayed, the normalized shape projection reads

$$x = \frac{a}{c}, \qquad y = \frac{b}{c}, \qquad x^2 + y^2 \sim 1.$$

In higher dimension the same norm layer has unit-sphere readout

$$S^{n-1} : \quad x_1^2 + \cdots + x_n^2 = 1$$

and symmetry readout

$$O(n) := \{A : A^T A = I\}.$$

The circle and the sphere are unit norm layers. The orthogonal interface is the automorphism read preserving that norm layer.

Theorem 9413.1135 (Quadratic normalization is a scale-to-shape transport)**.** *The quadratic-norm row transports a Pythagorean scale carrier to a unit-shape carrier, while the scale remains in the projection fiber.*

Proof. The two-dimensional case is Definition 9413.218. It sends (a, b, c) with $c\#0$ to $(a/c, b/c)$, preserving the normalized equation and forgetting the visible value of c. The higher-dimensional sphere and orthogonal rows do not change this ledger reading: they expose unit norm and norm-preserving symmetry, not the original scale coordinate. □

Definition 9413.1136 (Phase and transform atlas row)**.** *The* phase and transform row *reads the unit circle as phase, Fourier analysis as character projection, Laplace analysis as real-biased phase transport, and Mellin analysis as Laplace transport in logarithmic coordinates. Its kernels are*

$$e^{in\theta}, \qquad e^{-i\omega t}, \qquad e^{-st}, \qquad x^{-s}.$$

For $s = \sigma + i\omega$ the Laplace kernel factors as

$$e^{-st} = e^{-\sigma t} e^{-i\omega t}.$$

For $x = e^t$ the Mellin kernel reads

$$x^{-s} = e^{-s \log x}.$$

Theorem 9413.1137 (Mellin is logarithmic Laplace transport)**.** *The Mellin kernel x^{-s} is the Laplace kernel on the logarithmic coordinate of the multiplicative axis.*

Proof. Set $t = \log x$. Then $x = e^t$, and hence

$$x^{-s} = (e^t)^{-s} = e^{-st} = e^{-s \log x}.$$

The logarithm transports multiplication to addition:

$$\log(mn) = \log m + \log n.$$

Thus multiplicative arithmetic data can be read as additive Laplace data after the logarithmic transport row is displayed. This is the transport principle already recorded in Definition 9413.226. □

Definition 9413.1138 (Arithmetic spectral atlas row)**.** *The* arithmetic spectral row *reads a coefficient sequence $(a_n)_{n\geq 1}$ as the atomic logarithmic source*

$$\mu_a := \sum_{n\geq 1} a_n \delta_{\log n}$$

with Dirichlet/Laplace readout

$$\mathcal{L}[\mu_a](s) = \sum_{n\geq 1} a_n n^{-s}.$$

For $a_n = 1$, this is the zeta Dirichlet face on its convergence window, as in Definition 9413.224. When the coefficient and convergence rows license multiplicative regrouping, the same carrier has Euler-product face

$$\prod_p (1 - p^{-s})^{-1}.$$

The Dirichlet face is the additive list reality. The Euler face is the prime-local multiplicative reality.

Principle 9413.1139 (Zeta is a shared arithmetic carrier)**.** *Zeta is not merely a sum and not merely a product. In this atlas it is a shared arithmetic carrier whose Dirichlet, logarithmic Laplace, and prime-local faces are compatible only under their displayed convergence, factorization, and transport ledgers.*

Definition 9413.1140 (Theta-functional-equation atlas row)**.** *The* theta-functional-equation row *is the classical transport schema*

Gaussian → theta → Poisson/Fourier symmetry → Mellin readout → Γ-factor → zeta functional equation.

In unified reality, this row says that Fourier symmetry and Mellin/Laplace readout cooperate to produce a functional-equation transport, once the Gaussian, theta, Poisson, Mellin, and convergence ledgers are separately supplied.

Definition 9413.1141 (Prime-channel boundary row)**.** *For*

$$s = \frac{1}{2} + \delta + i\tau$$

the centered prime channel is

$$p^{1/2-s} = p^{-\delta} e^{-i\tau \log p}.$$

Its amplitude read is

$$|p^{1/2-s}| = p^{-\delta}.$$

Therefore the critical line is the prime-channel unitary surface, as recorded in Definition 9413.228.

Principle 9413.1142 (RH is zero-rigidity at the unitary boundary)**.** *The RH target is read in this atlas as a zero-rigidity boundary for the zeta carrier: nontrivial zeros in the critical strip must lie on the prime-channel unitary surface. This is a route statement, not the missing analytic bridge; the bridge obligations remain those isolated in section 9413.16.*

Definition 9413.1143 (Spectral-curve atlas row)**.** *The* spectral-curve row *is the chain*

rational generating function → linear recurrence → companion matrix → spectral polynomial → spectral curve →

For the quartic worked example this row is realized by

$$Z(t, y) = \frac{N(t, y)}{D(t, y)}, \qquad \det(\lambda I - T(y)) = \Pi(\lambda, y),$$

and by the elliptic normalization

$$E: \quad Y^2 = 4\lambda^3 - 4\lambda + 1.$$

Theorem 9413.1144 (Spectral curves mediate recurrence and zero reality)**.** *The quartic spectral row mediates recurrence algebra, matrix spectra, elliptic branch geometry, dominance, and endpoint-zero reality without identifying these projections as the same visible object.*

Proof. This is the content of Definition 9413.106. The recurrence, companion matrix, spectral polynomial, affine curve, elliptic normalization, dominance row, and endpoint-zero law are projections of the fixed quartic carrier. The carrier makes the projections comparable; it does not erase the boundary ledgers attached to each projection. □

Definition 9413.1145 (Partition and zero-boundary row)**.** *A* partition zero-boundary row *has exponential-sum form*

$$Z(\beta, h) := \sum_{\omega \in \Omega} e^{-\beta E(\omega) + hM(\omega)}.$$

It is a weighted Laplace/Fourier readout of a state space. Zeros of such a readout record phase cancellation or boundary behavior in the corresponding model. Any stronger theorem, such as a Lee-Yang location theorem, requires its own model-specific carrier and proof ledger.

Definition 9413.1146 (Heat-kernel and spectral-zeta row)**.** *For a displayed operator with eigenvalue ledger* (λ_n)*, the heat trace read is*

$$\mathrm{Tr}(e^{-t\Delta}) = \sum_n e^{-t\lambda_n}.$$

The spectral zeta read is

$$\zeta_\Delta(s) = \sum_n \lambda_n^{-s}.$$

Thus a geometric operator can project to a spectral measure, to its heat Laplace readout, and to its Mellin-type spectral zeta readout. Analytic continuation, pole structure, and determinant interpretations remain separate boundary ledgers.

Definition 9413.1147 (Elliptic, modular, and L-function row)**.** *An elliptic curve row has branch-cover form*

$$E: \quad Y^2 = P_3(X).$$

When a modular or automorphic bridge is displayed, the curve may be read through a modular packet f_E *and an L-function readout*

$$L(E,s) = L(f_E,s) = \sum_{n\geq 1} a_n n^{-s}.$$

In this atlas, the point is the transport shape: elliptic geometry, period data, modular spectra, Dirichlet/Mellin readouts, and zeros belong to one bridgeable packet only when the required bridge rows are present.

Definition 9413.1148 (Cross-domain bridge ledger)**.** *The* cross-domain bridge ledger *records high-level transports between realities. Examples include* $\mathsf{StoneDuality}^\uparrow$, $\mathsf{GelfandDuality}^\uparrow$, $\mathsf{PontryaginDuality}^\uparrow$, $\mathsf{TannakaKrein}^\uparrow$, $\mathsf{RiemannHilbert}^\uparrow$, $\mathsf{HodgeBridge}^\uparrow$, $\mathsf{Langlands}^\uparrow$, *and* $\mathsf{MirrorSymmetry}^\uparrow$, *as listed in section 9467.17. Each bridge is a transport ledger between realities, not a permission to conflate the source and target interfaces without the stated classifier and boundary rows.*

Layer	**Visible read**	**Unified-reality reading**
Quadratic norm	$a^2 + b^2 = c^2$	scale-shape carrier
Unit shape	$x_1^2 + \cdots + x_n^2 = 1$	normalized norm reality
Symmetry	$A^T A = I$	norm-preserving automorphism
Phase	$e^{i\theta}$	circle phase coordinate
Fourier	$e^{in\theta}$	character and frequency projection
Laplace	e^{-st}	phase with real damping direction
Mellin	x^{-s}	Laplace read on logarithmic coordinates
Zeta	$\sum n^{-s}$	arithmetic atomic source readout
Euler product	$\prod_p (1-p^{-s})^{-1}$	prime-local multiplicative face
Theta/Gamma	Poisson plus Mellin	functional-equation transport
Elliptic curve	$Y^2 = P_3(X)$	branch and period carrier
Spectral curve	$\Pi(\lambda, y) = 0$	recurrence-matrix-geometry carrier
Heat trace	$\sum e^{-t\lambda_n}$	operator-spectrum Laplace read
L-function	$\sum a_n n^{-s}$	arithmetic or automorphic spectral read
RH boundary	$\Re(s) = 1/2$	prime-channel unitary zero boundary

Theorem 9413.1149 (Relation atlas does not collapse projections)**.** *No row in the relation atlas may replace the carrier by one of its visible projections unless the corresponding classifier, transport, fiber, and boundary ledgers are displayed.*

Proof. This is the atlas form of Definition 9413.24. The quadratic row forgets scale under the circle projection. The Laplace and Mellin rows add damping and logarithmic transport not present in pure Fourier phase. The zeta row has both Dirichlet and Euler faces only with the relevant convergence and factorization ledgers. The spectral-curve row separates recurrence, matrix, branch, dominance, and endpoint-zero data. Therefore projection visibility is never sufficient by itself to replace the common carrier. □

Theorem 9413.1150 (Unified relation atlas principle)**.** *Triangles, circles, spheres, orthogonal symmetries, Fourier modes, Laplace kernels, Mellin kernels, zeta, spectral curves, elliptic carriers, heat traces, L-functions, and RH boundary rows form a compatible relation atlas when read as carrier projections connected by transport ledgers. Their compatibility is not object-level identity; it is common-carrier projection disciplined by noncollapse and boundary accounting.*

Proof. The common-carrier and generalized-continuation rules are Definition 9413.4 and Definition 9413.12. The Pythagorean scale-shape row is Definition 9413.218. The phase-transform-zeta chain is Definition 9413.232. The quartic spectral chain is Definition 9413.106. The RH boundary route is Definition 9413.1142. The cross-domain bridge layer is Definition 9413.1148. Taken together, these rows supply a relation atlas: transport between realities is licensed by displayed ledgers, and every projection remains boundary-relative. □

Chapter 9414

Reality-Constrained Approximation Towers

Mathematical approximation and physical adequacy are not the same relation. A mathematical object may admit several convenient representations, and those representations may be equivalent under a chosen mathematical classifier. When the representation is used as a model of a real system, however, the relevant classifier is no longer freely chosen. It is constrained by the reality-facing properties through which the system responds to admissible observation and intervention.

This chapter records the resulting conceptual framework. BEDC already treats equality, function, limit, real number, circle, and other mature objects as derived interfaces rather than primitive givens. Compression, packaging, projection, sealing, and identification must carry source, classifier, stability, and GAP ledger data. The same discipline applies to physical modelling: a mathematical representation is physically admissible only when the classifier that licenses it is compatible with the physical signature bundle under which the represented system is queried.

9414.1 Reality-facing signatures

Definition 9414.1 (Reality-facing property)**.** *A reality-facing property of a system is a property that can affect the system's stable interaction profile under some admissible physical procedure. Removing, smoothing, quotienting, or replacing such a property by an approximate surrogate can change at least one physically relevant response.*

Mass, charge, curvature, boundary differentiability, stress concentration, causal accessibility, optical response, and measurement-stable phase information are standard examples. A purely mathematical feature becomes reality-facing only when it enters such a response profile.

Definition 9414.2 (Mathematical classifier)**.** *A mathematical classifier $\sim_{\mathcal{M}}$ is an equivalence or comparison relation that groups mathematical representations according to selected mathematical features. It becomes physically relevant only when the grouped features coincide with the reality-facing properties activated by the physical system under the observation bundle in use.*

Definition 9414.3 (Ontic signature source)**.** *Let O be a system and let Π_{phys} be a bundle of physically admissible questions. The physical signature of O relative to Π_{phys} is written*

$$\mathrm{PhysSig}_{\Pi_{\mathrm{phys}}}(O).$$

The ontic signature source of O, relative to Π_{phys}, is the invariant source of this signature. It is not identified with any particular mathematical representation.

Two systems are physically indistinguishable at the resolution Π_{phys} only when their signatures agree:

$$\text{PhysSig}_{\Pi_{\text{phys}}}(O_1) \sim \text{PhysSig}_{\Pi_{\text{phys}}}(O_2).$$

This is a signature-level sameness judgment, not host-level identity.

Definition 9414.4 (Mathematical representation)**.** *A mathematical representation of an ontic signature source O is a structured mathematical object M together with a representation route*

$$\rho : O \rightsquigarrow M$$

and an interpretation procedure that reads features of M as candidate reality-facing properties of O.

The representation is mathematically adequate relative to a mathematical classifier $\sim_{\mathcal{M}}$ when it preserves the mathematical features selected by that classifier. It is physically adequate relative to Π_{phys} only when its induced physical signature agrees with the signature of the represented system:

$$\text{Sig}_{\Pi_{\text{phys}}}(M) \sim \text{PhysSig}_{\Pi_{\text{phys}}}(O).$$

Definition 9414.5 (Physical-fit relation)**.** *For mathematical representations M_1 and M_2, the physical-fit relation relative to Π_{phys} is*

$$M_1 \equiv_{\text{phys},\Pi} M_2$$

exactly when

$$\text{Sig}_{\Pi_{\text{phys}}}(M_1) \sim \text{Sig}_{\Pi_{\text{phys}}}(M_2).$$

The physical-fit relation may be strictly finer than a mathematical approximation relation. Polygonal approximations and a smooth circle may agree under area, perimeter, or Hausdorff-distance classifiers while separating under tangent-field, curvature, reflection, stress-response, or boundary-layer classifiers.

Definition 9414.6 (Representation gap)**.** *A representation gap occurs when two representations are identified by a mathematical classifier but separated by a physically active signature:*

$$M_1 \sim_{\mathcal{M}} M_2 \quad \textit{and} \quad M_1 \not\equiv_{\text{phys},\Pi} M_2.$$

The gap is evidence that the mathematical classifier is too coarse for the physical question being asked.

Definition 9414.7 (Reality-constrained classifier)**.** *A mathematical classifier $\sim_{\mathcal{M}}$ is reality-constrained by Π when*

$$M_1 \sim_{\mathcal{M}} M_2 \quad \Longrightarrow \quad M_1 \equiv_{\text{phys},\Pi} M_2.$$

Equivalently, every mathematical identification licensed by $\sim_{\mathcal{M}}$ preserves the physical signature exposed by Π.

Definition 9414.8 (Reality-constrained meaning)**.** *Let C be a closed observational context, let x be a displayed record or representation available to C, let ℓ be a label, and let κ be a classifier with $\kappa(x) = \ell$. The label has reality-constrained meaning for C relative to an observation bundle Π when the assignment is carried by*

$$\text{Meaning}_{C,\Pi}(x, \ell, \kappa) = (\text{SourceRecord}, \text{Classifier}, \text{RealityConstraint}, \text{ContinuationConsequence}, \text{GapLedger}).$$

The source record locates x in the finite observation history, the classifier supplies the label, the reality constraint requires the classifier to preserve the Π-signature, the continuation consequence records which downstream modelling, prediction, action, or proof use depends on the label, and the gap ledger records the provenance and unclosed supply exposed by that dependence.

Theorem 9414.9 (Classification alone does not supply meaning)**.** *A label assignment $\kappa(x) = \ell$ does not by itself supply reality-constrained meaning.*

Proof. By Definition 9414.8, reality-constrained meaning requires five fields: source record, classifier, reality-facing constraint, continuation consequence, and gap ledger. The equation $\kappa(x) = \ell$ supplies only the classifier field at the displayed record. It does not state that κ is reality-constrained by Π in the sense of Definition 9414.7; it does not specify the continuations for which the label is reused; and it does not record the provenance or unclosed residue exposed by that reuse. Hence the label assignment alone is insufficient. □

Corollary 9414.10 (Meaning is constrained continuation)**.** *Reality-constrained meaning is not an unsupported label attached to data. It is a classifier whose distinctions remain stable under the reality-facing continuations for which the label is used.*

Proof. The classifier field supplies the label, while the reality-constraint and continuation-consequence fields state why that label can be reused. If the relevant continuation exposes a signature separation, then Definition 9414.6 records a representation gap rather than a meaningful identification. □

Principle 9414.11 (Reality as meaning constraint)**.** *Reality does not enter this interface as a representation, label, or classifier. It enters as the stable source of signatures that can support, refine, or break the classifier when the record is continued through admissible observation, intervention, prediction, or proof use.*

Corollary 9414.12 (Far-end supply is not an object equation)**.** *When the reason a reality-constrained classifier continues to hold exceeds the closed record available to C, the exposed boundary is a T-supply socket. This does not assert an object-level equation $T = \mathrm{Reality}$.*

Proof. The excess is recorded in the gap-ledger field of Definition 9414.8. By the socket discipline of Definition 9462.842, a commitment exceeding closed records and closed-generation rules is exposed as a gap whose far end is the apophatic supply position T. This definition therefore permits the reading of T as the far-end position of reality-facing constraint, while refusing to internalize T as a system object, representation, or substrate axiom. □

Theorem 9414.13 (Formal consistency does not select actuality)**.** *Internal consistency of a representation, classifier, or label assignment does not imply reality-constrained meaning relative to an observation bundle.*

Proof. Internal consistency says that the displayed syntax, rules, or classifier rows do not contradict the system's own formation discipline. Reality-constrained meaning requires the stronger fields of Definition 9414.8: preservation of the reality-facing signature, stable downstream use, and a ledger for provenance and unclosed supply. A classifier can be internally consistent while still producing a representation gap in the sense of Definition 9414.6. Such a gap shows that the classifier is too coarse for the observation bundle. Hence formal possibility does not select actual physical order. □

Corollary 9414.14 (Logic licenses possibility, not physical order)**.** *Formal consistency licenses internal possibility. Physical order is reported only through signature preservation, continuation stability, and ledgered exposure of residue.*

Proof. The first clause is the internal consistency condition of Definition 9414.13. The second clause is exactly the additional reality-facing and ledgered structure required by Definition 9414.8. □

Theorem 9414.15 (The supply loop is not circular proof)**.** *The passage from classifier use to reality-facing response, and then to ledger refinement or exposed T-socket, is not a proof of a classifier by that same classifier.*

Proof. A circular proof would use the same internal assertion as both support and conclusion. The reality-constrained passage has a different shape. If the continuation yields a stable signature, the record ledger is enlarged by evidence of preservation. If the continuation separates the signatures, Definition 9414.6 records a gap rather than a theorem. If the reason for continued preservation exceeds the available closed record, the gap-ledger field exposes the far-end supply position described in Definition 9414.12. In none of these cases is the classifier licensed merely by repeating its own label assignment. □

Concretized in §1213: Reality-constrained signature residues realize the representation-gap row as a finite NameCert packet separating mathematical classifier agreement from physical adequacy.

Concretized in §1303: Reality-constrained signature descents realize operation descent as a finite packet joining mathematical classifier transport, physical-signature exposure, GAP rows, representation certificates, and a descent witness.

Concretized in §1348: External supply signature seals realize the reality-facing signature and no-free-transfer discipline as one finite GAP, descent, ledger, and NameCert packet.

9414.2 Ledgered approximation towers

Definition 9414.16 (GAP-admissible compression)**.** *A compression*

$$C : X \rightsquigarrow Y$$

is GAP*-admissible when it carries a source domain of admissible histories, a signature-generation policy, a package policy assigning visible tokens to signatures, a gap ledger recording which source histories lie behind each visible token, and a stability condition specifying which operations descend through the compression.*

This is the physical reading of BEDC's finite globalization discipline. Package tokens are not quotient classes accepted without provenance. They are visible rows whose source histories remain available through GAP and package policies; see chapter 9389 and chapter 9395.

Definition 9414.17 (Approximation tower)**.** *An approximation tower is a finite or transfinite chain of* GAP*-admissible compressions*

$$O \longrightarrow D_0 \longrightarrow D_1 \longrightarrow \cdots \longrightarrow D_n \longrightarrow M,$$

where O is the ontic signature source, the intermediate D_i are observation histories, finite data, discrete models, continuous models, smooth models, or other certified representation layers, and M is the visible mathematical object used for reasoning.

Each arrow compresses, packages, hides, regularizes, completes, or idealizes source material. The tower is admissible only when each arrow carries a ledger and the composite tower carries the composite ledger.

Definition 9414.18 (Operational descent)**.** *An operation F descends through a classifier $\sim$ when there is a target classifier $\sim'$ such that*

$$x \sim y \quad \Longrightarrow \quad F(x) \sim' F(y).$$

A descent certificate is a proof that the operation respects the source classifier and lands in the target classifier.

Without such a certificate, sameness before applying F does not imply sameness after applying F. The physically important case is differentiation: a classifier that identifies two shapes by coarse geometric approximation does not automatically permit tangent fields, curvature measures, boundary conditions, or dynamics to descend through it.

Definition 9414.19 (Physical representation certificate)**.** *A physical representation certificate for a model M of a system O relative to Π is a five-field certificate*

$$\mathrm{PhysCert}(M, O; \Pi) = (\mathrm{SourceSpec}, \mathrm{PatternSpec}, \mathrm{ClassifierSpec}, \mathrm{StabilityCert}, \mathrm{LedgerPolicy}).$$

The fields record the observation traces and conditions that license the model, the stable pattern claimed by the model, the comparison rule between model-generated and reality-facing signatures, the stability data supporting reuse and prediction, and the record of what was compressed, ignored, idealized, or hidden.

Principle 9414.20 (Reality-signature priority)**.** *Physical equivalence is determined by reality-facing signatures, not by mathematical convenience alone. If*

$$M_1 \sim_{\mathrm{math}} M_2$$

but

$$\mathrm{Sig}_{\Pi_{\mathrm{phys}}}(M_1) \not\sim \mathrm{Sig}_{\Pi_{\mathrm{phys}}}(M_2),$$

then M_1 and M_2 are mathematically similar but physically inequivalent relative to Π_{phys}.

Principle 9414.21 (No free transfer of structure)**.** *If a compression identifies two source histories, no operation on those histories may be transported across the compression unless a stability or descent certificate has been supplied.*

Principle 9414.22 (Compression requires physical memory)**.** *Every physically meaningful idealization must record what it hides. When a model replaces rough, discrete, finite, noisy, or staged source material by a smooth visible object, the lost source structure must remain available in a ledger whenever later physical questions may depend on it.*

9414.3 Physical adequacy theorems

Theorem 9414.23 (Mathematical approximation does not imply physical equivalence)**.** *Let M_1 and M_2 be mathematical representations. Suppose $M_1 \sim_{\mathrm{math}} M_2$ under a mathematical classifier. If*

$$\mathrm{Sig}_{\Pi_{\mathrm{phys}}}(M_1) \not\sim \mathrm{Sig}_{\Pi_{\mathrm{phys}}}(M_2),$$

then M_1 and M_2 are not physically equivalent relative to Π_{phys}.

Proof. By Definition 9414.5, physical equivalence relative to Π_{phys} is sameness of induced physical signatures. The hypothesis gives failure of such signature sameness. Therefore the physical-fit relation does not hold, although the mathematical classifier identifies the two representations. □

Corollary 9414.24 (Physics may refine mathematical equivalence)**.** *A physical classifier may refine, split, or reject a mathematical equivalence class.*

Proof. Let $[M]_{\text{math}}$ be a mathematical equivalence class. If there are $M_1, M_2 \in [M]_{\text{math}}$ whose physical signatures differ, then Definition 9414.23 separates them in the physical-fit relation. Thus the physical classifier partitions the mathematical class into finer classes or rejects some members as inadequate for the intended physical use. □

Corollary 9414.25 (Mathematical convenience is not a physical certificate)**.** *A mathematically convenient representation is physically admissible only when the classifier that licenses its convenience is reality-constrained for the intended signature bundle.*

Proof. Mathematical convenience supplies a reason to choose a representation or classifier. By Definition 9414.23, however, mathematical equivalence under that classifier does not by itself imply preservation of physical signature. Physical admissibility therefore requires the additional reality-constrained condition of Definition 9414.7. □

Theorem 9414.26 (Polygonal convergence does not certify differentiability descent)**.** *Let P_n be regular polygons approximating a circle C, and let $\sim_0$ be a coarse geometric classifier such as agreement in area, perimeter, finite-resolution visibility, or Hausdorff distance. If the polygonal histories and the circle history are packaged into the same visible circle-like token under $\sim_0$, then an operation extracting differentiable boundary structure does not automatically descend through $\sim_0$.*

Proof. The classifier $\sim_0$ records coarse shape agreement. It does not, by itself, record tangent-field or curvature data. Each finite polygon has vertices at which the boundary direction changes discontinuously. The circle has a tangent at every point and constant curvature. Hence polygonal source histories and smooth-circle histories may agree under coarse signatures while separating under differentiability signatures. If differentiable-boundary extraction descended through $\sim_0$, coarse sameness would imply sameness after extraction. The displayed separation contradicts that implication. A separate descent certificate is therefore required. □

Corollary 9414.27 (Circle-like tokens are classifier-relative)**.** *A visible package token produced by polygonal approximation may behave as a circle under coarse shape queries while failing to be a smooth circle under differentiability-sensitive queries.*

Proof. By Definition 9414.26, the coarse classifier may license a shared visible token without licensing differentiability descent. The token is therefore circle-like only relative to the classifier that licensed the package. □

Corollary 9414.28 (Hidden vertices remain physically relevant when queried)**.** *If a physical system is sensitive to tangent discontinuity, curvature concentration, stress concentration, or boundary scattering, then polygonal approximants and a smooth circle may belong to different physical-fit classes.*

Proof. Vertex singularities affect tangent and curvature structure and may affect stress, reflection, or boundary dynamics. If the observation bundle Π includes such responses, then the induced physical signatures of the polygonal approximants and the smooth circle separate. By Definition 9414.5, this separation is exactly failure of physical-fit equivalence. □

Theorem 9414.29 (Composite towers retain source dependence)**.** *Let*

$$X_0 \xrightarrow{C_1} X_1 \xrightarrow{C_2} X_2 \xrightarrow{C_3} \cdots \xrightarrow{C_n} X_n$$

be an approximation tower in which each compression carries a GAP *ledger satisfying coverage. Then the composite compression from X_0 to X_n has a composite ledger recording which original source histories in X_0 lie behind each final visible token in X_n.*

Proof. For two stages, a source $x \in X_0$ lies behind a final token $z \in X_2$ exactly when there exists an intermediate token $y \in X_1$ such that x lies in the C_1 ledger behind y and y lies in the C_2 ledger behind z. This is the composite-gap construction. For more stages, apply the two-stage construction inductively: the composite ledger to X_{n-1} composes with the ledger for C_n, yielding a ledger from X_0 to X_n. □

Corollary 9414.30 (Hidden source structure can become physically active)**.** *A feature hidden at an early level of an approximation tower may become relevant when a later physical query depends on it.*

Proof. By Definition 9414.29, the hidden source structure is retained by a ledger-complete tower. If a later query, such as differentiation, curvature response, stress concentration, or causal propagation, depends on that hidden structure, then the query must inspect the ledger rather than only the final visible token. □

Theorem 9414.31 (Physical admissibility requires signature preservation and descent)**.** *Let M be a mathematical representation of a system O, and let Π_{phys} be the physical signature bundle relevant to the intended modelling context. If M is physically admissible for O relative to Π_{phys}, then the following conditions hold:*

$$\mathrm{Sig}_{\Pi_{\text{phys}}}(M) \sim \mathrm{PhysSig}_{\Pi_{\text{phys}}}(O),$$

and every operation used to extract physical predictions from M descends through the classifier by which M was admitted.

Proof. If signature preservation fails, M does not reproduce the relevant reality-facing properties of O and is not physically admissible. If operational descent fails, then there is an operation F and classifier-same inputs $M_1 \sim M_2$ with $F(M_1) \not\sim' F(M_2)$. Predictions depending on F are then not well defined at the visible package level; they depend on hidden source history rather than on the admitted model token. Both conditions are therefore necessary. □

Corollary 9414.32 (Physical representation is unique only up to physical fit)**.** *There may be many mathematical descriptions of one system, but relative to a complete physical signature bundle they occupy one admissible physical-fit class.*

Proof. If M_1 and M_2 are physically admissible representations of the same O, Definition 9414.31 gives

$$\mathrm{Sig}_{\Pi_{\text{phys}}}(M_1) \sim \mathrm{PhysSig}_{\Pi_{\text{phys}}}(O) \sim \mathrm{Sig}_{\Pi_{\text{phys}}}(M_2).$$

By transitivity of signature sameness, $M_1 \equiv_{\text{phys},\Pi} M_2$. □

Theorem 9414.33 (Refining physical questions refines model fit)**.** *Let* $\Pi \subseteq \Pi'$ *be physical signature bundles, and let* $\equiv_\Pi$ *and* $\equiv_{\Pi'}$ *be the induced physical-fit relations. Then*

$$M_1 \equiv_{\Pi'} M_2 \quad \Longrightarrow \quad M_1 \equiv_\Pi M_2.$$

The converse need not hold.

Proof. Agreement under Π' includes agreement on every question in Π, since every question in Π is also in Π'. Hence agreement under the larger bundle restricts to agreement under the smaller bundle. The converse fails when Π' contains a question omitted by Π. Polygonal approximants and a smooth circle may agree under a coarse shape bundle while separating under a differentiability or curvature bundle. □

Corollary 9414.34 (Approximation is tower-relative)**.** *An approximation statement is indexed by the tower level and signature bundle at which it is asserted.*

Proof. By Definition 9414.33, changing the signature bundle can refine the equivalence relation. Since an approximation tower is a staged sequence of classifiers and compressions, an approximation judgment is meaningful only relative to the layer and bundle that license it. □

Theorem 9414.35 (Physical adequacy requires a representation certificate)**.** *If a model* M *is used as a physically adequate representation of a system* O *relative to* Π*, then* M *must carry a physical representation certificate.*

Proof. Physical adequacy requires an observational source, a pattern extracted from that source, a classifier comparing model-generated and reality-facing signatures, a stability condition licensing continuation beyond observed data, and a ledger recording the compression performed by the model. Without source data the model is disconnected from observation. Without a pattern there is no stated behaviour being modelled. Without a classifier there is no fit judgment. Without stability data finite fit cannot support prediction. Without a ledger hidden source structure cannot be recovered when it becomes physically relevant. These are precisely the fields of Definition 9414.19. □

Corollary 9414.36 (An equation is not yet a physical model)**.** *An equation becomes a physical model only when embedded in a certificate specifying source, pattern, classifier, stability, and ledger.*

Proof. An equation gives a formal relation among mathematical symbols. It does not by itself specify which observations licensed it, which physical signatures it preserves, what classifier compares it with reality, why it may be reused predictively, or what idealizations it hides. By Definition 9414.35, those fields are required for physical adequacy. □

9414.4 Interface–constraint–section packets

Remark 9414.37 (Paper-side status)**.** *This section gives a paper-side interface discipline for reality-constrained inquiry and has no Lean target in this chapter: a source is not consumed as a bare object, an observation interface compresses it to records, constraints decide which records remain jointly admissible, sections supply licensed fiber-level meaning, and the public surface is the ledger that makes these passages auditable. The packet is a derived vision interface over* Hist*,* hsame*,* Cont*,* Sig*,* Pkg*,* Gap*, and* NameCert*; it is not a primitive of the BEDC finite kernel and not an object-level theory of consciousness, probability, or quantum mechanics.*

Definition 9414.38 (Interface–constraint–section packet)**.** *An* interface–constraint–section packet *is a finite records-side packet*

$$\mathcal{I} = (X, \sim_X, \Lambda_X, Y, \sim_Y, O, C, Q, \pi, \sigma, K, \Lambda, A)$$

with the following rows:

1. *X is a displayed source carrier with classifier $\sim_X$ and source ledger Λ_X;*
2. *$O : X \to Y$ is an observation interface into a displayed record carrier with classifier $\sim_Y$;*
3. *C is a constraint row on X, or on a displayed relation over X, whose purpose is to decide which source witnesses are jointly admissible for the active observation bundle;*
4. *Q is a quotient, package, or compressed visible surface reached from X by a displayed projection $\pi : X \to Q$;*
5. *$\sigma : Q \to X$ is an optional section row, admitted only when its authorization, action-response, witness, boundary, and stability ledgers are displayed;*
6. *K is an outcome kernel or weight row attached to an interface, used only as a bridge row when the source discipline supplies such weights;*
7. *Λ is the public ledger recording observation, outcome, constraint, section, gap, and provenance rows;*
8. *A is the audit row refusing bare source access, unledgered compression, quotient equality as meaning, hidden section choice, outcome selection by a subject, and object-level resolution of indistinguishable bridge interpretations.*

Principle 9414.39 (Layer discipline)**.** *The packet separates four layers. The source layer records what may generate observations. The interface layer records what is available to a finite observer. The section layer records fiber-level meaning only when a section is licensed by displayed authorization and witness data. The ledger layer records which parts of the preceding passage are public, transportable, and open to defeat. Collapsing these layers erases the certificate fields required by reality-constrained meaning in Definition 9414.8.*

Definition 9414.40 (Readout layer)**.** *For a displayed source carrier X, a* readout layer *is a packet*

$$\mathcal{L} = (R, \sim_R, P, \Lambda_R, \mathsf{NameCert}_{\mathcal{L}})$$

where R is a displayed record carrier, $\sim_R$ is its classifier, $P : X \to R$ is a readout row, Λ_R records provenance and gap data, and $\mathsf{NameCert}_{\mathcal{L}}$ names the carrier-classifier surface. The discrete case is the special case in which $\sim_R$ is the equality classifier at the displayed resolution.

Definition 9414.41 (Layer fiber family)**.** *For a readout layer $\mathcal{L}$ and a record $r : R$, the fiber over r is*

$$\mathrm{Fib}_{\mathcal{L}}(r) := \{x \in X \mid P(x) \sim_R r\}.$$

The layer-infinite residue of $\mathcal{L}$ is the fiber family

$$\infty_{\mathcal{L}} : R \to \mathsf{Type}, \qquad \infty_{\mathcal{L}}(r) := \mathrm{Fib}_{\mathcal{L}}(r).$$

Thus the residue is not a further point of R; it is the family of source witnesses still hidden behind each displayed record row.

Definition 9414.42 (Total fiber surface)**.** *The total fiber surface of a readout layer is*

$$\mathrm{Tot}(\infty_{\mathcal{L}}) := \sum_{r:R} \mathrm{Fib}_{\mathcal{L}}(r).$$

When $\sim_R$ has a displayed reflexivity row, the readout P induces a source-to-total map

$$\Phi_{\mathcal{L}} : X \to \mathrm{Tot}(\infty_{\mathcal{L}}), \qquad \Phi_{\mathcal{L}}(x) := (P(x), (x, \mathrm{refl}_{P(x)})).$$

There is also the source projection

$$\Psi_{\mathcal{L}} : \mathrm{Tot}(\infty_{\mathcal{L}}) \to X, \qquad \Psi_{\mathcal{L}}(r, x, \epsilon) := x.$$

Theorem 9414.43 (Displayed source readback)**.** *For every readout layer with displayed reflexivity for $\sim_R$,*

$$\Psi_{\mathcal{L}} \circ \Phi_{\mathcal{L}} = \mathrm{id}_X.$$

Consequently the total fiber surface remembers every displayed source row, even when the public record carrier R forgets source distinctions.

Proof. For a source row $x : X$, the map $\Phi_{\mathcal{L}}$ sends x to $(P(x), (x, \mathrm{refl}_{P(x)}))$. Applying $\Psi_{\mathcal{L}}$ forgets the displayed record and the classifier witness, leaving x. This proves the stated identity. □

Definition 9414.44 (Readout refinement)**.** *Let*

$$\mathcal{L} = (R, \sim_R, P, \Lambda_R, \mathsf{NameCert}_{\mathcal{L}})$$

and

$$\mathcal{M} = (S, \sim_S, Q, \Lambda_S, \mathsf{NameCert}_{\mathcal{M}})$$

be readout layers over the same source carrier X. The layer $\mathcal{M}$ refines $\mathcal{L}$ when there is a displayed readback map

$$\rho : S \to R$$

such that every source row satisfies

$$\rho(Q(x)) \sim_R P(x).$$

Theorem 9414.45 (Refinement partitions the previous fiber)**.** *If $\mathcal{M}$ refines $\mathcal{L}$, then every element of $\mathrm{Fib}_{\mathcal{L}}(r)$ determines an element of*

$$\sum_{s:S} (\rho(s) \sim_R r) \times \mathrm{Fib}_{\mathcal{M}}(s).$$

In the discrete case, when both classifiers are equality classifiers and $P = \rho \circ Q$, this construction is an equivalence.

Proof. Given $(x, \epsilon) \in \mathrm{Fib}_{\mathcal{L}}(r)$, put $s := Q(x)$. The refinement row gives $\rho(Q(x)) \sim_R P(x)$, while ϵ gives $P(x) \sim_R r$. Transitivity of the displayed classifier gives $\rho(s) \sim_R r$, and reflexivity gives $(x, \mathrm{refl}_{Q(x)}) \in \mathrm{Fib}_{\mathcal{M}}(s)$. This is the announced map. In the discrete case the reverse map sends $(s, q, (x, h))$ to $(x, P(x) = r)$ using

$$P(x) = \rho(Q(x)) = \rho(s) = r.$$

The two composites are the identity by equality elimination. □

Principle 9414.46 (Layer residue is fiber data)**.** *An interface record closes only the displayed classifier value. The residual content of the layer is the fiber family behind that value, and a finer layer can expose that residue only by displaying the readback map, the classifier transport, and the accompanying ledger rows. This is the formal reason that quotient equality is not yet section-level meaning.*

Definition 9414.47 (Interface fiber and compressed reality)**.** *For a packet $\mathcal{I}$ with interface $O : X \to Y$, the interface fiber of a source row x is*

$$[x]_O := \{x' \in X \mid O(x') \sim_Y O(x)\}.$$

The compressed records-side reality exposed by O is the pair

$$\mathsf{Real}_O(\Lambda) := (O(X), \Lambda_O),$$

where Λ_O is the ledger of displayed observation rows, interface provenance, and gap reports. This is not the bare source X.

Definition 9414.48 (Constraint compatibility)**.** *Let $A : X \to A_0$ and $B : X \to B_0$ be two displayed readout rows and let C be a constraint row. The records a and b are compatible under C, written $a \ \mathsf{compat}_C \ b$, when there is a source witness x such that*

$$\begin{aligned} &C(x), \\ &A(x) \sim a, \\ &B(x) \sim b. \end{aligned}$$

The readout A determines B under C on the active surface when, for each displayed a, the set of compatible B-readouts has at most one classifier value.

Theorem 9414.49 (Constraint projection)**.** *If the current packet records $C(x)$ and $A(x) \sim a$, then every admissible B-readout lies in*

$$B\big(\{u \in X \mid C(u) \text{ and } A(u) \sim a\}\big).$$

If this displayed image has one classifier value b, then $A = a$ determines $B = b$ under C on the active surface.

Proof. The premise $C(x)$ restricts admissible source witnesses to the constraint row. The premise $A(x) \sim a$ further restricts them to the fiber of the active A-readout. Reading B from the remaining witnesses gives exactly the displayed image. If that image has one classifier value, every compatible source witness has the same B-readout, so the determination claim follows. □

Definition 9414.50 (Self-similar readout diagram)**.** *A self-similar readout diagram over an interface–constraint packet is a displayed index family I whose ith row is a packet*

$$\mathcal{S}_i = (R_i, \sim_i, P_i, C_i, \alpha_i, \Lambda_i, \mathsf{Cert}_i, A_i).$$

Here R_i is the visible record carrier, $\sim_i$ is its classifier, $P_i : X \to R_i$ is its source readout, C_i is its admissibility row, $\alpha_i : R_i \to R_i$ is its self-similar continuation operation, Λ_i is the provenance and gap ledger, Cert_i is the name, stability, transport, and replay certificate surface, and A_i is the audit row. For each displayed edge $j \to i$ the diagram contains a projection row

$$\rho_{ji} : R_j \to R_i$$

such that source readout and continuation are compatible:

$$\rho_{ji}(P_j(x)) \sim_i P_i(x),$$
$$\rho_{ji}(\alpha_j(r)) \sim_i \alpha_i(\rho_{ji}(r)).$$

The family I is part of the displayed packet; it is not an untyped quantification over all possible self-similar systems.

Definition 9414.51 (Compatibility-limit carrier)**.** *For a self-similar readout diagram $\mathcal{D}$, the compatibility-limit carrier is*

$$T_{\mathcal{D}} := \left\{ (r_i)_{i\in I} \in \prod_{i\in I} R_i : \begin{array}{c} C_i(r_i) \text{ for every displayed } i, \\ \rho_{ji}(r_j) \sim_i r_i \text{ for every displayed edge } j \to i \end{array} \right\}.$$

Its public packet includes the coordinate projections $\pi_i : T_{\mathcal{D}} \to R_i$, the induced ledger $\Lambda_{\mathcal{D}}$, and the audit row $A_{\mathcal{D}}$ recording all readout, projection, classifier, constraint, certificate, and gap compatibilities. Thus $T_{\mathcal{D}}$ is a ledgered packet carrier, not a bare product set.

Definition 9414.52 (Compatibility-limit operation)**.** *Assume the displayed self-similar operations preserve the compatibility-limit carrier: whenever $(r_i)_{i\in I} \in T_{\mathcal{D}}$, the family $(\alpha_i(r_i))_{i\in I}$ again lies in $T_{\mathcal{D}}$. The compatibility-limit operation is the packet operation*

$$\Omega_{\mathcal{D}} : T_{\mathcal{D}} \to T_{\mathcal{D}}, \qquad \Omega_{\mathcal{D}}((r_i)_i) := (\alpha_i(r_i))_i.$$

It is the common operation only at the level of the full packet carrying readout, classifier, constraint, ledger, certificate, and audit rows.

Theorem 9414.53 (Self-similar operations are coordinate projections)**.** *For every displayed $i \in I$,*

$$\pi_i \circ \Omega_{\mathcal{D}} \sim_i \alpha_i \circ \pi_i.$$

Proof. Let $r = (r_j)_{j\in I} \in T_{\mathcal{D}}$. By definition of $\Omega_{\mathcal{D}}$,

$$\Omega_{\mathcal{D}}(r) = (\alpha_j(r_j))_{j\in I}.$$

Applying the ith coordinate projection gives

$$\pi_i(\Omega_{\mathcal{D}}(r)) = \alpha_i(r_i).$$

Since $\pi_i(r) = r_i$, the right-hand side is also

$$(\alpha_i \circ \pi_i)(r).$$

The two readouts therefore agree at classifier resolution $\sim_i$. □

Corollary 9414.54 (Binary observation as projected operation)**.** *Suppose the diagram contains a binary observation row $R_B = \{B_0, B_1\}$ with projection $\pi_B : T_{\mathcal{D}} \to R_B$. If $b_0 \in T_{\mathcal{D}}$ satisfies $\pi_B(b_0) = B_0$ and*

$$\pi_B(\Omega_{\mathcal{D}}(b_0)) = B_1,$$

then B_1 is the binary-layer readout of the full packet operation at b_0. The informal notation $B_1 = \Omega_{\mathcal{D}}(B_0)$ abbreviates this projected statement; the typed packet statement applies $\Omega_{\mathcal{D}}$ to b_0 and reads the result through π_B.

Proof. The operation $\Omega_{\mathcal{D}}$ has domain $T_{\mathcal{D}}$, while B_0 and B_1 are records in the binary observation carrier. Therefore the operation cannot be applied to B_0 as a bare record. The displayed source point is b_0, and the binary observation after one packet operation is exactly $\pi_B(\Omega_{\mathcal{D}}(b_0))$. The assumed equality identifies that readout with B_1. □

Principle 9414.55 (Packet-level reading of common self-similarity)**.** *Prime-coordinate generation, Zeckendorf carry normalization, window constraint continuation, analytic readout, and recovered-zeta carrier formation may be compared as projections of one compatibility-limit operation only after their carrier, classifier, projection, constraint, ledger, certificate, and audit rows are all displayed. Without those rows, the comparison is merely an analogy between operations and not a reality-constrained packet claim.*

Definition 9414.56 (Constraint geometry surface)**.** *Let*

$$\mathcal{L} = (R, \sim_R, P, \Lambda_R, \mathsf{NameCert}_{\mathcal{L}})$$

be a readout layer over X, and let $C : R \to \mathsf{Prop}$ be a displayed constraint row on the record carrier. The visible constraint geometry is

$$|\mathcal{L}, C|_{\mathrm{vis}} := \sum_{r:R} C(r).$$

The source constraint geometry is

$$|\mathcal{L}, C|_{\mathrm{src}} := \sum_{x:X} C(P(x)).$$

The first surface records which visible rows satisfy the constraint. The second surface records which source witnesses are accepted by the constraint after readout. The two surfaces are not interchangeable unless the fiber and classifier ledgers identify the relevant source witnesses at the displayed resolution.

Theorem 9414.57 (Constraints generate auditable geometry)**.** *For a readout layer $\mathcal{L}$ and displayed constraint row C, every element of $|\mathcal{L}, C|_{\mathrm{src}}$ carries both a source witness and a constraint witness. Consequently the geometry generated by C is auditable precisely through the readout, classifier, fiber, and ledger rows of $\mathcal{L}$.*

Proof. An element of $|\mathcal{L}, C|_{\mathrm{src}}$ is a pair (x, γ) with $x : X$ and $\gamma : C(P(x))$. The first component is the source witness. The second component records that the visible readout of that source row lies on the constraint surface. The readout row P, the classifier $\sim_R$, the fiber family of Definition 9414.41, and the ledger Λ_R therefore determine the public audit route for the displayed geometric claim. □

Principle 9414.58 (Geometry as constraint–fiber–section structure)**.** *Within this packet, geometry is not a primitive point-set carrier. A point is a source witness accepted by a displayed constraint; a curve or surface is a stable family of such witnesses under one or more readout rows; a boundary is a classifier or constraint-change row; and an unresolved infinitary direction is the fiber family left behind a visible record. Section-level geometric meaning is licensed only when the corresponding section binding certificate is displayed.*

Remark 9414.59 (Recovered-carrier geometry)**.** *The same reading applies to recovered analytic carriers. A zero ledger, a fixed-half row, a prime-channel unit row, or a Laplace-bias refusal is geometric only after it is displayed as a constraint on a named readout carrier together with its provenance, fiber, transport, and gap rows. The geometric image does not discharge the analytic incompatibility required to exclude a non-fixed zero; it only states the audited surface on which that obligation lives.*

Definition 9414.60 (Invariant observation descent)**.** *Suppose a displayed action of a symmetry carrier G on X is available. An observation interface $O : X \to Y$ is invariant under the action when*

$$O(g \cdot x) \sim_Y O(x)$$

for every displayed action row $g \cdot x$. The orbit projection is written

$$\pi : X \to Q.$$

Theorem 9414.61 (Invariant observation descends to the compressed surface)**.** *If O is invariant under the displayed G-action, then the observation read factors through the compressed surface: there is a unique displayed readout $\bar{O} : Q \to Y$ with*

$$O = \bar{O} \circ \pi.$$

Proof. Define $\bar{O}(\pi(x)) := O(x)$. If $\pi(x) = \pi(y)$, then y is related to x by a displayed action row. Invariance gives $O(y) \sim_Y O(x)$, so the definition is independent of the representative at the displayed classifier resolution. Since every row of Q is represented by some x, the readout is unique at that resolution. □

Definition 9414.62 (Anti-invariant label)**.** *Let $L : X \to \{0, 1\}$ be a label row and let τ be a displayed involution in the symmetry carrier. The label is anti-invariant along τ when*

$$L(\tau \cdot x) = 1 - L(x)$$

for every displayed source row x.

Theorem 9414.63 (Anti-invariant labels do not descend)**.** *If L is anti-invariant along a displayed involution τ, then there is no quotient-level label $\bar{L} : Q \to \{0, 1\}$ satisfying*

$$L = \bar{L} \circ \pi$$

on the displayed action surface.

Proof. Assume such a $\bar{L}$ exists. Since τ is an action row, $\pi(\tau \cdot x) = \pi(x)$. Hence

$$L(\tau \cdot x) = \bar{L}(\pi(\tau \cdot x)) = \bar{L}(\pi(x)) = L(x).$$

Anti-invariance gives $L(\tau \cdot x) = 1 - L(x)$. The two equations contradict the binary label classifier. Therefore no such quotient-level label exists. □

Definition 9414.64 (Section binding certificate)**.** *A* section binding certificate *for $\pi : X \to Q$ and $\sigma : Q \to X$ is a finite certificate row*

$$\mathsf{SectionBindingCert}(Q, X, \pi, \sigma)$$

with source, authorization, action-response, witness, boundary, stability, and forbidden-claim ledgers, and with

$$\pi \circ \sigma = \mathrm{id}_Q.$$

It records that σ is not canonical output of the compressed surface Q alone; it is supplied by licensed action, authorization, binding, or certificate data.

Definition 9414.65 (Section-relative meaning)**.** *Given a label row $L : X \to \{0,1\}$ and a section binding certificate for σ, the section-relative meaning readout is*

$$L_\sigma : Q \to \{0,1\}, \qquad L_\sigma(q) := L(\sigma(q)).$$

Theorem 9414.66 (Sections license fiber-level meaning)**.** *If $\mathsf{SectionBindingCert}(Q, X, \pi, \sigma)$ is displayed and L is a licensed label row on X, then $L_\sigma = L \circ \sigma$ is a licensed readout on Q.*

Proof. The certificate makes σ an admitted map from the compressed surface back to a source representative. The label certificate makes L an admitted map on the source side. Their composite is therefore an admitted readout, and its source, authorization, witness, boundary, stability, and gap ledgers are obtained by composing the two certificate rows. □

Definition 9414.67 (Matched-twin observation protocol)**.** *A matched-twin observation protocol consists of displayed pairs (x_j^0, x_j^1) such that*

$$\begin{aligned} x_j^1 &= \tau \cdot x_j^0, \\ O(x_j^0) &\sim_Y O(x_j^1), \\ L(x_j^1) &= 1 - L(x_j^0). \end{aligned}$$

A decision rule is quotient-measurable when it factors through the compressed observation surface and therefore reads the same value on $O(x_j^0)$ and $O(x_j^1)$.

Theorem 9414.68 (Matched-twin null)**.** *In a balanced matched-twin observation protocol, every quotient-measurable binary decision rule has accuracy $1/2$.*

Proof. For each displayed pair, quotient-measurability gives the same decision on x_j^0 and x_j^1, because their observation rows have the same compressed value. The labels are opposite. Hence the decision is correct on exactly one member of the pair. Balanced exposure of the two members therefore gives pairwise accuracy $1/2$, and averaging over displayed pairs preserves that value. □

Corollary 9414.69 (Above-null performance requires an exposed extra row)**.** *If a classifier exceeds the matched-twin null boundary, then the packet must expose at least one of the following: leakage outside the compressed surface, licensed section access, or a failure of the announced protocol.*

Proof. Definition 9414.68 proves the null boundary for all quotient-measurable decision rules. Exceeding the boundary therefore means that the decision rule is not purely quotient-measurable on the announced protocol, or that the protocol itself did not satisfy the matched-twin rows. □

Definition 9414.70 (Probe selection and outcome row)**.** *For a focused history h_t, a probe policy assigns an admissible interface family to each action row:*

$$\Pi(h_t, a_t) = I_{t+1}.$$

The outcome is then generated by an outcome kernel or weight row

$$K_{I_{t+1}}(x, dr),$$

and the focused record advances by

$$h_{t+1} = \mathsf{Cont}(h_t, r_t).$$

Theorem 9414.71 (Action selects an interface, not an outcome)**.** *If an action row enters only through $\Pi(h_t, a_t) = I_{t+1}$ and outcomes are generated by $K_{I_{t+1}}(x, dr)$, then the action selects the next probe interface and does not by itself determine the outcome unless the kernel is degenerate on the displayed source row.*

Proof. The action variable appears in the policy row selecting I_{t+1}. The outcome variable appears in the kernel row attached to the selected interface and source witness. Unless that kernel has a single displayed outcome, the selected interface leaves multiple admissible outcome rows. Therefore the action does not directly specify the resulting record. □

Principle 9414.72 (Bridge boundary for probability and collapse language)**.** *Probability rows in this packet are normalized interface weights, not bare randomness and not conserved physical charge. A quantum-facing bridge may read a Hilbert-state projection family as an outcome-weight interface, but the BEDC core row remains the ledger update*

$$h_{t+1} = \mathsf{Cont}(h_t, r_t).$$

Any stronger claim about physical collapse, preferred basis selection, or consciousness as an outcome chooser is a bridge or gap claim, not an object-layer theorem of the packet.

Theorem 9414.73 (Layered reality decomposition)**.** *If $O : X \to Y$ is not injective at the displayed classifier resolution, then the source layer and interface layer are not equivalent as public records. If an anti-invariant label does not descend to Q, then the compressed layer does not determine section-relative meaning. If no ledger is displayed, then section-relative meaning is not a public auditable reality-constrained claim.*

Proof. Non-injectivity gives source rows x, x' with different source classifiers but the same interface readout; the interface record therefore erases a source distinction. Anti-invariant no-descent is Definition 9414.63; it says that the compressed surface cannot determine the label. Finally, without a ledger, the source, authorization, stability, and boundary data for a section readout are not auditable, so the readout cannot become a public reality-constrained claim in the sense of Definition 9414.8. □

Theorem 9414.74 (Interface–constraint–section synthesis)**.** *For an interface–constraint–section packet, invariant observations descend to compressed surfaces, anti-invariant labels do not descend, licensed sections recover fiber-level meaning, constraint rows restrict admissible readouts, focused time is append-only* Cont *growth, and actions select probe interfaces rather than outcomes.*

Proof. Invariant descent is Definition 9414.61. No-descent for anti-invariant labels is Definition 9414.63. Section-relative meaning is licensed by Definition 9414.66. Constraint restriction is Definition 9414.49. Focused time is the update row $h_{t+1} = \mathsf{Cont}(h_t, r_t)$ in Definition 9414.70. The interface role of action is Definition 9414.71. These clauses exhaust the packet-level synthesis and add no kernel primitive. □

Remark 9414.75 (Forbidden readings)**.** *The packet forbids six readings: source reality is not identical with the compressed interface surface; quotient-level observation is not already meaning; a section is not hidden choice without a certificate; a subject does not choose outcomes by fiat; normalized interface weight is not the same physical quantity as conserved charge; and indistinguishable metaphysical bridge explanations cannot be promoted to object-layer theorems.*

Concretized in §7582: Reality-constrained selector boundaries realize the interface–constraint–section refusal that selector rows must expose source records, classifier fit, physical constraint, failure surface, and gap ledger before a section read is public.

9414.5 Self-similar operations and exponential readouts

The compatibility-limit operation of Definition 9414.52 is a packet operation. It acts on the full carrier $T_{\mathcal{D}}$, whose rows include readouts, classifiers, constraints, ledgers, certificates, and audit surfaces. A scalar constant belongs to a later analytic readout layer. The two objects therefore have different types even when the scalar is a faithful shadow of the operation under a chosen projection.

Definition 9414.76 (Operation–readout type boundary)**.** *Let $\mathcal{D}$ be a self-similar readout diagram and let*

$$\Omega_{\mathcal{D}} : T_{\mathcal{D}} \to T_{\mathcal{D}}$$

be its compatibility-limit operation. A scalar analytic readout is a displayed map

$$\chi : T_{\mathcal{D}} \to A$$

into a scalar carrier A, together with the classifier, normalization, analytic structure, and ledger rows that make χ public. A scalar $c \in A$ has the type of a readout value, while $\Omega_{\mathcal{D}}$ has the type of a packet operation. Thus the expression

$$\Omega_{\mathcal{D}} = c$$

has no packet-level meaning. The meaningful claims are typed readout claims such as

$$\chi(\Omega_{\mathcal{D}}(b)) = c$$

or flow readout claims such as

$$\chi(\Omega_t(b)) = c(t).$$

Theorem 9414.77 (Constants are not packet operations)**.** *For any scalar readout $\chi : T_{\mathcal{D}} \to A$, no scalar constant $c \in A$ is identical with the packet operation $\Omega_{\mathcal{D}} : T_{\mathcal{D}} \to T_{\mathcal{D}}$. In particular, the analytic constant e can only occur as a scalar readout value or as the value of a scalar readout function; it is not the operation $\Omega_{\mathcal{D}}$.*

Proof. The operation $\Omega_{\mathcal{D}}$ has domain and codomain $T_{\mathcal{D}}$. A scalar constant c is an element of A. Unless a separate coding row embeds operations into scalar values and back with displayed inverse data, these types are distinct. The interface packet does not contain such a coding row. It contains only readout maps from the packet carrier to visible carriers. Therefore a scalar can be compared only with a scalar readout of the operation, not with the operation itself. □

Definition 9414.78 (Continuous packet flow)**.** *A continuous packet flow over $\mathcal{D}$ is a displayed family of packet operations*

$$(\Omega_t)_{t\in\mathbb{R}}, \qquad \Omega_t : T_{\mathcal{D}} \to T_{\mathcal{D}},$$

with ledgered rows

$$\Omega_0 = \mathrm{id}_{T_{\mathcal{D}}}, \qquad \Omega_{t+u} = \Omega_t \circ \Omega_u.$$

The flow is a packet object only when the same classifier, constraint, ledger, certificate, and audit rows remain visible along the parameter.

Definition 9414.79 (Normalized self-change readout)**.** *Let $(\Omega_t)_{t\in\mathbb{R}}$ be a continuous packet flow and let $\chi : T_{\mathcal{D}} \to \mathbb{R}$ be a scalar analytic readout. For $b \in T_{\mathcal{D}}$, write*

$$y_b(t) := \chi(\Omega_t(b)).$$

The readout is normalized self-changing along b when its analytic ledger contains

$$y_b(0) = 1, \qquad \frac{d}{dt} y_b(t) = y_b(t).$$

Theorem 9414.80 (Exponential readout shadow)**.** *If y_b is a normalized self-change readout, then*

$$y_b(t) = \exp(t).$$

Consequently,

$$y_b(1) = e.$$

Thus e is the unit-time value of this scalar readout, not the compatibility-limit operation itself.

Proof. Define

$$z(t) := \exp(-t)y_b(t).$$

The displayed derivative row gives

$$\begin{aligned} z'(t) &= -\exp(-t)y_b(t) + \exp(-t)y_b'(t) \\ &= \exp(-t)(y_b'(t) - y_b(t)) \\ &= 0. \end{aligned}$$

Hence z is constant in the analytic readout layer. Since

$$z(0) = \exp(0)y_b(0) = 1,$$

we have $z(t) = 1$ and therefore $y_b(t) = \exp(t)$. At $t = 1$ this gives $y_b(1) = e$. □

Definition 9414.81 (Discrete scale readout)**.** *A discrete scale readout of the packet operation is a scalar sequence*

$$x_n := \chi(\Omega_{\mathcal{D}}^n(b))$$

whose displayed ledger contains

$$x_{n+1} = \lambda x_n.$$

The scalar λ is a readout scale for that coordinate, not a replacement for $\Omega_{\mathcal{D}}$.

Proposition 9414.82 (Analytic interpolation of a scale readout)**.** *If $x_{n+1} = \lambda x_n$ and the analytic readout layer supplies a chosen branch of $\log \lambda$, then the scalar function*

$$x(t) := \exp(t \log \lambda)x_0$$

interpolates the displayed discrete readout at integer times:

$$x(n) = x_n.$$

Proof. The recurrence gives $x_n = \lambda^n x_0$. For each integer n, the chosen logarithm branch supplies

$$\exp(n \log \lambda) = \lambda^n.$$

Therefore

$$x(n) = \exp(n \log \lambda)x_0 = \lambda^n x_0 = x_n.$$

□

Principle 9414.83 (Constants classify readout modes)**.** *The constants attached to self-similar phenomena classify readout modes. The normalized continuous self-change readout gives e. A Fibonacci second-order recursive readout gives the golden scale φ as in Definition 9347.14. A prime Euler-product readout gives the local channel p^{-s} as in Definition 9252.3. These constants are coordinate shadows of packet-level generation; none is the packet operation itself.*

Definition 9414.84 (Prime exponential kernel readout)**.** *Let a prime-occupancy row be a finite-support function*

$$k : \mathsf{Prime}^{\uparrow} \to \mathbb{N},$$

with associated integer packet

$$n(k) = \prod_{p \in \mathsf{Prime}^{\uparrow}} p^{k_p}.$$

The logarithmic energy readout is

$$E(k) := \log n(k) = \sum_{p} k_p \log p.$$

For a complex parameter s, the exponential kernel readout is

$$W_s(k) := \exp(-sE(k)).$$

Proposition 9414.85 (Exponential kernel gives Dirichlet weight)**.** *For every displayed prime-occupancy row k,*

$$W_s(k) = n(k)^{-s}.$$

Proof. By definition, $E(k) = \log n(k)$. Therefore

$$W_s(k) = \exp(-s \log n(k)) = n(k)^{-s}.$$

□

Principle 9414.86 (Zeta readout boundary)**.** *The zeta-facing expression $n^{-s} = \exp(-s \log n)$ is the analytic readout by which prime multiplicative occupancy enters the Dirichlet and Euler-product surfaces. It does not identify ζ, e, or any Euler factor with $\Omega_{\mathcal{D}}$. It says that when the zeta carrier is a coordinate of the self-similar diagram, the zeta coordinate reads the packet through an exponential kernel, Euler gluing, continuation, functional-equation, pole, zero-ledger, and transport surface.*

Definition 9414.87 (Holographic readout analogy)**.** *A holographic readout analogy for a self-similar diagram $\mathcal{D}$ is a records-side dictionary between a boundary packet*

$$\partial \mathbb{G}_{\mathcal{D}}$$

and a bulk packet

$$\mathbb{G}_{\mathcal{D}}.$$

The boundary packet consists of finite visible readouts such as finite windows, prime windows, prime fingerprints, and channel codes. The bulk packet is the compatibility-limit carrier $T_{\mathcal{D}}$ together with the operation $\Omega_{\mathcal{D}}$, its projection rows, constraint rows, residual fibers, continuation rows, ledgers, certificates, and audit surface. The analogy is only this records-side dictionary. It is not a claim that the packet is a physical anti-de Sitter spacetime, a conformal field theory, a gravitational theory, or a string-theoretic duality.

Principle 9414.88 (Boundary–bulk dictionary)**.** *The holographic readout analogy is governed by the following dictionary: finite boundary windows correspond to coordinate projections of $T_{\mathcal{D}}$; extension depth corresponds to the ledgered passage from finite readout to compatibility-limit carrier; window defects correspond to obstruction rows in the bulk packet; unit-amplitude boundary channels correspond to fixed-surface constraints in the bulk packet; and non-unit radial factors in exponential channels correspond to off-fixed displacement rows. Each correspondence is a typed readout or ledger relation, not an equality of physical theories.*

Definition 9414.89 (Zeta radial and phase coordinates)**.** *In the zeta information-channel coordinate*

$$s = \frac{1}{2} + \delta + i\tau,$$

the centered prime channel of Definition 9252.3 is

$$U_p(\delta, \tau) = p^{-\delta} e^{-i\tau \log p}.$$

The factor $e^{-i\tau \log p}$ is the phase-clock readout, while $p^{-\delta} = e^{-\delta \log p}$ is the radial exponential readout. The fixed surface is the row $\delta = 0$, equivalently the unit-amplitude row

$$|U_p(\delta, \tau)| = 1$$

for every displayed prime channel.

Proposition 9414.90 (Off-fixed packets carry radial exponent)**.** *If a zeta information-channel packet has $\delta \neq 0$, then every displayed prime row $p > 1$ carries the non-unit radial factor*

$$e^{-\delta \log p}.$$

If $\delta = 0$, the same channel is purely phase:

$$U_p(0, \tau) = e^{-i\tau \log p}.$$

Proof. By Definition 9414.89,

$$U_p(\delta, \tau) = e^{-\delta \log p} e^{-i\tau \log p}.$$

When $\delta = 0$, the first factor is $\exp(0) = 1$, so the channel is the phase factor $e^{-i\tau \log p}$. When $\delta \neq 0$ and $p > 1$, the exponent $-\delta \log p$ is nonzero, so the displayed channel contains a non-unit radial exponential factor. □

Definition 9414.91 (Zero-ledger exponential rigidity target)**.** *The zero-ledger exponential rigidity target is the statement that a zeta zero-ledger packet in the information band admits only pure phase prime channels:*

$$\mathsf{Cancel}_{\mathcal{P}}(\delta, \tau) \wedge \mathsf{InfoBand}(\delta) \Longrightarrow \forall p \in \mathsf{Prime}^{\uparrow},\ |U_p(\delta, \tau)| = 1.$$

Equivalently, in the boundary–bulk dictionary, a zero-ledger boundary row cannot extend to a bulk packet with a nonzero radial exponent.

Theorem 9414.92 (Exponential rigidity is the fixed-half obligation)**.** *The zero-ledger exponential rigidity target is equivalent to the fixed-half form of the RH information-channel target in Definition 9252.14.*

Proof. The rigidity target is exactly the third displayed form in Definition 9252.14. That theorem proves it equivalent to

$$\mathsf{Cancel}_{\mathcal{P}}(\delta, \tau) \wedge \mathsf{InfoBand}(\delta) \Longrightarrow \delta = 0,$$

which is the fixed-half form after substituting $s = 1/2 + \delta + i\tau$. □

Principle 9414.93 (Holographic proof boundary)**.** *The boundary–bulk analogy identifies the shape of the remaining obligation but does not discharge it. To prove the zeta fixed-half target, one must derive zero-ledger exponential rigidity from the displayed Dirichlet row, Euler row, analytic-continuation row, Archimedean completion row, functional-equation row, zero ledger, and transport ledger. Stating that an off-fixed packet has a radial factor is only the readout diagnosis; the missing theorem is the incompatibility between that radial factor and the completed zero-ledger packet.*

Principle 9414.94 (Full-constraint self-similar closure)**.** *For a self-similar diagram $\mathcal{D}$, the operation $\Omega_{\mathcal{D}}$ generates only objects with a position inside the compatibility-limit carrier and its displayed projections. A legal object therefore has no tower-external position: it must be read as a coordinate, fiber, section, ledger row, certificate row, or audit row of some $x \in T_{\mathcal{D}}$. This closure principle is a discipline on admissibility. It does not say that every coordinate is fixed by every involution or that every zeta zero row satisfies the fixed-half condition.*

Definition 9414.95 (Tower-internal position)**.** *Let y be a visible record in a carrier R_i of the diagram. The record y has a tower-internal position when there exists $x \in T_{\mathcal{D}}$ such that*

$$y \sim_i \pi_i(x).$$

When the public use of y depends on more than the visible record, its tower-internal position also includes the source, projection, constraint, ledger, certificate, and audit rows through which this comparison is made.

Theorem 9414.96 (Legal records have tower-internal position)**.** *If a record is legal only by being generated, read out, constrained, and ledgered by the self-similar diagram $\mathcal{D}$, then it has a tower-internal position.*

Proof. By the stated legality condition, the record occurs in some displayed carrier R_i together with the source, constraint, projection, certificate, ledger, and audit rows that make it public. Those rows are part of a compatible packet $x \in T_{\mathcal{D}}$. The visible record is therefore classified by the ith projection $\pi_i(x)$, which is exactly the tower-internal position condition. □

Corollary 9414.97 (A legal RH counterexample would be tower-internal)**.** *If a counterexample to the fixed-half zeta target were a legal BEDC object, it would be a zeta or zero-ledger projection of some $x \in T_{\mathcal{D}}$. It could not be a tower-external object.*

Proof. Apply Definition 9414.96 to the zeta zero-ledger carrier and its critical-strip readout rows. □

Proposition 9414.98 (Closure does not imply fixedness)**.** *A closed self-similar carrier may contain non-fixed points.*

Proof. Let $X = \{a, b\}$ and let $\Omega : X \to X$ exchange the two elements:

$$\Omega(a) = b, \qquad \Omega(b) = a.$$

The carrier X is closed under Ω, and every element lies in an Ω-orbit. If $J = \Omega$, then

$$J(a) = b \neq a.$$

Thus closure under a self-similar operation does not imply membership in the equalizer of id and J. □

Definition 9414.99 (Off-fixed zero exclusion target)**.** *In zeta information-channel coordinates $s = 1/2 + \delta + i\tau$, the off-fixed zero exclusion target is*

$$\mathsf{Cancel}_{\mathcal{P}}(\delta, \tau) \wedge \mathsf{InfoBand}(\delta) \wedge \mathsf{ApartNonFix}(\delta) \Longrightarrow \bot.$$

Its constructive strengthening is the local-global exclusion row

$$\mathsf{InfoBand}(\delta) \wedge \mathsf{ApartNonFix}(\delta) \Longrightarrow \mathsf{Apart}_0(\zeta(1/2 + \delta + i\tau)).$$

This target says that an off-fixed packet may be a tower-internal candidate, but it cannot be inhabited as a zero-ledger packet.

Theorem 9414.100 (Off-fixed exclusion gives fixed-half zero ledger)**.** *If the off-fixed zero exclusion target holds and the real-part readout is located, then every legal zero-ledger packet in the information band lies on the fixed-half surface.*

Proof. Let a legal zero-ledger packet have information coordinates (δ, τ) and assume $\mathsf{InfoBand}(\delta)$. To prove the fixed-half conclusion it suffices, by locatedness of the real-part readout, to rule out every positive apartness witness for δ. Assume such a witness, namely $\mathsf{ApartNonFix}(\delta)$. Together with the zero-ledger row $\mathsf{Cancel}_{\mathcal{P}}(\delta, \tau)$ and the information-band row, the off-fixed zero exclusion target gives a contradiction. Hence no positive off-fixed displacement remains, so $\delta = 0$ and the packet is on the fixed-half surface. □

Principle 9414.101 (Closure-plus-exclusion form of the RH route)**.** *The self-similar closure route has two logically separate parts. First, full-constraint closure places every legal object, including any proposed RH counterexample, inside the tower. Second, off-fixed zero exclusion rules out the tower-internal packets whose zeta readout is both zero-ledger and off-fixed. The first part supplies admissibility and location; the second part is the substantive analytic obstruction. The remaining proof obligation is therefore the incompatibility between off-fixed displacement and the completed zero-ledger carrier, not the absence of tower-external objects.*

Definition 9414.102 (Internal closure witness)**.** *For a claim A whose public use depends on a self-similar diagram $\mathcal{D}$, an internal closure witness is a packet*

$$\mathsf{Wit}_{\mathcal{D}}(A)$$

consisting of a tower point $x \in T_{\mathcal{D}}$, a displayed projection $\pi_i(x)$, a carrier certificate, a readback certificate, an invariant transport certificate, and an audit row showing how these data inhabit the claim surface for A. Such a witness is internal because its evidence is read through the tower; it is still a witness because the claim is not licensed by tower membership alone.

Theorem 9414.103 (Closure does not cancel witnesses)**.** *Full-constraint closure does not turn every legal claim into an automatic theorem. It only locates the objects that a legal claim may mention. A claim still requires a witness packet for its carrier, readback, invariant, exclusion, or audit obligations.*

Proof. By Definition 9414.96, a legal record has a tower-internal position. This supplies a source and projection surface, but it does not by itself prove any predicate over that surface. To prove a predicate one must also display the relevant classifier preservation, readback, invariant transport, exclusion, or audit row. These rows are exactly the components listed in Definition 9414.102. Therefore closure relocates the witness into the tower but does not remove the witness obligation. □

Definition 9414.104 (Object-layer closure and truth-total reflection)**.** *Object-layer closure is the claim that legal objects are generated, projected, and ledgered inside $T_{\mathcal{D}}$. Truth-total reflection would be a stronger claim: an internal truth classifier for all statements represented by the diagram. Formally, it would require a predicate assigning truth to every represented sentence together with an audit certificate that this assignment is correct for the whole represented fragment.*

Principle 9414.105 (Object-layer closure is not truth closure)**.** *The self-similar closure used in the RH route is object-layer closure. It is not truth-total reflection. It may say where legal zeta packets, zero ledgers, defects, and exclusion certificates live; it may not supply a universal internal truth predicate for all claims about those packets. This is the same stratification recorded*

in chapter 9461: the primitive loop may close, while truth-total reflection remains outside the internal object layer.

Corollary 9414.106 (Witness form of the closure route)**.** *The RH route through $\Omega_{\mathcal{D}}$ has the form*

tower location+zero-ledger soundness+off-fixed defect production+defect-zero incompatibility+located real readbac

The first term prevents tower-external escape. The remaining terms are internal witness obligations. In particular, the substantive certificate is still the exclusion of tower-internal off-fixed zero packets.

Proof. Tower location is supplied by Definition 9414.97. Off-fixed exclusion gives fixed-half zero ledger by Definition 9414.100. The definition of the off-fixed zero exclusion target names the needed defect-zero incompatibility form. Located real readback converts absence of positive off-fixed displacement into $\delta = 0$. These are separate witness rows, not consequences of closure alone. □

9414.6 Zero-ledger rigidity route

The closure route of Definition 9414.101 separates location from exclusion. Full-constraint closure places a legal zeta packet inside the self-similar tower. The fixed-half conclusion still requires a certificate that the tower-internal zero ledger cannot coexist with an off-fixed radial defect.

Principle 9414.107 (Finite induction and global coinduction)**.** *Finite readout layers may be closed by ordinary induction over displayed depths, windows, or recursive constructors. The full self-similar tower is not used as an ordinary well-founded chain with an absolute bottom. It is a closed compatibility carrier whose projections and residual fibers can restart the same tower structure. Global statements about the tower are therefore invariant statements: one proves that the relevant row is preserved by the boundary readouts, fiber readbacks, compatibility maps, and the self-similar operation. In the zeta direction, the invariant of interest is fixed-half zero-ledger rigidity.*

Definition 9414.108 (Self-similar zeta coordinate row)**.** *Let $\mathcal{D}$ be a self-similar diagram with zeta projection*

$$\pi_\zeta : T_{\mathcal{D}} \to R_\zeta.$$

A self-similar zeta coordinate row assigns to each tower point $x \in T_{\mathcal{D}}$ an information-channel readout

$$s_x = \pi_\zeta(x) = \frac{1}{2} + \delta_x + i\tau_x,$$

together with the transport rows connecting $\mathsf{ZetaZero}(s_x)$, $\mathsf{Cancel}_{\mathcal{P}}(\delta_x, \tau_x)$, *and* $\mathsf{InfoBand}(\delta_x)$ *to the RH normal forms of Definition 9252.14.*

Definition 9414.109 (Zero-ledger atom)**.** *For a tower point $x \in T_{\mathcal{D}}$ with zeta coordinate s_x, a zero-ledger atom is the packet row*

$$\mathsf{ZeroAtom}_{\mathcal{D}}(x) := \mathsf{ZeroLedger}(\pi_\zeta(x)).$$

Equivalently, it is a zeta-value evaluation packet

$$(s_x, z_x, \mathsf{ZetaVal}(s_x, z_x), z_x\mathsf{hsame0})$$

together with the zero classifier, source ledger, transport rows, and audit rows that make the zero event public. Thus a zero atom is not a bare complex point. The phrase that a zeta zero is generated by the self-similar operation means generation at the zeta-zero ledger layer: there is a tower point whose zeta projection is admitted by the zero ledger.

Definition 9414.110 (Zeta zero-ledger payload)**.** *The zeta zero-ledger payload of a tower point x is the displayed packet of rows*

$$\begin{aligned}\mathsf{ZetaZeroPayload}_{\mathcal{D}}(x) := (s_x,\ z_x,\ \mathsf{ZetaVal}(s_x, z_x),\ z_x\mathsf{hsame0},\ \mathsf{InfoBand}(\delta_x),\\ \mathsf{CompletedZetaCarrier}(\pi_\zeta(x)),\ \mathsf{ZeroLedger}(\pi_\zeta(x)),\ \mathsf{Ledger}_\zeta(x)).\end{aligned}$$

The payload records the point coordinate only as one field of a larger carrier. Its public status depends on evaluation, classifier, completed carrier, ledger, and audit rows. Therefore the zero-ledger route never treats $\mathsf{ZetaZero}$ *as a subset of bare complex points.*

Definition 9414.111 (Coinductive zero-ledger invariant)**.** *A coinductive zero-ledger invariant for a self-similar diagram $\mathcal{D}$ is a predicate $\mathcal{R}$ on $T_{\mathcal{D}}$ such that for every tower point x:*

$$\mathcal{R}(x)$$

is stable under the zeta boundary readout, the residual fiber readback, the compatibility maps of the diagram, and the operation $\Omega_{\mathcal{D}}$. The invariant is RH-facing when it contains the zero-rigidity implication

$$\mathsf{ZeroAtom}_{\mathcal{D}}(x) \wedge \mathsf{InfoBand}(\delta_x) \Longrightarrow \delta_x = 0.$$

Principle 9414.112 (Atomization boundary for zeta zeros)**.** *Atomization at the zero-ledger layer means minimality with respect to the displayed zero classifier: the packet is a basic auditable zero event in the ledger. It does not assert that the analytic zero is simple, and it does not provide a finite listing of all non-trivial zeros. A fixed zeta value can be approximated through its evaluation rows, while exact zero-ledger admission is a constructive packet obligation that is not generally decided by finite approximation alone.*

Definition 9414.113 (Non-trivial zero atom and counterpacket)**.** *The non-trivial zero atoms of the self-similar zeta coordinate are*

$$\mathsf{NTZeroAtom}_{\mathcal{D}}(x) := \mathsf{ZeroAtom}_{\mathcal{D}}(x) \wedge \mathsf{InfoBand}(\delta_x).$$

The corresponding tower-internal RH counterpacket type is

$$\mathsf{CounterAtom}_{\mathsf{RH},\mathcal{D}} := \sum_{x:T_{\mathcal{D}}} \mathsf{ZeroAtom}_{\mathcal{D}}(x) \times \mathsf{InfoBand}(\delta_x) \times \mathsf{ApartNonFix}(\delta_x).$$

This is the constructive disproof shape of Definition 9239.8 read through the self-similar tower: a zero-ledger atom in the information band, together with a positive off-fixed witness.

Definition 9414.114 (Zero-ledger fiber geometry)**.** *The zero geometry carried by the self-similar zeta coordinate is the zero-ledger fiber*

$$\mathbb{Z}_{\zeta,\mathcal{D}} := \sum_{x:T_{\mathcal{D}}} \mathsf{ZeroAtom}_{\mathcal{D}}(x).$$

Its non-trivial part is

$$\mathbb{Z}^{\mathsf{nt}}_{\zeta,\mathcal{D}} := \sum_{x:T_{\mathcal{D}}} \mathsf{ZeroAtom}_{\mathcal{D}}(x) \times \mathsf{InfoBand}(\delta_x).$$

The RH target is the assertion that this non-trivial zero-ledger fiber projects into the fixed-half surface, equivalently into the fixed locus of the information-channel mirror.

Definition 9414.115 (Self-similar zero rigidity)**.** *For such a zeta coordinate row, the self-similar zero-rigidity statement is*

$$\mathsf{ZeroRigidity}_{\mathcal{D}} := \forall x \in T_{\mathcal{D}},\ \mathsf{Cancel}_{\mathcal{P}}(\delta_x, \tau_x) \wedge \mathsf{InfoBand}(\delta_x) \Longrightarrow \delta_x = 0.$$

Equivalently, by Definition 9252.14, every tower-internal zero-ledger atom in the information band has unit amplitude on all displayed prime channels. This is a rigidity condition on zero-ledger atoms, not a procedure for listing the atoms.

Definition 9414.116 (Self-similar off-fixed exclusion)**.** *The off-fixed exclusion form is*

$$\mathsf{NoOffFixedZero}_{\mathcal{D}} := \forall x \in T_{\mathcal{D}},\ \mathsf{Cancel}_{\mathcal{P}}(\delta_x, \tau_x) \wedge \mathsf{InfoBand}(\delta_x) \wedge \mathsf{ApartNonFix}(\delta_x) \Longrightarrow \bot.$$

It is the tower-internal version of the exclusion target in Definition 9414.99.

Theorem 9414.117 (Off-fixed exclusion gives zero rigidity)**.** *If* $\mathsf{NoOffFixedZero}_{\mathcal{D}}$ *holds and the real-part readout is located with tight apartness, then*

$$\mathsf{ZeroRigidity}_{\mathcal{D}}$$

holds.

Proof. Fix $x \in T_{\mathcal{D}}$ and assume

$$\mathsf{Cancel}_{\mathcal{P}}(\delta_x, \tau_x) \wedge \mathsf{InfoBand}(\delta_x).$$

To prove $\delta_x = 0$, the located real-part readout reduces the task to ruling out every positive apartness witness for δ_x. If $\mathsf{ApartNonFix}(\delta_x)$ were present, the three displayed rows would inhabit the premise of $\mathsf{NoOffFixedZero}_{\mathcal{D}}$ and hence give $\bot$. Therefore no positive off-fixed displacement remains, and tightness of the located readout gives $\delta_x = 0$. □

Definition 9414.118 (Prime-window radial defect)**.** *For a finite prime window* $W \subset_{\mathrm{fin}} \mathsf{Prime}^{\uparrow}$*, the prime-window radial defect of a tower point* x *is a displayed defect row*

$$\mathsf{RadDef}_W(x)$$

whose amplitude ledger reads

$$|\mathsf{RadDef}_W(x)| = |\delta_x| \sum_{p \in W} \log p.$$

For $W \neq \varnothing$*, a positive value of this row records a visible finite-prime trace of off-fixed radial displacement.*

Definition 9414.119 (Defect-zero incompatibility certificate)**.** *The defect-zero incompatibility certificate for* $\mathcal{D}$ *is the conditional row*

$$\mathsf{DefectZeroIncompat}_{\mathcal{D}} := \forall x \in T_{\mathcal{D}}, \mathsf{CompletedZetaCarrier}(\pi_\zeta(x)) \wedge \sum_{W \subset_{\mathrm{fin}} \mathsf{Prime}^{\uparrow}} (W \neq \varnothing) \times (|\mathsf{RadDef}_W(x)| > 0)$$
$$\Longrightarrow \mathsf{Apart}_0(\zeta(s_x)).$$

Thus a completed zeta carrier with a positive finite-window radial defect is separated from the zero row.

Definition 9414.120 (Off-fixed-to-defect certificate)**.** *The off-fixed-to-defect certificate is*

$$\mathsf{OffFixedToDefect}_{\mathcal{D}} := \forall x \in T_{\mathcal{D}}, \mathsf{InfoBand}(\delta_x) \wedge \mathsf{ApartNonFix}(\delta_x) \\ \implies \sum_{W \subset_{\mathrm{fin}} \mathsf{Prime}^{\uparrow}} (W \neq \varnothing) \times (|\mathsf{RadDef}_W(x)| > 0).$$

It supplies the finite prime window in which a nonzero radial displacement becomes visible to the ledger.

Definition 9414.121 (Zero-ledger soundness row)**.** *The zero-ledger soundness row is*

$$\mathsf{ZeroLedgerSound}_{\mathcal{D}} := \forall x \in T_{\mathcal{D}},\ \mathsf{Cancel}_{\mathcal{P}}(\delta_x, \tau_x) \implies \zeta(s_x)\mathsf{hsame0}.$$

It says that the cancellation row used by the information-channel normal form is sound for the completed zeta value carried by the same tower point.

Principle 9414.122 (Zero-ledger soundness and completeness boundary)**.** *The exclusion route requires zero-ledger soundness:*

$$\mathsf{ZeroLedger}(\pi_\zeta(x)) \implies \zeta(s_x)\mathsf{hsame0}.$$

The converse direction,

$$\zeta(s_x)\mathsf{hsame0} \implies \mathsf{ZeroLedger}(\pi_\zeta(x)),$$

is a separate zero-ledger completeness target for the completed carrier. It is not needed to refute an off-fixed zero-ledger atom. Soundness is the row that turns $\mathsf{Apart}_0(\zeta(s_x))$ *into a contradiction with zero-ledger admission.*

Definition 9414.123 (Same-source zeta defect dictionary)**.** *A same-source zeta defect dictionary for* $\mathcal{D}$ *is a certificate that, for each* $x \in T_{\mathcal{D}}$*, the following rows are projections of the same tower point and are transported by the same zeta classifier:*

$$\mathsf{ZeroAtom}_{\mathcal{D}}(x), \qquad \mathsf{CompletedZetaCarrier}(\pi_\zeta(x)), \\ \mathsf{RadDef}_W(x), \qquad \mathsf{ArchimedeanRow}(\pi_\zeta(x)), \qquad \mathsf{FunctionalEquationRow}(\pi_\zeta(x)).$$

This dictionary prevents a boundary defect and a bulk zero row from being read as unrelated objects with the same printed coordinate. The finite-prime boundary, Archimedean row, functional-equation row, and zero-ledger row must all be fields of the same completed zeta payload.

Definition 9414.124 (Projection-recovery defect obligation)**.** *The projection-recovery defect obligation states that a positive finite-prime radial defect obtained from the information-channel boundary survives as a defect row of the completed zeta carrier:*

$$\mathsf{DefectRecovery}_{\mathcal{D}} := \forall x \in T_{\mathcal{D}}, \sum_{W \subset_{\mathrm{fin}} \mathsf{Prime}^{\uparrow}} (W \neq \varnothing) \times (|\mathsf{RadDef}_W(x)| > 0) \\ \implies \mathsf{CompletedDefectRow}_{\mathcal{D}}(x).$$

It is the carrier-level version of saying that analytic continuation, Archimedean completion, functional equation, and branch transport do not erase the source of the displayed radial defect.

Theorem 9414.125 (Defect incompatibility gives off-fixed exclusion)**.** *Assume the completed-carrier row is present for every zero-ledger tower point. If*

$$\mathsf{DefectZeroIncompat}_{\mathcal{D}}, \qquad \mathsf{OffFixedToDefect}_{\mathcal{D}}, \qquad \mathsf{ZeroLedgerSound}_{\mathcal{D}}$$

hold, then

$$\mathsf{NoOffFixedZero}_{\mathcal{D}}$$

holds.

Proof. Fix $x \in T_{\mathcal{D}}$ and assume

$$\mathsf{Cancel}_{\mathcal{P}}(\delta_x, \tau_x) \wedge \mathsf{InfoBand}(\delta_x) \wedge \mathsf{ApartNonFix}(\delta_x).$$

The last two rows, through $\mathsf{OffFixedToDefect}_{\mathcal{D}}$, give a finite nonempty prime window W with

$$|\mathsf{RadDef}_W(x)| > 0.$$

Together with the completed-carrier row, this is the premise of $\mathsf{DefectZeroIncompat}_{\mathcal{D}}$, hence

$$\mathsf{Apart}_0(\zeta(s_x)).$$

The zero-ledger soundness row applied to $\mathsf{Cancel}_{\mathcal{P}}(\delta_x, \tau_x)$ gives

$$\zeta(s_x)\mathsf{hsame}0.$$

The apartness row and the zero row cannot both be inhabited. Therefore the assumed off-fixed zero-ledger atom yields $\perp$, uniformly in x. □

Corollary 9414.126 (Defect route gives zero rigidity)**.** *Assume the completed-carrier row is present for every zero-ledger tower point. If*

$$\mathsf{DefectZeroIncompat}_{\mathcal{D}}, \qquad \mathsf{OffFixedToDefect}_{\mathcal{D}}, \qquad \mathsf{ZeroLedgerSound}_{\mathcal{D}}$$

hold and the real-part readout is located with tight apartness, then

$$\mathsf{ZeroRigidity}_{\mathcal{D}}$$

holds.

Proof. By Definition 9414.125, the three certificate rows give $\mathsf{NoOffFixedZero}_{\mathcal{D}}$. Then Definition 9414.117 gives $\mathsf{ZeroRigidity}_{\mathcal{D}}$. □

Theorem 9414.127 (Closure and zero rigidity give the BEDC RH target)**.** *Assume every legal non-trivial zero-ledger atom has a tower-internal position as in Definition 9414.97, and assume the zeta coordinate row transports the BEDC zero and strip predicates to* $\mathsf{Cancel}_{\mathcal{P}}(\delta_x, \tau_x)$ *and* $\mathsf{InfoBand}(\delta_x)$*. If*

$$\mathsf{ZeroRigidity}_{\mathcal{D}}$$

holds, then the BEDC RH predicate of Definition 9239.7 holds.

Proof. Let s be the zeta coordinate of a legal non-trivial zero-ledger atom. By tower-internal location, there is $x \in T_{\mathcal{D}}$ whose zeta projection carries the same zero and critical-strip data. The transport rows give

$$\mathsf{Cancel}_{\mathcal{P}}(\delta_x, \tau_x) \wedge \mathsf{InfoBand}(\delta_x).$$

Zero rigidity gives $\delta_x = 0$. By Definition 9252.14, this is the critical-line form of the same packet. Transporting back through the zeta classifier gives $\mathsf{OnCritLine}(s)$, which is the BEDC RH conclusion. □

Theorem 9414.128 (Coinductive defect route gives the BEDC RH target)**.** *Assume every legal non-trivial zero-ledger atom has a tower-internal position in the full self-similar carrier. Assume also that the zeta coordinate row is a same-source row: its zero ledger, completed zeta carrier, finite prime-window defects, and information-channel readouts are all read from the same tower point and transported through the same classifier. If*

$$\mathsf{DefectZeroIncompat}_{\mathcal{D}}, \qquad \mathsf{OffFixedToDefect}_{\mathcal{D}}, \qquad \mathsf{ZeroLedgerSound}_{\mathcal{D}}$$

hold, and the real-part readout is located with tight apartness, then the BEDC RH predicate of Definition 9239.7 holds.

Proof. Let s be the zeta coordinate of a legal non-trivial zero-ledger atom. Tower closure supplies $x \in T_{\mathcal{D}}$ carrying the same zero and information-band rows. If this atom were off-fixed, then $\mathsf{OffFixedToDefect}_{\mathcal{D}}$ would supply a finite nonempty prime window whose radial defect is positive. The same-source condition places that defect and the zero-ledger row in the same completed zeta carrier. By Definition 9414.125, the three certificate rows exclude the off-fixed zero atom. Hence Definition 9414.126 gives $\mathsf{ZeroRigidity}_{\mathcal{D}}$. Applying Definition 9414.127 yields the BEDC RH target. □

Definition 9414.129 (Constructive RH witness extracted from exclusion)**.** *The witness extracted from the zero-ledger exclusion route is the function schema*

$$\Phi_{\mathcal{D}} : \mathbb{Z}^{\mathsf{nt}}_{\zeta,\mathcal{D}} \to \mathrm{Fix}_{1/2},$$

where $\mathrm{Fix}_{1/2}$ *denotes the fixed-half output surface of Definition 9252.14. On an input* $(x, \mathsf{ZeroAtom}_{\mathcal{D}}(x), \mathsf{InfoBand}(\delta_x$ *the function first excludes* $\mathsf{ApartNonFix}(\delta_x)$ *by the defect-incompatibility route and then uses located real readback to return the witness* $\delta_x = 0$.

Principle 9414.130 (Exact boundary of the self-similar route)**.** *Self-similar closure contributes tower location. It excludes an external place for a legal RH counterexample but does not by itself exclude an off-fixed tower-internal zero-ledger atom. The certificate that performs the exclusion is the defect-zero incompatibility row together with off-fixed-to-defect, zero-ledger soundness, completed-carrier, and located real readback data. In witness form, the route is precisely the chain recorded in Definition 9414.106.*

Concretized in §9142: Zero-ledger rigidity is realized as finite visible-route, replay, provenance, and no-hidden-ledger NameCert data.

9414.7 Layered projection theory

Remark 9414.131 (Paper-side theory status)**.** *This section records the paper-side form of layered projection theory. It is tracked against the Lean readout-system and product-normal-form carriers. Its role is to make explicit the theory carried implicitly by the interface–constraint–section packet: every public layer is a readout surface over a source carrier, every loss of visible distinction leaves a fiber family, every legitimate refinement must display its readback map, and every numerical half-value claim must arise from a witnessed involutive symmetry rather than from an unledgered statistical convention.*

Lean4 (definition) `BEDC.RealityConstrained.ReadoutSystem`
Lean4 (definition) `BEDC.RealityConstrained.AxisProductNormalForm`

Definition 9414.132 (Layered projection datum)**.** *A* layered projection datum *over a displayed source carrier X is a finite family*

$$\mathfrak{P} = (\mathcal{L}_i, \rho_{i+1,i}, \Lambda_{i+1,i})_{i<n}$$

where each $\mathcal{L}_i$ is a readout layer in the sense of Definition 9414.40, each $\rho_{i+1,i} : R_{i+1} \to R_i$ is a displayed readback map witnessing that $\mathcal{L}_{i+1}$ refines $\mathcal{L}_i$, and each $\Lambda_{i+1,i}$ records classifier transport, source provenance, refinement exactness, and the residual gap surface.

Definition 9414.133 (Inherited predicate)**.** *Let $\mathcal{L}_{i+1}$ refine $\mathcal{L}_i$ through $\rho_{i+1,i} : R_{i+1} \to R_i$. A predicate $A_i : R_i \to \mathsf{Prop}$ on the i-th layer induces the predicate*

$$A_{i+1} := A_i \circ \rho_{i+1,i}$$

on the refined layer. The induction is legitimate only with the displayed readback map and the classifier-respect row for A_i.

Theorem 9414.134 (Predicate inheritance)**.** *Suppose $\mathcal{L}_{i+1}$ refines $\mathcal{L}_i$ and A_i respects $\sim_i$. If $A_i(P_i(x))$ holds for a source row $x : X$, then the inherited predicate satisfies*

$$A_{i+1}(P_{i+1}(x)).$$

Proof. By definition,

$$A_{i+1}(P_{i+1}(x)) = A_i(\rho_{i+1,i}(P_{i+1}(x))).$$

The refinement row gives $\rho_{i+1,i}(P_{i+1}(x)) \sim_i P_i(x)$. Since A_i respects $\sim_i$, the premise $A_i(P_i(x))$ transports across this classifier witness and gives the inherited claim. □

Definition 9414.135 (Concept layer)**.** *A* concept layer *is a readout layer together with an operation and certificate surface*

$$\mathcal{C} = (R, \sim_R, P, \mathsf{Op}, \mathsf{Cert}, \Lambda).$$

Here Op *is the family of constructions licensed at the layer, and* Cert *records closure, compatibility, stability, and replay obligations for those constructions.*

Definition 9414.136 (Concept tower)**.** *A* concept tower *is a finite or countable sequence $(\mathcal{C}_i)$ of concept layers together with refinement certificates*

$$\mathcal{C}_{i+1} \preceq \mathcal{C}_i.$$

The tower order is not a chronology of discovery. It is a dependency order for forming predicates and operations without hidden supply.

Definition 9414.137 (Tower-internal concept)**.** *Let $\mathcal{T} = (\mathcal{C}_i)$ be a concept tower. A concept is* tower-internal *when its carrier, predicate, operation, or section data is obtained from a finite prefix of $\mathcal{T}$ by the displayed formation rules of the prefix: readout along a layer map, pullback along a refinement map, dependent sum or product over a displayed carrier, fiber formation, section formation, equality transport along a classifier witness, and application of an operation whose certificate row belongs to one of the layers.*

Definition 9414.138 (BEDC-generable concept)**.** *Relative to a displayed concept tower $\mathcal{T}$, a* BEDC-generable concept *is a concept whose complete formation record is a finite BEDC expression over the source carrier, the displayed layer carriers, the readout and refinement maps, the classifier witnesses, and the certified operation rows of $\mathcal{T}$. The phrase does not range over untyped host-language ideas; it ranges only over objects whose dependencies are present in the tower ledger.*

Theorem 9414.139 (Tower closure for BEDC-generable concepts)**.** *Every BEDC-generable concept relative to $\mathcal{T}$ is tower-internal.*

Proof. The formation record of a BEDC-generable concept is finite. Induct on its formation. A source carrier, layer carrier, readout, refinement map, classifier witness, or certified operation row is already present in a finite prefix of $\mathcal{T}$, hence is tower-internal. Pullback, dependent sum, dependent product, fiber formation, section formation, and equality transport are exactly the allowed tower-internal formation rules. The induction step therefore preserves tower-internality for every constructor in the finite record. □

Corollary 9414.140 (Relative absence of outside concepts)**.** *If the word "concept" is restricted to BEDC-generable concepts relative to $\mathcal{T}$, then there is no concept outside $\mathcal{T}$.*

Proof. By Definition 9414.139, each concept in the restricted range is tower-internal. Thus no concept in that range is both BEDC-generable and outside the tower. □

Principle 9414.141 (Typed boundary of the outside-concept claim)**.** *The unqualified sentence "no concept is outside the tower" is not a closed BEDC claim. It becomes a theorem only after the quantifier is typed as ranging over BEDC-generable concepts relative to a displayed tower. Without this restriction the sentence quantifies over an unstated host-language domain and has no carrier, equality, or formation ledger.*

Theorem 9414.142 (Layered infinity theorem)**.** *For every readout layer $\mathcal{L}$ over X, the layer residue is the fiber family*

$$\infty_{\mathcal{L}}(r) = \mathrm{Fib}_{\mathcal{L}}(r).$$

It is not an element of the visible carrier R. If a finer layer $\mathcal{M}$ refines $\mathcal{L}$, then the finer layer partitions each previous fiber through the map of Definition 9414.45.

Proof. The first assertion is Definition 9414.41. The second assertion follows because the type of $\infty_{\mathcal{L}}$ is a family indexed by R, not a row of R. The refinement assertion is exactly Definition 9414.45. □

Principle 9414.143 (No point replacement for residue)**.** *Whenever a projection hides a source distinction, the hidden content may be named only as fiber data, section-relative meaning, or a gap row. It may not be replaced by a single additional visible point unless a new carrier, classifier, readout, and naming certificate have been displayed.*

Definition 9414.144 (Pre-prime tower segment)**.** *The pre-prime segment of a concept tower has the dependency shape*

$$\mathsf{Distinction} \to \mathsf{Hist} \to \mathsf{Cont} \to \mathsf{Unary} \to \mathsf{Nat} \to \mathsf{Order} \to \mathsf{Add} \to \mathsf{Mul} \to \mathsf{Div} \to \mathsf{Unit} \to \mathsf{Prime}.$$

The divisibility predicate is formed only after multiplication:

$$d \mid n \quad :\Longleftrightarrow \quad \exists q,\ n = dq.$$

The prime predicate is then the layer expression

$$\mathsf{Prime}(p) \quad :\Longleftrightarrow \quad p > 1 \ \wedge\ \forall d,\ d \mid p \Rightarrow d = 1 \vee d = p.$$

Theorem 9414.145 (Prime is not a primitive layer)**.** *In the pre-prime tower segment,* Prime *cannot be formed before the multiplication and divisibility layers.*

Proof. The displayed definition of $\mathsf{Prime}(p)$ contains the predicate $d \mid p$. The displayed definition of $d \mid p$ contains the product dq. Without the multiplication layer there is no displayed divisibility predicate, and without divisibility there is no displayed prime predicate. □

Definition 9414.146 (Prime-coordinate readout)**.** *Once a unique-factorization certificate is displayed, the prime-coordinate readout sends a positive integer n to the finite-support family*

$$\Phi(n) = (p \mapsto v_p(n)) \in \mathbb{N}^{(\mathbb{P})}.$$

Each prime p determines the coordinate vector e_p with value 1 at p and value 0 at every other prime.

Definition 9414.147 (Prime-occupancy carrier)**.** *The prime-occupancy carrier is the finite-support configuration space*

$$T_{\mathbb{P}} := \mathbb{N}^{(\mathbb{P})}.$$

Its elements are rows

$$k : \mathbb{P} \to \mathbb{N}$$

with finite support. The coordinate k_p records how many times the prime axis p is occupied. The carrier $T_{\mathbb{P}}$ is therefore the multiplicative-divisibility presentation of positive arithmetic after unique factorization has been displayed; it is not the set of primes $\mathbb{P}$ alone and not the absolute base of the whole BEDC tower.

Definition 9414.148 (Arithmetic multiplication presentation)**.** *The arithmetic multiplication presentation is the readout*

$$\Phi : \mathbb{N}_{>0} \to T_{\mathbb{P}}$$

of Definition 9414.146, together with the readback

$$\Psi(k) := \prod_{p \in \mathbb{P}} p^{k_p}.$$

The product is finite because k has finite support. The readout and readback are licensed only relative to the multiplication, divisibility, unit, order, natural-number, and unique-factorization certificates of the pre-prime tower segment.

Theorem 9414.149 (Multiplication becomes coordinate addition)**.** *For positive integers m, n with displayed unique factorization,*

$$\Phi(mn) = \Phi(m) + \Phi(n).$$

Proof. Unique factorization gives

$$m = \prod_p p^{v_p(m)}, \qquad n = \prod_p p^{v_p(n)}.$$

Multiplying the two expressions gives

$$mn = \prod_p p^{v_p(m)+v_p(n)}.$$

Uniqueness of the factorization certificate identifies the p-coordinate of mn with $v_p(m) + v_p(n)$ for every prime p. □

Principle 9414.150 (Prime ontology is relative arithmetic presentation)**.** *The phrase "the ontology is prime" can be used in BEDC only in the relative sense that the positive multiplicative arithmetic layer is read through $T_{\mathbb{P}}$. In that presentation, the unit is the zero configuration, multiplication is coordinate addition, divisibility is coordinatewise comparison,*

$$m \mid n \quad \Longleftrightarrow \quad \forall p,\ v_p(m) \le v_p(n),$$

and the gcd and lcm rows are coordinatewise minimum and maximum:

$$v_p(\gcd(m,n)) = \min(v_p(m), v_p(n)), \qquad v_p(\operatorname{lcm}(m,n)) = \max(v_p(m), v_p(n)).$$

This gives a strong coordinate presentation of the multiplicative layer; it does not erase the pre-prime construction of multiplication, divisibility, unit, order, and natural-number structure.

Theorem 9414.151 (Prime axes are independent)**.** *If $p_1, \ldots, p_k$ are pairwise distinct primes and*

$$\sum_{i=1}^{k} a_i e_{p_i} = 0,$$

then $a_i = 0$ for every i.

Proof. Fix j. Evaluating the displayed equality at the coordinate p_j gives $a_j = 0$, because every other basis vector has value 0 at p_j. Since j is arbitrary, all coefficients vanish. □

Definition 9414.152 (p-adic local readout)**.** *For a fixed prime p, the p-adic valuation readout on a nonzero rational is the p-coordinate of its prime factorization:*

$$v_p(x) = \Phi(x)(p).$$

The symbol $v_p(0) = \infty_{\mathrm{val}}$ is an added valuation-top row, not a natural number, integer, rational, or prime.

Principle 9414.153 (Prime axis locality)**.** *The p-adic layer is a local readout of the prime-coordinate layer. It does not create the prime axis; it consumes the already displayed unique-factorization and coordinate certificates.*

Definition 9414.154 (Symmetric readout layer)**.** *A readout layer is symmetric when it carries an involution $\tau : X \to X$ and the visible readout is invariant:*

$$P(\tau x) \sim_R P(x).$$

A numerical readout $H : X \to A$ is anti-invariant when the codomain has an involution $j : A \to A$ and

$$H(\tau x) = j(H(x)).$$

Theorem 9414.155 (Quotient readout forces a fixed point)**.** *Let τ be invisible to a quotient readout $P : X \to R$. If an anti-invariant readout $H : X \to A$ also descends through P, so that $H = \bar{H} \circ P$, then every displayed source row satisfies*

$$H(x) = j(H(x)).$$

Proof. Since H descends through P and $P(\tau x) \sim_R P(x)$, the quotient readout gives $H(\tau x) = H(x)$ at the displayed classifier resolution. Anti-invariance gives $H(\tau x) = j(H(x))$. Combining the two equalities yields $H(x) = j(H(x))$. □

Definition 9414.156 (Half-value layer)**.** *Let $Z \subseteq X$ be a displayed source subcarrier. A* half-value layer *over Z is a triple*

$$\mathcal{H} = (B, b, h)$$

where B is a displayed half-value carrier, $b : Z \to B$ is a readout, and $h \in B$ is the distinguished fixed half-value row.

Definition 9414.157 (Fixed half fiber)**.** *For a half-value layer $\mathcal{H} = (B, b, h)$, the fixed half fiber is*

$$\mathrm{Fix}_{\mathcal{H}} := \sum_{z:Z} (b(z) = h),$$

with projection

$$\pi_{\mathcal{H}} : \mathrm{Fix}_{\mathcal{H}} \to Z, \qquad \pi_{\mathcal{H}}(z, p) := z.$$

Definition 9414.158 (Half-value section)**.** *The half-value section type of $\mathcal{H}$ is*

$$\mathsf{Sec}_{\mathcal{H}} := \sum_{\sigma : Z \to \mathrm{Fix}_{\mathcal{H}}} (\pi_{\mathcal{H}} \circ \sigma = \mathrm{id}_Z).$$

Theorem 9414.159 (Half-value propositions are sections)**.** *The proposition*

$$\prod_{z:Z} (b(z) = h)$$

is naturally equivalent to $\mathsf{Sec}_{\mathcal{H}}$.

Proof. Given $u : \prod_{z:Z} (b(z) = h)$, define

$$\sigma_u(z) := (z, u(z)).$$

Then $\pi_{\mathcal{H}}(\sigma_u(z)) = z$, so σ_u is a section. Conversely, a section σ sends each z to a pair (z', p) with $p : b(z') = h$. The section condition identifies z' with z, and transport gives $p : b(z) = h$. These constructions are inverse by equality elimination. □

Theorem 9414.160 (Half value as fixed point)**.** *Over the rationals, the equation*

$$x = 1 - x$$

holds if and only if

$$x = \frac{1}{2}.$$

Proof. If $x = 1 - x$, then $2x = 1$, hence $x = 1/2$. Conversely, substituting $x = 1/2$ gives $1 - x = 1/2 = x$. □

Corollary 9414.161 (Matched-twin half value)**.** *For a balanced matched-twin protocol in the sense of Definition 9414.67, the value* $1/2$ *is the fixed point forced by the invisible involution on the quotient surface.*

Proof. Definition 9414.68 gives pairwise accuracy $1/2$ for every quotient-measurable binary rule. The preceding theorem identifies this number as the unique fixed point of $x \mapsto 1 - x$. □

Definition 9414.162 (Critical-line mirror)**.** *For* $s \in \mathbb{C}$*, write*

$$s = \frac{1}{2} + \delta + i\tau_s.$$

The critical-line mirror is

$$J(s) := 1 - \overline{s}.$$

Theorem 9414.163 (Critical line as mirror fixed surface)**.** *If* $s = \frac{1}{2} + \delta + i\tau_s$*, then*

$$J(s) = \frac{1}{2} - \delta + i\tau_s.$$

Consequently $J(s) = s$ *exactly when* $\Re(s) = 1/2$*.*

Proof. The conjugate is $\overline{s} = 1/2 + \delta - i\tau_s$. Therefore

$$J(s) = 1 - \overline{s} = \frac{1}{2} - \delta + i\tau_s.$$

The equality $J(s) = s$ is then equivalent to $-\delta = \delta$, hence to $\delta = 0$, which is precisely $\Re(s) = 1/2$. □

Theorem 9414.164 (Symmetric half-value unification)**.** *The matched-twin null value, the rational fixed point of* $x \mapsto 1-x$*, and the critical-line condition* $\Re(s) = 1/2$ *are instances of the same paper-side pattern: an involution is invisible at a quotient layer, an anti-invariant readout is forced to a fixed surface if it is claimed to descend, and the fixed surface is the half-value layer.*

Proof. For matched twins, the involution swaps two source witnesses while the quotient-visible observation remains unchanged; the binary label is anti-invariant, and Definition 9414.68 gives the half-value. For rational scores, the involution is $x \mapsto 1 - x$, whose fixed point is $1/2$ by Definition 9414.160. For the critical line, the mirror $J(s) = 1 - \overline{s}$ flips the bias coordinate δ and fixes exactly $\Re(s) = 1/2$ by Definition 9414.163. The three cases share the same quotient-invisibility and anti-invariance form. □

Theorem 9414.165 (Layered projection synthesis)**.** *Layered projection theory consists of the following paper-side closure schema:*

1. *a layer exposes only the classifier value of a readout;*
2. *the residual source content is a fiber family, not a point of the visible carrier;*
3. *refinements decompose previous fibers only through displayed readback maps and classifier transport;*
4. *concept predicates may be formed only after their operational dependencies have appeared in the tower;*
5. *BEDC-generable concepts are tower-internal relative to their displayed formation record;*
6. *predicates inherit only through displayed readback maps and classifier-respect rows;*
7. *half-value claims are fixed-point claims induced by displayed involutions and anti-invariant readouts, equivalently section claims into fixed half fibers.*

Proof. The first two clauses are Definition 9414.142. The third clause is Definition 9414.45. The fourth clause is represented by Definition 9414.145. Predicate inheritance is Definition 9414.134. The relative closure of generable concepts is Definition 9414.139, with the typing boundary recorded by Definition 9414.141. The fixed-point reading of half values is Definition 9414.164, and the section reading is Definition 9414.159. These clauses are independent of additional axioms; they use only displayed carriers, readout maps, classifier witnesses, refinement maps, and ledgered certificates. □

9414.8 Layered extension theory

Remark 9414.166 (Paper-side theory status)**.** *This section records the paper-side form of layered extension theory. It is tracked against the basic Lean readout and layer-extension carriers. Its role is to separate extension from endpoint imagery: a refinement layer is a compatible readout of the same source carrier, and the material available for refinement is the fiber family of the preceding layer rather than a single terminal point.*

Lean4 (definition) `BEDC.RealityConstrained.LayerExtension`

Definition 9414.167 (Layer residue)**.** *Let*

$$\mathcal{L}_n = (R_n, \sim_n, P_n, \Lambda_n, \mathsf{NameCert}_n)$$

be a readout layer over a displayed source carrier T. For $r : R_n$, the residual fiber at r is

$$\mathrm{Res}_n(r) := \sum_{t:T} (P_n(t) \sim_n r).$$

The layer residue is the family

$$\infty_n : R_n \to \mathsf{Type}, \qquad \infty_n(r) := \mathrm{Res}_n(r).$$

Thus ∞_n is a surface of source fibers indexed by R_n, not a row of R_n.

Principle 9414.168 (Residue is a fiber surface)**.** *The residue of a layer may be read only as the family $r \mapsto \mathrm{Res}_n(r)$. Replacing that family by a single visible endpoint loses the section data required by Definition 9414.41 and violates the point replacement boundary of Definition 9414.143.*

Definition 9414.169 (Compatible layered extension)**.** *Let $\mathcal{L}_n$ and $\mathcal{L}_{n+1}$ be readout layers over the same source carrier T:*

$$\mathcal{L}_i = (R_i, \sim_i, P_i, \Lambda_i, \mathsf{NameCert}_i).$$

The layer $\mathcal{L}_{n+1}$ is a compatible layered extension *of $\mathcal{L}_n$ when there is a displayed readback map*

$$\rho_{n+1,n} : R_{n+1} \to R_n$$

such that every source row $t : T$ satisfies

$$\rho_{n+1,n}(P_{n+1}(t)) \sim_n P_n(t).$$

The notation

$$\mathcal{L}_{n+1} \rightsquigarrow \mathcal{L}_n$$

records this compatibility row.

Theorem 9414.170 (Extension preserves the source carrier)**.** *If $\mathcal{L}_{n+1} \rightsquigarrow \mathcal{L}_n$, then $\mathcal{L}_{n+1}$ introduces no tower-external source object. It is a further readout of T, and its readback agrees with the preceding readout at the $\sim_n$ resolution.*

Proof. The refined readout has source

$$P_{n+1} : T \to R_{n+1}.$$

Thus every refined record row is still read from T. The compatibility certificate gives

$$\rho_{n+1,n}(P_{n+1}(t)) \sim_n P_n(t)$$

for each $t : T$. Hence the refinement is not a second source carrier; it is a compatible representation of the same source through a finer record surface. □

Lean4 ✓ `BEDC.RealityConstrained.LayerExtension.read forget commutes`

Definition 9414.171 (Fiber-distinguishing extension)**.** *A compatible layered extension $\mathcal{L}_{n+1} \rightsquigarrow \mathcal{L}_n$ is* fiber-distinguishing *at $r : R_n$ when there exist source rows $t_0, t_1 : T$ such that*

$$P_n(t_0) \sim_n r, \qquad P_n(t_1) \sim_n r,$$

but

$$P_{n+1}(t_0) \not\sim_{n+1} P_{n+1}(t_1).$$

It is fiber-distinguishing when this occurs at some displayed $r : R_n$.

Definition 9414.172 (Generalized analytic continuation)**.** *A* generalized analytic continuation *of $\mathcal{L}_n$ is a compatible layered extension*

$$\mathcal{L}_{n+1} \rightsquigarrow \mathcal{L}_n$$

that is fiber-distinguishing for a residue of $\mathcal{L}_n$. The word "analytic" here records the continuation role: a later layer keeps the earlier readout available by readback while expressing source structure that the earlier carrier did not separate.

Theorem 9414.173 (Continuation is residual separation)**.** *Every generalized analytic continuation separates two source rows that belonged to one residual fiber of the preceding layer.*

Proof. By Definition 9414.172, the extension is fiber-distinguishing. Hence there are $r : R_n$ and $t_0, t_1 : T$ with

$$P_n(t_0) \sim_n r, \qquad P_n(t_1) \sim_n r,$$

while the refined layer satisfies

$$P_{n+1}(t_0) \not\sim_{n+1} P_{n+1}(t_1).$$

Thus the refined layer separates rows that the preceding layer left in a single residual fiber. □

Definition 9414.174 (Fiber-certified geometric continuation)**.** *Let* $\mathcal{L}_n = (R_n, \sim_n, P_n, \Lambda_n, \mathsf{NameCert}_n)$ *be a readout layer over* T*, and let* $C_n : R_n \to \mathsf{Prop}$ *be a displayed constraint row. A* fiber-certified geometric continuation *of* $(\mathcal{L}_n, C_n)$ *consists of a compatible layered extension*

$$\mathcal{L}_{n+1} \rightsquigarrow \mathcal{L}_n,$$

a displayed constraint row $C_{n+1} : R_{n+1} \to \mathsf{Prop}$*, and ledger rows certifying:*

$$\rho_{n+1,n}(P_{n+1}(t)) \sim_n P_n(t)$$

for every $t : T$*,*

$$C_{n+1}(r) \to C_n(\rho_{n+1,n}(r))$$

for every displayed $r : R_{n+1}$*, and a fiber-distinguishing witness for some residue of* $\mathcal{L}_n$*. The certificate rows include source identity, readback transport, constraint transport, fiber separation, and ledger closure.*

Theorem 9414.175 (Geometric continuation unfolds residual fibers)**.** *Every fiber-certified geometric continuation recovers its higher record surface as compatible source readout data over the preceding layer, rather than as a tower-external geometric carrier.*

Proof. The continuation contains a compatible layered extension, so Definition 9414.170 shows that the later readout is still a readout of the same source carrier T and readbacks to the preceding layer. The constraint-transport row sends every later admissible record to an earlier admissible record. The fiber-distinguishing witness then says that the later layer separates two source rows inside one residue of the earlier layer. Hence the higher record surface unfolds residual fiber data already indexed by R_n, with compatibility and ledger rows making the passage auditable. □

Lean4 ✓ `BEDC.RealityConstrained.LayerExtension.realized fiber commutes`

Principle 9414.176 (Continuation recovers carriers, not remote values)**.** *The restriction-style image of analytic continuation should not be read as the discovery of a value at a distant point. In BEDC terms it is the recovery of a carrier whose later readout restricts to the earlier one and whose residue, constraint, branch, and transport rows are ledgered. The same pattern governs high-dimensional geometry: lower-dimensional projections expose residual fibers, and a lawful continuation displays the carrier, readback, constraint transport, fiber separation, and audit rows that make those fibers available as geometric structure.*

Definition 9414.177 (Local-cluster extension)**.** *A compatible layered extension is* local-clustered *when its refined readout is assembled from a displayed family of local readouts*

$$P_{n+1,i} : T \to R_{n+1,i}, \qquad i : I_n,$$

together with a record assembly row

$$P_{n+1}(t) = \big(P_{n+1,i}(t)\big)_{i:I_n}$$

and readback data

$$\rho_{n+1,n}\big(P_{n+1}(t)\big) \sim_n P_n(t).$$

The indices $i : I_n$ are local windows, places, valuations, sections, or other displayed coordinates over the residual surface of $\mathcal{L}_n$.

Theorem 9414.178 (Local clusters refine fibers, not endpoints)**.** *In a local-cluster extension, the later layer refines the family $r \mapsto \mathrm{Res}_n(r)$ rather than a distinguished endpoint of R_n.*

Proof. The data of Definition 9414.177 supplies readouts $P_{n+1,i}$ from the same source T and a readback row to R_n. For a record $r : R_n$, the relevant source rows are exactly the fiber

$$\mathrm{Res}_n(r) = \sum_{t:T} (P_n(t) \sim_n r).$$

The local coordinates can distinguish such rows only through their source readouts and the displayed readback certificate. No clause of the definition selects a terminal row of R_n. □

Example 9414.179 (Place completions as local clusters)**.** *Let the source carrier be the rational field and let the local index set be the displayed set of places*

$$V_{\mathbb{Q}} = \{\infty\} \cup \mathsf{Prime}^{\uparrow}.$$

For $v = \infty$ the local completion is the archimedean completion $\mathbb{Q}_\infty = \mathbb{R}$. For a prime p, the local completion is the p-adic completion $\mathbb{Q}_p$, read through the valuation coordinate described in Definition 9414.152. The family

$$(\mathbb{Q}_v)_{v:V_{\mathbb{Q}}}$$

is therefore a place-indexed local-cluster extension of rational readout. It is not generated by a single point at infinity; it is generated by the displayed valuation and completion rows for the places.

Definition 9414.180 (Orthogonal cluster readouts)**.** *Let a local-cluster extension have readouts $(P_{n+1,i})_{i:I_n}$. The cluster is* orthogonal *when the ledger contains an independence certificate saying that changing the i-th coordinate, within its admissible source fiber, does not consume or force the j-th coordinate for $i \neq j$.*

Theorem 9414.181 (Prime-coordinate clusters are orthogonal)**.** *The prime-coordinate readouts supplied by unique factorization form an orthogonal cluster.*

Proof. Definition 9414.151 states that distinct prime axes are independent. The p-adic readout of Definition 9414.152 consumes the p-coordinate of this factorization surface. Hence the prime-local coordinates form an orthogonal cluster in the sense of Definition 9414.180. □

Definition 9414.182 (Composite extension information)**.** *Let $a, b : T \to R$ be orthogonal readouts in a layer. A record $c : T \to C$ is* composite extension information *when the ledger contains a formation row*

$$(a, b) \rightsquigarrow c$$

and no row expressing c from a alone or from b alone. The role of c is to record structure carried by the joint source readout rather than by either marginal projection.

Principle 9414.183 (Composite coordinates may force a layer)**.** *When a theory requires a composite record c as in Definition 9414.182, the layer that contains only the marginal readouts is not closed under the required expression. A compatible extension must display a carrier for c, its classifier, its readback to the marginal rows, and its gap ledger.*

Definition 9414.184 (Extension tower)**.** *An* extension tower *over T is a finite or countable sequence of readout layers*

$$\mathcal{L}_0, \mathcal{L}_1, \mathcal{L}_2, \dots$$

together with compatible readback maps

$$\mathcal{L}_{n+1} \rightsquigarrow \mathcal{L}_n$$

for every displayed successor pair.

Definition 9414.185 (Restriction-style continuation)**.** *Let $U \subset V$ be displayed domains. A classical restriction-style continuation has an upper record carrier of functions on V, a lower record carrier of functions on U, and the readback map*

$$\rho(F) = F|_U.$$

The compatibility row for a lower record f is

$$\rho(F) = f.$$

Theorem 9414.186 (Classical analytic continuation is a special case)**.** *Classical analytic continuation is a compatible layered extension whose readback map is restriction.*

Proof. In Definition 9414.185, the readback map is $F \mapsto F|_U$. The usual continuation condition says precisely that the refined record F restricts to the preceding record f. This is the compatibility equation of Definition 9414.169. □

Principle 9414.187 (Continuation need not be linear extension)**.** *The restriction-style case does not exhaust layered extension. A later layer may be obtained by place completions, valuation coordinates, orthogonal local clusters, completion rows, or recovered-carrier compatibility ledgers. The invariant is readback to the preceding layer, not geometric continuation from a terminal point.*

Definition 9414.188 (Zeta as a recovered extension carrier)**.** *The zeta carrier of Definition 9243.2 is read here as a multi-row extension carrier. Its displayed rows include the Dirichlet-series projection, Euler-product projection, analytic continuation row, archimedean completion row, functional-equation mirror row, pole ledger, zero ledger, branch ledger, and transport ledger.*

Principle 9414.189 (Zeta extension tower)**.** *The zeta carrier is not a single formula with a later decorative completion. It is a recovered carrier whose rows are compatible readouts of one source object across domains, prime-local channels, archimedean completion, mirror transport, and zero ledgers. The Dirichlet row is a projection of this carrier on its convergence half-plane, while the completed carrier supplies the surface on which zero-ledger statements are typed.*

Principle 9414.190 (RH target as extension compatibility obstruction)**.** *Within the zeta extension tower, the object named* $\mathsf{LocalGlobalZeroExclusion}_\zeta$ *in Definition 9246.1 is the remaining zero-ledger compatibility obstruction: a row separated from the functional-equation fixed surface by a positive local defect must be shown incompatible with a completed zeta-zero row. This principle does not assert the obstruction has been discharged; it identifies the carrier-level obligation isolated by Definition 9246.13.*

9414.9 Cataphatic-apophatic layering

This section records the reality-constrained reading of the rational, located, and apophatic layers. The named base line is the displayed rational layer $\mathbb{Q}$: a value at this layer is a finite rational name together with the exact equality relation already carried by $\mathsf{Rat}^{\uparrow}$. The cataphatic extension is the located-real layer: a real presentation is read through witnessed rational approximations, finite windows, moduli, and apartness evidence, not through an uninspected quotient representative. The apophatic far end is the socket at which a request for unsupported pointification, arbitrary supremum, or global representative selection is refused rather than imported.

Lean4 (definition) `BEDC.Derived.NonCollapseInvariantUp.NonCollapseInvariant`

Lean4 (definition) `BEDC.Derived.NonCollapseInvariantUp.NonCollapseWitness`

Lean4 ✓ `BEDC.Derived.NonCollapseInvariantUp.NonCollapseInvariant no rat retraction`

Lean4 ✓ `BEDC.Derived.NonCollapseInvariantUp.RatMetricKitConcrete no noncollapse witness`

Principle 9414.191 (Non-collapse invariant)**.** *Let w be a located-real presentation. The formal non-collapse invariant requires every rational q to be separated from w by displayed apartness evidence and, more strongly, to keep producing such evidence beyond any proposed equality modulus at a fixed displayed separation scale for that q. With a separating rational metric kit, this invariant rules out an exact rational retraction: there is no $q : \mathbb{Q}$ such that w is* $\mathsf{LRealEq}$*-equivalent to the stationary rational presentation of q.*

Proof. The Lean theorem cited above is the checked core. An assumed retraction supplies an equality modulus. The invariant supplies, beyond that same modulus, a rational snapshot of w apart from q. The separating metric law says that the displayed apartness and the displayed equality-close row cannot both hold at that snapshot. □

The slogan for the layer is: *The Omega does not deny points; it refuses unjustified pointification.* Thus the refusal is not a refusal of rational points, named located windows, or certified limits. It is a refusal to collapse a located or residual surface to a rational name, selected representative, arbitrary supremum, or terminal object without the certificate that performs that specific collapse.

The geometric language sometimes attached to this picture is only an intuition. Calling the rational layer an "axis", calling located apartness a transverse read, or drawing a three-way picture of rational names, located approximation, and apophatic sockets does not assert an inner product, a projection operation, a three-way law, a pro-object construction, or a universal-property theorem about future refinements. In BEDC terms, "undiscovered axis" means stability under later universe-polymorphic or context-extension refinements, not a quantified family of future directions.

The constructive boundary is the same one used by located analysis. Located suprema, located cuts, and finite-window apartness may be admitted when their moduli and witnesses are displayed. An arbitrary supremum or unrestricted representative selector is not admitted by this section. Such a selector would be an external supply socket in the sense of chapter 9395, and any use of it must remain visibly socketed through $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ rather than silently converted into a point of the cataphatic layer.

Remark 9414.192 (Formal scope)**.** *The checked Lean content is the invariant-to-no-retraction theorem and the exact-kit boundary theorem: every point in the exact rational metric kit retracts to a rational snapshot, so that kit does not carry a non-collapse witness. This section does not claim a checked $\sqrt{2}$ construction, a diagonal irrational construction, a located-supremum theorem, a rational trichotomy theorem, or an apophatic universal-property theorem. Those are separate arithmetic and interface targets.*

9414.10 Recursive orthogonal-axis normal forms

Remark 9414.193 (Paper-side theory status)**.** *This section records the paper-side form of recursive orthogonal-axis normal forms. It has no Lean target in this chapter. Its role is to make precise the relation between finite expression, orthogonal coordinate axes, and normalisation: a finite object is not merely listed as data, but is read through a certified normal form whose axes are generated by the available classifiers.*

Principle 9414.194 (Primes are not the absolute first layer)**.** *In the arithmetic tower, the prime layer is the first canonical orthogonal splitting layer after multiplication, divisibility, unit, and the required order and natural-number structure have been displayed. It is not the absolute base of the tower. This is the axis-form reading of Definition 9414.145.*

Definition 9414.195 (Axis layer)**.** *An* axis layer *over a displayed source carrier T is a packet*

$$\mathcal{A}_n = (A_n, R_n, \Phi_n, \mathsf{NF}_n, \Lambda_n)$$

where A_n is a displayed family of coordinate axes, R_n is the record carrier expressible at the layer, Φ_n is a finite-support coordinate readout

$$\Phi_n : R_n \to C^{(A_n)},$$

NF_n is a normal-form classifier on such coordinate records, and Λ_n records formation, uniqueness, readback, and residual gap data.

Definition 9414.196 (Finite axis expression)**.** *Given an axis layer $\mathcal{A}_n$, a finite expression of a record $x : R_n$ is a coordinate row*

$$\Phi_n(x) = \sum_{a \in A_n}^{\text{fin}} c_a e_a$$

together with a normal-form certificate

$$\mathsf{NF}_n\big((c_a)_{a \in A_n}\big)$$

and a readback certificate identifying the coordinate expression with x at the classifier resolution of R_n.

Definition 9414.197 (Finite code prime window)**.** *Suppose a layer has a finite natural-number code*

$$\mathrm{code}_n : R_n \to \mathsf{Nat}^{\uparrow}$$

and a partial readback on the image of the code,

$$\mathrm{decode}_n : \mathrm{im}(\mathrm{code}_n) \to R_n.$$

For a finite set $S \subset_{\text{fin}} \mathsf{Prime}^{\uparrow}$, the prime-window readout of $x : R_n$ is

$$\Pi_{n,S}(x) := \big(v_p(\mathrm{code}_n(x))\big)_{p \in S}.$$

The full prime-coordinate readout is the finite-support family

$$\Pi_{n,\mathsf{Prime}^{\uparrow}}(x) := \big(v_p(\mathrm{code}_n(x))\big)_{p \in \mathsf{Prime}^{\uparrow}}.$$

Theorem 9414.198 (Finite codes have prime-coordinate normal forms)**.** *Assume $x : R_n$ has a finite code and that the readback row satisfies*

$$\mathrm{decode}_n(\mathrm{code}_n(x)) \sim_n x.$$

Then x admits a finite-support prime-coordinate expression.

Proof. By unique factorization, the positive natural code has a prime factorization

$$\mathrm{code}_n(x) = \prod_{p \in \mathsf{Prime}^{\uparrow}} p^{v_p(\mathrm{code}_n(x))}$$

with only finitely many nonzero exponents. Hence the family

$$\left(v_p(\mathrm{code}_n(x))\right)_{p \in \mathsf{Prime}^{\uparrow}}$$

is finite-support. The displayed readback row then returns the code to a record classified with x. Thus the prime-coordinate row is a normal-form expression of x at the layer resolution. □

Definition 9414.199 (Axis-generation operator)**.** *An* axis-generation operator $\mathcal{G}$ *assigns to an axis family A the family generated by the admissible formation rows*

$$\begin{aligned}\mathcal{G}(A) = A \cup \mathsf{PrimeSplit}(A) \cup \mathsf{Ratio}(A) \cup \mathsf{EquationRoot}(A)\\ \cup \mathsf{Completion}(A) \cup \mathsf{OrthogonalJoin}(A) \cup \mathsf{Transform}(A).\end{aligned}$$

Here PrimeSplit *reads finite codes through prime axes,* Ratio *forms fraction axes,* EquationRoot *records roots forced by displayed equations,* Completion *records limit and completion axes,* OrthogonalJoin *records independent coordinate joins, and* Transform *records Fourier, Laplace, zeta, or analogous transform axes when their carriers and readbacks are displayed.*

Definition 9414.200 (Recursive axis tower)**.** *A* recursive axis tower *is a monotone sequence of axis families*

$$A_0 \subseteq A_1 \subseteq A_2 \subseteq \cdots$$

with

$$A_{n+1} = \mathcal{G}(A_n)$$

for the displayed axis-generation operator. Its expressive union is

$$A_\omega := \bigcup_{n<\omega} A_n.$$

The union is a tower-internal expressive surface over T, not a second source carrier.

Theorem 9414.201 (Relative absence of tower-external axes)**.** *If an axis concept is defined as an axis obtained by finitely many applications of $\mathcal{G}$, or as a finite normal-form combination of such axes, then it belongs to some A_n.*

Proof. Induct on the formation height of the axis concept. At height zero the concept belongs to the initial displayed family A_0 or to a finite combination over it. At successor height, the concept is produced by one of the formation rows contained in $\mathcal{G}$ from concepts already available at bounded height. By the induction hypothesis those inputs belong to some common A_n. The defining equation $A_{n+1} = \mathcal{G}(A_n)$ places the output in A_{n+1}. A finite normal-form combination uses only finitely many such axes, hence lies in a sufficiently high finite layer. □

Definition 9414.202 (Multiplicative atom normal form)**.** *The multiplicative atom normal form of a positive natural number is its prime-coordinate expression*

$$n = \prod_{p \in \mathsf{Prime}^{\uparrow}} p^{v_p(n)}.$$

Its classifier is multiplicative divisibility with unit rows and unique-factorization certificates.

Definition 9414.203 (Recursive additive normal form)**.** *A recursive additive normal form is a finite expression*

$$n = \sum_k \varepsilon_k F_k$$

whose allowed coefficients and local exclusion rules are supplied by a recursive axis grammar. In the Zeckendorf case,

$$\varepsilon_k \in \{0, 1\}, \qquad \varepsilon_k \varepsilon_{k+1} = 0.$$

Its classifier is additive value together with the no-adjacent normal grammar.

Principle 9414.204 (Prime and Zeckendorf normal forms are complementary)**.** *Prime factorization and Zeckendorf normal form are both unique finite-expression schemes, but they answer different classifier questions. Prime factorization reads multiplicative atoms; Zeckendorf normal form reads recursive additive axes with a local exclusion rule. Neither classifier replaces the other.*

Definition 9414.205 (Classifier-relative irreducible axis)**.** *Let $\mathcal{A}_n$ be an axis layer whose normal-form classifier admits a displayed composition operation*

$$\star_n : R_n \times R_n \to R_n$$

with a unit row 1_n, or more generally a displayed finite generation grammar. A row $p : R_n$ is a classifier-relative irreducible axis *when it is not classified with the unit and every licensed decomposition of p is trivial at the layer classifier:*

$$p \not\sim_n 1_n$$

and

$$p \sim_n a \star_n b \quad \Longrightarrow \quad a \sim_n 1_n \text{ or } b \sim_n 1_n.$$

In a generation grammar without a single binary operation, the same phrase means that p is a normal axis row not obtainable by a non-trivial lower formation rule allowed by the classifier and ledger.

Definition 9414.206 (BEDC-generable self-similar axis system)**.** *A* BEDC-generable self-similar axis system *over a source carrier T is a packet*

$$\mathcal{S} = (X, F, \theta, P, \mathsf{NF}, \rho, \Lambda)$$

where X is a displayed record carrier, F is the recursive shape operator, θ is a self-similar decomposition row

$$\theta : X \to F(X),$$

$P : T \to X$ is the source readout, NF is a finite normal-form classifier for the displayed expressions of X, ρ is the recursive readback map from normal expressions to X, and Λ records formation, stability, irreducible-support, and gap data. The system is read as BEDC-generable only through this packet; the self-similar equation is not admitted as a bare untyped object.

Definition 9414.207 (Irreducible support basis)**.** *An irreducible support basis for Definition 9414.206 is a displayed axis family $B_{\mathcal{S}}$ such that every non-unit normal expression has a finite support row*

$$\mathrm{supp}_{\mathcal{S}}(x) \subset_{\mathrm{fin}} B_{\mathcal{S}}$$

and every $b \in B_{\mathcal{S}}$ is a classifier-relative irreducible axis in the sense of Definition 9414.205. The basis is part of the certificate data; it is not inferred from self-similarity alone.

Theorem 9414.208 (Relative priming of self-similar normal forms)**.** *Let $\mathcal{S}$ be a BEDC-generable self-similar axis system equipped with finite normal forms, recursive readback, classifier stability, and an irreducible support basis. Then every non-unit normal row of $\mathcal{S}$ exposes classifier-relative irreducible axes. These axes are prime-like only relative to the classifier and ledger of $\mathcal{S}$.*

Proof. Let $x : X$ be a non-unit normal row. By the finite normal-form clause of Definition 9414.206, x has a finite normal expression. By Definition 9414.207, the support of this expression is a finite row

$$\mathrm{supp}_{\mathcal{S}}(x) \subset_{\mathrm{fin}} B_{\mathcal{S}}.$$

Since x is non-unit, its normal support contains at least one displayed axis $b \in B_{\mathcal{S}}$. The basis certificate says that each such b is classifier-relative irreducible. The recursive readback row ρ and the classifier-stability ledger identify the normal expression with x at the resolution of $\mathcal{S}$, so the exposed irreducible axes are invariants of the displayed normal row. No statement about ordinary integer primes follows unless the classifier is the multiplicative-divisibility classifier of Definition 9414.202. □

Principle 9414.209 (Self-similar priming is relative)**.** *The phrase "prime-like atom" is meaningful in this chapter only after the source carrier, classifier, normal-form grammar, readback map, and irreducible-support ledger have been displayed. In the multiplicative-divisibility classifier the atoms are ordinary primes. In a recursive additive classifier they are Zeckendorf or Fibonacci axes. In a spectral classifier they may be conjugate characteristic roots, as in Definition 9346.13. In a local completion classifier they may be places or valuation rows. In a zeta-facing classifier they may be prime-local probes or zero-ledger invariant rows. These are classifier-relative invariants, not one absolute layer of objects shared by all self-similar systems.*

Definition 9414.210 (Fibonacci-type recursive axis system)**.** *A recursive orthogonal-axis system is* Fibonacci type *when its local normalisation row contains the carry rule*

$$e_k + e_{k+1} \rightsquigarrow e_{k+2}$$

and its normal records forbid simultaneous activation of adjacent axes.

Theorem 9414.211 (Fibonacci-type normal forms are Zeckendorf-type)**.** *In a Fibonacci-type recursive axis system, every normal finite expression is Zeckendorf-type: it is a finite sum of non-adjacent recursive axes.*

Proof. The carry row

$$e_k + e_{k+1} \rightsquigarrow e_{k+2}$$

identifies adjacent activation as non-normal. Repeatedly applying the local normalisation row eliminates adjacent pairs and replaces them by a higher recursive axis. A normal expression is therefore precisely one in which no adjacent pair remains. This is the Zeckendorf-type grammar recorded in Definition 9347.1 and in the finite-support layer of Definition 9347.10. □

Theorem 9414.212 (Golden scale from second-order local recursion)**.** *Assume a positive recursive axis scale* (a_n) *satisfies*

$$a_{n+2} = a_{n+1} + a_n$$

and that the ratio

$$\lambda = \lim_{n\to\infty} \frac{a_{n+1}}{a_n}$$

exists. Then

$$\lambda^2 = \lambda + 1.$$

Consequently, the positive scale is the golden scale φ*.*

Proof. Divide the recurrence by a_{n+1}:

$$\frac{a_{n+2}}{a_{n+1}} = 1 + \frac{a_n}{a_{n+1}}.$$

Taking the displayed limit gives

$$\lambda = 1 + \frac{1}{\lambda}.$$

Equivalently, $\lambda^2 = \lambda + 1$. The positive solution is the golden scale φ. □

Principle 9414.213 (Scope of Fibonacci and golden appearances)**.** *Fibonacci and golden-scale rows are licensed when the relevant carrier has a second-order local recursion, adjacent-axis exclusion, and a normal-form or self-similar growth certificate. They are not universal explanations of unrelated phenomena. In the Axis-Zeckendorf route this scope is enforced by the fold ledger, residual-fiber row, and cannot-claim boundary of Definition 9346.38.*

Principle 9414.214 (Axis formation sequence)**.** *The general motion of a recursive axis tower is*

displayed axes → *orthogonal combination* → *local conflict* → *normalisation* → *derived axis.*

This sequence is a formation pattern over the same source carrier T*. It does not license an unledgered passage to an external ontology.*

Principle 9414.215 (Finite expression as audited normal form)**.** *The finite expression of a mathematical source item is an audited normal-form row over a generated axis family. Prime decompositions, Zeckendorf decompositions, algebraic root extensions, completions, orthogonal joins, and transform carriers are different ways of displaying such rows, each under its own classifier, readback map, and residual ledger.*

9414.11 Constructive information generation

Remark 9414.216 (Paper-side theory status)**.** *This section records the paper-side synthesis named* constructive information generation*. It is tracked against the Lean information-generation witness and finite trace carriers. Its role is to give one vocabulary for the preceding projection, extension, and recursive-axis normal-form sections: information is not treated as a pre-existing collection of objects, but as an auditable structure generated from a source carrier through interfaces, classifiers, orthogonal axes, compatible extensions, and ledger closure.*

Lean4 (definition) `BEDC.RealityConstrained.InfoGenWitness`
Lean4 (definition) `BEDC.RealityConstrained.GenerationTrace`

Definition 9414.217 (Constructive information generation layer)**.** *Let T be a displayed source carrier. A* constructive information generation layer *over T is a packet*

$$\mathcal{I}_n = (R_n, \sim_n, P_n, \Lambda_n, \mathsf{Cert}_n, \mathsf{Aud}_n)$$

where R_n is the record carrier, $\sim_n$ is the layer classifier,

$$P_n : T \to R_n$$

is the source readout, Λ_n is the provenance and gap ledger, Cert_n records naming, stability, transport, and replay certificates, and Aud_n records the audit rows by which a consumer may check formation and readback.

Definition 9414.218 (Layer-generated information)**.** *For a source row $t : T$, the information generated at layer n is the certified record*

$$\mathsf{Info}_n(t) := \big(P_n(t), \Lambda_n(t), \mathsf{Cert}_n(t), \mathsf{Aud}_n(t)\big).$$

The visible part of this information is $P_n(t)$. The full information row includes the ledger and certificate data that explain why the visible record is licensed.

Principle 9414.219 (No bare information objects)**.** *In constructive information generation, an information object is not admitted merely by being named. It enters the theory through a source history, a signature or record surface, a package or domain row, an evidence row, a classifier, and a gap or audit ledger. This is the vision-level reading of the* `BaseReflectionSetup` *interface:* `Hist`*,* `SigObj`*,* `Pkg`*,* `Pi`*,* `Domain`*,* `Evidence`*, together with relations such as* `hsame`*,* `InDom`*,* `SigGen`*,* `TokIntro`*, and* `InGapSig`*.*

Definition 9414.220 (Information residue)**.** *For a generation layer $\mathcal{I}_n$ and a record $r : R_n$, the information residue over r is*

$$\mathrm{InfoFib}_n(r) := \sum_{t:T} (P_n(t) \sim_n r).$$

The layer-infinite information surface is the family

$$\infty_n^{\mathsf{info}} : R_n \to \mathsf{Type}, \qquad \infty_n^{\mathsf{info}}(r) := \mathrm{InfoFib}_n(r).$$

It is a residual source family over R_n, not a further row of R_n.

Theorem 9414.221 (Visible records need not exhaust source rows)**.** *Let $\mathcal{I}_n$ be a generation layer. If there are source rows $t_0, t_1 : T$ with t_0 separated from t_1 at the source classifier and*

$$P_n(t_0) \sim_n P_n(t_1),$$

then the visible record $P_n(t_0)$ does not exhaust the source information over that record.

Proof. Put $r := P_n(t_0)$. The row t_0 gives an element of

$$\mathrm{InfoFib}_n(r) = \sum_{t:T} (P_n(t) \sim_n r)$$

by reflexivity at the displayed classifier. The displayed relation $P_n(t_0) \sim_n P_n(t_1)$, read symmetrically when needed by the layer classifier, gives an element over the source row t_1 in the same fiber. Since the source rows remain separated, the visible record r has not identified all source information. It is a record surface with a non-trivial residual source family. □

Principle 9414.222 (Layer infinity is not a terminal record)**.** *The expression* ∞_n^{info} *denotes the family*

$$r \mapsto \mathrm{InfoFib}_n(r)$$

over R_n*. It is not an element of* R_n *and not a final object at the end of the layer. It names the residual source family through which a later compatible refinement may continue to read the same source carrier.*

Definition 9414.223 (Compatible information refinement)**.** *Let* $\mathcal{I}_n$ *and* $\mathcal{I}_{n+1}$ *be generation layers over the same source carrier* T*. A* compatible information refinement *is a displayed readback map*

$$\rho_{n+1,n} : R_{n+1} \to R_n$$

with

$$\rho_{n+1,n}(P_{n+1}(t)) \sim_n P_n(t)$$

for every $t : T$*, together with the transport, audit, and gap rows that make this readback reproducible.*

Theorem 9414.224 (Information generation is fiber refinement)**.** *If* $\mathcal{I}_{n+1}$ *is a compatible information refinement of* $\mathcal{I}_n$ *and separates two rows in one information residue of* $\mathcal{I}_n$*, then the refined layer generates no tower-external information. It further distinguishes the residual source fiber of the preceding layer.*

Proof. The readout of the refined layer is still

$$P_{n+1} : T \to R_{n+1},$$

so the source carrier has not changed. The readback condition of Definition 9414.223 is exactly the compatibility row of Definition 9414.169. Hence Definition 9414.170 applies. If the refined layer separates two rows in one residue, then Definition 9414.173 identifies the generation as a residual separation of the preceding layer. □

Lean4 ✓ `BEDC.RealityConstrained.info monotone`
Lean4 ✓ `BEDC.RealityConstrained.readback consistent`

Definition 9414.225 (Information generation axes)**.** *An information generation layer carries an* axis family A_n *when its visible records admit finite-support coordinate expressions over* A_n *in the sense of Definition 9414.196. A subfamily* $(a_i : T \to A_i)_{i:I}$ *is orthogonal when the layer ledger contains the independence certificate of Definition 9414.180.*

Definition 9414.226 (Constructive information generation operator)**.** *The constructive information generation operator is the axis-generation operator of Definition 9414.199 equipped with a ledger-closure clause:*

$$\mathcal{G}_{\mathsf{info}}(A) = A \cup \mathsf{PrimeSplit}(A) \cup \mathsf{Ratio}(A) \cup \mathsf{EquationRoot}(A)$$
$$\cup \mathsf{Completion}(A) \cup \mathsf{OrthogonalJoin}(A) \cup \mathsf{Transform}(A) \cup \mathsf{LedgerClosure}(A).$$

The final clause records that a generated expression is not fully admitted until provenance, readback, stability, and gap rows have been entered in the layer ledger.

Definition 9414.227 (Constructive information generation tower)**.** *A* constructive information generation tower *over T is a packet*

$$\mathfrak{I} = \left(T, \mathcal{I}_n, A_n, \mathcal{G}_{\mathsf{info}}, \rho_{n+1,n}, \Lambda_n, \mathsf{Cert}_n, \mathsf{Aud}_n\right)_{n<\omega}$$

such that

$$A_{n+1} = \mathcal{G}_{\mathsf{info}}(A_n)$$

and each successor layer is equipped with a compatible information refinement row whenever its visible records extend the preceding layer.

Definition 9414.228 (Generated auditable information)**.** *Relative to a tower $\mathfrak{I}$, a row is* generated auditable information *when it is obtained by finitely many applications of $\mathcal{G}_{\mathsf{info}}$, finite coordinate formation, compatible readback, residual fiber separation, or ledger closure, and its formation record includes the certificates required by the layers it uses.*

Theorem 9414.229 (Relative absence of tower-external information)**.** *Every generated auditable information row relative to $\mathfrak{I}$ belongs to a finite layer of the tower.*

Proof. The formation record is finite by Definition 9414.228. Induct on its length. Initial source and layer rows belong to the first finite layer in which they are displayed. A successor formation step is one of the clauses of $\mathcal{G}_{\mathsf{info}}$, a finite coordinate formation, a compatible readback, a residual separation, or a ledger-closure row. Each such step is displayed in the next layer or in a finite later layer. The induction therefore places the generated row in some $\mathcal{I}_n$. □

Definition 9414.230 (Corecursive readout loop)**.** *A* corecursive readout loop *over a source carrier T is a finite or cyclic family of generation layers*

$$\mathcal{I}_0, \mathcal{I}_1, \ldots, \mathcal{I}_n$$

with source readouts

$$P_i : T \to R_i$$

and displayed readback maps

$$\rho_{j,i} : R_j \to R_i$$

whenever the loop returns a later visible surface to an earlier one, such that

$$\rho_{j,i}(P_j(t)) \sim_i P_i(t)$$

for every $t : T$. A loop row is admitted only together with the transport, audit, and gap ledgers that make each readback reproducible.

Principle 9414.231 (Visible origins are gauges)**.** *An initial visible surface is an observation origin, not an absolute source. A binary surface*

$$P_B : T \to \{B_0, B_1\}$$

displays a minimal two-row classifier for the current inquiry, but the rows B_0 and B_1 are not themselves the whole source carrier. Their residual source families are

$$\mathrm{Fib}(B_i) := \sum_{t:T} (P_B(t) = B_i).$$

Changing the observation origin replaces the visible gauge; it does not replace the source carrier unless a separate recovered-carrier certificate is supplied.

Theorem 9414.232 (Binary visible rows are not bottom points)**.** *Let $P_B : T \to \{B_0, B_1\}$ be a binary visible surface. If for some $i \in \{0, 1\}$ the fiber*

$$\sum_{t:T} (P_B(t) = B_i)$$

contains two source-separated rows, then B_i is not a bottom point of the source carrier.

Proof. If B_i were a bottom point of the source carrier at this interface, then a source row over B_i would be fully represented by that visible marker. The displayed fiber instead contains two source-separated rows with the same visible marker. Thus the marker is a quotient record of the source carrier, not a source atom. □

Definition 9414.233 (Binary fiber self-similarity)**.** *A binary visible surface $P_B : T \to \{B_0, B_1\}$ is* fiber-self-similar *when for each displayed $i \in \{0, 1\}$ the fiber*

$$T_{B_i} := \sum_{t:T} (P_B(t) = B_i)$$

carries a further binary readout

$$P_{B,i} : T_{B_i} \to \{B_0, B_1\}$$

with a readback certificate to the original binary classifier.

Theorem 9414.234 (Binary fiber self-similarity gives finite path certificates)**.** *If a binary visible surface is fiber-self-similar, then every source row $t : T$ determines binary prefixes*

$$B_{i_0}, B_{i_1}, \ldots, B_{i_k}$$

of arbitrary finite length, and each prefix is accompanied by a finite iterated-fiber certificate.

Proof. The first marker is $P_B(t) = B_{i_0}$. This supplies an element of the fiber $T_{B_{i_0}}$. The self-similar readout on that fiber supplies the next marker B_{i_1} and a certificate that the source row lies in the corresponding refined fiber. Repeating this finite construction gives any requested finite prefix. Each step contributes one displayed readout and one readback certificate, so the prefix certificate remains finite. □

Definition 9414.235 (Locally finite global corecursive tower)**.** *A constructive information tower is* locally finite and globally corecursive *when every admitted information row has a finite formation record in the sense of Definition 9414.228, while the displayed source carrier may be read again through residual fibers and readback loops as in Definition 9414.230. The global structure is not required to expose an absolute bottom layer, but every accepted row must have a finite audit prefix.*

Theorem 9414.236 (Corecursive towers have finite audit prefixes)**.** *In a locally finite globally corecursive tower, every generated auditable information row is certified by a finite prefix of the readout loop.*

Proof. By Definition 9414.235, the row has a finite formation record. Each occurrence of a loop return is a displayed readback map of Definition 9414.230, equipped with transport, audit, and gap ledgers. Replacing each loop return in the formation record by its finite readback certificate yields a finite prefix using the same clauses as Definition 9414.228. Hence Definition 9414.229 places the row in a finite layer. □

Principle 9414.237 (Readout cycles enrich fibers)**.** *A readout cycle is not a logical circular definition. Returning from a later layer to an earlier visible surface identifies the earlier classifier row by readback, while the intervening formation record remains in the ledger. Thus a cycle may return to the same visible marker, but it returns with a richer residual fiber and a longer audit surface. Proofs in such a tower are carried by invariants transported through displayed readback maps, as in Definition 9414.134, rather than by appeal to an absolute tower bottom.*

Theorem 9414.238 (Readout loops are not layer equalities)**.** *A corecursive readout loop from $\mathcal{I}_n$ back to $\mathcal{I}_0$ does not imply $\mathcal{I}_n = \mathcal{I}_0$. It implies only that the later visible row reads back to the earlier classifier:*

$$\rho_{n,0}(P_n(t)) \sim_0 P_0(t).$$

Proof. The loop condition is a statement in the record carrier R_0 and its classifier $\sim_0$. It supplies neither an equality of carriers $R_n = R_0$ nor an equality of readouts $P_n = P_0$. The higher layer may carry additional ledgers, certificates, and fiber-separation rows that are compressed by $\rho_{n,0}$ when read back to R_0. □

Theorem 9414.239 (Bottomless corecursive tower principle)**.** *Let $\mathfrak{I}$ be a tower over one source carrier T. If each layer is a source readout, each successor layer has compatible readback, each visible record retains its information residue, every accepted information row has a finite formation record, and predicates are transported by displayed readback invariants, then the tower may be globally bottomless while all admitted information remains locally finite and auditable.*

Proof. All layers read from the same source carrier by assumption, and compatible readback prevents successor layers from becoming tower-external source objects. Information residues keep visible records from being terminal source atoms. Finite formation records give finite audit prefixes by Definition 9414.236. Predicate transport through readback maps gives the invariant proof discipline of Definition 9414.134. These clauses allow the global readout system to be corecursive without requiring any visible origin to be an absolute bottom. □

Theorem 9414.240 (Lawful nontrivial generation is generalized extension)**.** *Let a successor layer in $\mathfrak{I}$ produce a visible record not separated by the preceding layer. If the successor carries a compatible readback row and separates a preceding information residue, then that generation is a generalized analytic continuation in the sense of Definition 9414.172.*

Proof. The readback row gives

$$\rho_{n+1,n}(P_{n+1}(t)) \sim_n P_n(t)$$

for every source row. Thus the successor is a compatible layered extension. The assumed residual separation says exactly that it is fiber-distinguishing. By Definition 9414.172, this is a generalized analytic continuation. □

Principle 9414.241 (Normal forms as information-generation classifiers)**.** *Prime decomposition and Zeckendorf decomposition are canonical examples of information generation by classifier-specific normal forms. The prime-coordinate normal form of Definition 9414.202 reads multiplicative atoms. The recursive additive normal form of Definition 9414.203 reads no-adjacent recursive axes. Their complementarity is the content of Definition 9414.204.*

Principle 9414.242 (Second-order recursion and golden scale)**.** *The golden scale is licensed in this theory only when the carrier has the second-order recursion, adjacent-axis exclusion, and growth certificate of Definition 9414.212. It is therefore a structural invariant of a specific normalisation grammar, not an unrestricted explanatory constant.*

Principle 9414.243 (Recovered carriers as ledgered information)**.** *Recovered carriers are information-generation rows whose identity is distributed across compatible projections, completions, transforms, and ledgers. The zeta carrier of Definition 9243.2 is read in this way: Dirichlet, Euler, continuation, archimedean completion, functional-equation, pole, zero, branch, and transport rows jointly license the carrier. This principle records typing and compatibility; it does not discharge the zero-ledger obstruction named in Definition 9414.190.*

Definition 9414.244 (Constructive information generation theory)**.** Constructive information generation theory *is the study of towers*

$$\mathfrak{I} = \left(T, \mathcal{I}_n, A_n, \mathcal{G}_{\mathsf{info}}, \rho_{n+1,n}, \Lambda_n, \mathsf{Cert}_n, \mathsf{Aud}_n\right)_{n<\omega}$$

and of the finite auditable rows they generate from T through orthogonal splitting, recursive combination, local completion, compatible extension, transform formation, normalisation, and ledger closure.

Theorem 9414.245 (Core form of constructive information generation)**.** *In a constructive information generation tower, every finite auditable information row is produced by a finite chain of source readout, classifier formation, orthogonal-axis generation, compatible extension, normal-form certification, and ledger closure.*

Proof. By Definition 9414.228, an admitted information row has a finite formation record using exactly the displayed generation operations and their audit rows. The source readout and classifier formation place the row in a typed layer. Orthogonal-axis generation and normal-form certification give its finite expression when coordinates are used. Compatible extension supplies readback to earlier layers, and ledger closure supplies provenance, stability, replay, and gap data. Hence the row is produced by the stated finite chain. □

Concretized in §9066: The finite trace packet realizes constructive information generation as visible rows plus residue and refinement data.

9414.12 Quantum measurement as information generation

Concretized in §8949: Measurement residue ledgers are realized as finite projection, fiber, section-update, and audit NameCert rows.

Remark 9414.246 (Paper-side boundary)**.** *This section records a structural interface between constructive information generation and quantum measurement. It is not a formulation of quantum mechanics, not a substitute for Hilbert-space dynamics, and not a derivation of the Born rule. Its role is narrower: to identify the measurement, projection, residue, and update grammar that a later physical quantum interface would have to certify.*

Lean4 (definition) `BEDC.RealityConstrained.MeasurementBasis`
Lean4 (definition) `BEDC.RealityConstrained.MeasurementInterface`

Definition 9414.247 (Quantum-facing generation layer)**.** *A* quantum-facing generation layer *over a source carrier T is a constructive information generation layer*

$$\mathcal{I}_n = (R_n, \sim_n, P_n, \Lambda_n, \mathsf{Cert}_n, \mathsf{Aud}_n)$$

together with a displayed measurement-context row M_n. The readout

$$P_n : T \to R_n$$

is interpreted as the measurement-interface projection for that context, and R_n is the corresponding outcome carrier. The context row records the preparation surface, observable or probe family, instrument configuration, and public outcome ledger. Without M_n, the same source readout is only an abstract projection row.

Principle 9414.248 (Measurement results are licensed records)**.** *A quantum-facing outcome is not treated as a bare pre-existing value. It is an information row of the form*

$$\mathsf{Info}_n(t) = (P_n(t), \Lambda_n(t), \mathsf{Cert}_n(t), \mathsf{Aud}_n(t))$$

as in Definition 9414.218, with the additional measurement-context row of Definition 9414.247. The visible outcome is $P_n(t)$; the licensed record includes the preparation, interface, classifier, evidence, replay, and audit data that make the outcome public.

Lean4 (definition) `BEDC.RealityConstrained.MeasurementGenerationWitness`

Lean4 ✓ `BEDC.RealityConstrained.MeasurementInterface.readback entry listed and projected`

Definition 9414.249 (Measurement residue)**.** *For a quantum-facing generation layer and an outcome $r : R_n$, the measurement residue is the information fiber*

$$\mathrm{QFib}_n(r) := \sum_{t:T} (P_n(t) \sim_n r).$$

It is the source structure not separated by the chosen measurement interface. It is not a hidden classical value and not an additional outcome row of R_n.

Principle 9414.250 (Projection is not hidden-variable assignment)**.** *Reading a source through a measurement interface compresses it to a public outcome and leaves a residual fiber. This does not assert that the source already carried a definite classical value for every possible measurement. It asserts only that a chosen layer has exposed one record surface while the remaining source distinctions are retained as fiber and ledger data.*

Definition 9414.251 (Hilbert-style axis packet)**.** *A* Hilbert-style axis packet *is a candidate physical refinement of an information-generation axis family. It consists of a displayed carrier H, a finite or certified orthogonal probe family*

$$E = \{e_i : i \in I\},$$

projection rows $\Pi_i : H \to H_i$, scalar readbacks c_i, and a ledger recording inner-product, normalization, and probe provenance. When such a packet is available, a state-like row may be displayed in the form

$$\psi = \sum_{i \in I} c_i e_i$$

at the certified resolution of the packet.

Principle 9414.252 (Measurement bases are readout layers)**.** *Different quantum measurement bases correspond, in this vocabulary, to different readout layers over the same source carrier. A position-like readout, a momentum-like readout, and two spin-direction readouts need not share a single classical refinement layer. When no displayed common refinement and readback ledger is present, the theory may compare the layers only through certified bridge rows, not by treating all outcomes as simultaneously present classical coordinates.*

Principle 9414.253 (Noncommutativity as absence of a classical common refinement)**.** *For quantum-facing layers, noncommuting observables may be read structurally as a failure of a common classicalizing refinement: two readout surfaces over T do not jointly descend to one visible carrier that records both outcome families with compatible readback maps. This principle is a typing guide. It does not by itself supply the operator commutator, the uncertainty bound, or the Hilbert-space theorem behind a particular physical model.*

Definition 9414.254 (Born-weight layer)**.** *A* Born-weight layer *over a Hilbert-style axis packet is an additional measure ledger assigning an outcome weight*

$$\mu_n(i)$$

to each displayed projection row. In the usual quantum semantics this weight is

$$\mu_n(i) = \|\Pi_i \psi\|^2.$$

The layer must include normalization, positivity, finite or countable additivity at the declared scope, and calibration rows connecting the weights to empirical frequencies.

Principle 9414.255 (Born rule is not supplied by projection grammar)**.** *Constructive information generation supplies source, readout, residue, axis, and ledger grammar. It does not, by itself, choose the Born weight map. A quantum physical theory must add the Born-weight layer of Definition 9414.254, together with the physical calibration and experimental prediction rows that make those weights empirical.*

Definition 9414.256 (Section-style measurement update)**.** *Given an outcome $r : R_n$, a section-style measurement update is a licensed map*

$$U_r : R_n \to \mathrm{QFib}_n(r)$$

or, in a Hilbert-style packet, a normalized post-outcome row such as

$$\psi \mapsto \frac{\Pi_r \psi}{\|\Pi_r \psi\|}.$$

Such an update is admissible only when its domain, nonzero denominator condition, post-outcome carrier, and replay ledger are displayed.

Principle 9414.257 (State update is a certified section)**.** *The section-style reading of measurement update does not make collapse a mysterious primitive. It treats post-measurement state selection as a licensed section from a visible outcome surface into an admissible post-outcome fiber. Without the section certificate, the visible outcome does not determine a unique source row.*

Definition 9414.258 (Entanglement as non-product residue)**.** *Let a composite source be read through local outcome carriers R_A and R_B. A composite residue over (r_A, r_B) is* non-product *when there is no displayed equivalence*

$$\mathrm{QFib}_{AB}(r_A, r_B) \simeq \mathrm{QFib}_A(r_A) \times \mathrm{QFib}_B(r_B)$$

compatible with the local readback ledgers. Such non-product residue is the information-generation form of an entanglement boundary.

Principle 9414.259 (Entanglement keeps the source global)**.** *An entangled composite may have local readouts while its residual source fiber remains global. Local outcomes do not exhaust the source, and a product of local fibers is not available without a displayed product decomposition certificate. This is the fiber-language counterpart of the usual refusal to treat an entangled state as a product state.*

Principle 9414.260 (Qubit boundary)**.** *A two-outcome readout resembles the binary carriers used in the Axis-Zeckendorf and golden conjugate interfaces, but a qubit is not just a two-point set. A qubit requires complex amplitudes, phase, normalization, admissible measurement axes, and Born weights. The binary carrier supplies only the visible outcome alphabet; the physical quantum content lives in the certified amplitude, phase, weight, and update layers.*

Principle 9414.261 (Quantum physical closure obligations)**.** *To turn the preceding grammar into a quantum physical theory one must add at least: Hilbert-space carrier laws, complex amplitude rows, observable/operator laws, unitary time-evolution rows, Born-weight calibration, measurement-update rules, tensor-product composition, and experiment-facing prediction ledgers. Without these rows the chapter records only the information-generation and measurement-projection syntax.*

9414.13 Finite observation and open fit

Definition 9414.262 (Reality trace)**.** *For a physical system R, a reality trace of length n is a finite sequence*

$$H_n(R) = (o_0, o_1, \ldots, o_n)$$

of observations generated by interacting with R through an admissible observation protocol.

The trace is not reality itself. It is the finite observational history through which reality becomes available to a model.

Definition 9414.263 (Observation bundle)**.** *An observation bundle Π is a finite or recursively extendable family of admissible questions. Given R, M, and a trace H_n, the observed and model-generated signatures are written*

$$\mathrm{ObsSig}_\Pi(R \mid H_n), \qquad \mathrm{ModSig}_\Pi(M \mid H_n).$$

Definition 9414.264 (Finite observational fit)**.** *A model M has finite observational fit to a system R at trace length n, relative to Π, when*

$$\mathrm{ModSig}_\Pi(M \mid H_n) \sim_\Pi \mathrm{ObsSig}_\Pi(R \mid H_n).$$

This judgment is denoted $\mathrm{Fit}_n(M, R; \Pi)$.

Finite fit says only that M has not been separated from R by the finite observations available up to H_n. It does not assert $M = R$.

Definition 9414.265 (Open physical fit)**.** *Open physical fit, written* $\mathrm{OpenFit}(M, R; \Pi)$*, is the continuing condition that every actually obtained finite trace carries a finite fit certificate, while no internal final certificate is assumed for*

$$\forall n, \mathrm{Fit}_n(M, R; \Pi).$$

Concretized in §1131: Finite observation fit becomes a finite NameCert packet with explicit refutation and open-continuation ledgers.

Concretized in §1168: Open physical fit becomes a finite residue-gate NameCert packet whose refutation row stays visible.

Concretized in §2247: Observation residual fit is realized as finite observed-signature, model-signature, residual-row, refutation-surface, open-continuation, transport, replay, provenance, and NameCert data.

Definition 9414.266 (Physical induction certificate)**.** *A physical induction certificate is a stability certificate*

$$\mathrm{PhysInd}(M, R; \Pi)$$

licensing a transition from previously observed fit to predicted continuation fit:

$$\mathrm{Fit}_n(M, R; \Pi) \rightsquigarrow \mathrm{PredFit}_{n+1}(M, R; \Pi).$$

This differs from mathematical induction. Mathematical induction applies after the carrier and its constructors are already closed. Physical induction is a stability claim about future observations of a system whose complete generative law is not externally given.

Definition 9414.267 (Final-fit oracle)**.** *A final-fit oracle for M and R is a hypothetical judgment $\Omega(M, R; \Pi)$ such that*

$$\Omega(M, R; \Pi) \Longleftrightarrow \forall H,\ \mathrm{ModSig}_\Pi(M \mid H) \sim_\Pi \mathrm{ObsSig}_\Pi(R \mid H),$$

where H ranges over all admissible actual and counterfactual observation histories.

The framework rejects such an oracle as an internally available physical object. It would be an observer above all observers, contrary to the no-global-standpoint discipline of chapter 9419.

9414.14 Open-fit theorems

Theorem 9414.268 (Finite fit does not imply total fit)**.** *For any finite trace length n,*

$$\mathrm{Fit}_n(M, R; \Pi)$$

does not imply

$$\forall k \geq n, \mathrm{Fit}_k(M, R; \Pi).$$

Proof. By Definition 9414.264, $\mathrm{Fit}_n(M, R; \Pi)$ compares model and system only on the finite trace H_n. The judgment contains no information about observations not yet made. Two continuations

$$H_n \cdot o_{n+1} \quad \text{and} \quad H_n \cdot o'_{n+1}$$

may agree on the prefix and separate at the next observation. A model can match R on the prefix and fail on one continuation. To infer future fit one must add a stability or physical induction certificate. □

Corollary 9414.269 (Empirical truth is not model identity)**.** *A successful finite model fit supports undefeatedness by the displayed trace, not model-reality identity.*

Proof. By Definition 9414.268, finite fit cannot imply total fit. Since identity would require agreement across all admissible observations and all reality-facing properties, finite fit is weaker than identity. □

Theorem 9414.270 (Mathematical induction and physical induction have different closures)**.** *Mathematical induction is valid when the target carrier is closed under known constructors. Physical induction requires an additional stability certificate because the complete future observation carrier of reality is not internally given.*

Proof. Mathematical induction over a carrier such as $\mathbb{N}$ relies on a closed generation rule:

$$0 \in \mathbb{N}, \qquad n \in \mathbb{N} \Longrightarrow S(n) \in \mathbb{N}.$$

The base case and successor step range over the closure of that carrier. Physical observation begins from a finite trace $H_n = (o_0, \ldots, o_n)$, but the observer does not possess a constructor theorem saying that every future reality-facing observation arises by a known successor rule compatible with the model. The transition from Fit_n to future fit therefore requires PhysInd as additional stability data. □

Corollary 9414.271 (Physical intuition is a classifier prior)**.** *What is often called physical intuition is a pre-formal expectation that future observations will remain within the current classifier.*

Proof. By Definition 9414.270, future fit does not follow from finite fit alone. Expectations based on prior experience, symmetry, scale, or dynamical regularity function as priors over admissible continuations. They await certification by further observation or by a displayed stability argument. □

Corollary 9414.272 (Physical law as stability certificate)**.** *A physical law is not merely an equation. It is a certified stability claim that a model-generated signature continues to match observed signatures under admissible extensions of observation.*

Proof. By Definition 9414.270, finite fit alone does not justify future prediction. Prediction requires a certificate licensing continuation from current fit to later fit. Since a physical law is used precisely to support such continuation, its certificate role is stability over an open observation process, together with an open surface on which future observations can refute the licensed continuation. □

Theorem 9414.273 (No internal final-fit oracle)**.** *No observer internal to the physical inquiry process can supply a final-fit oracle* $\Omega(M, R; \Pi)$*.*

Proof. An internal observer has a finite history and local observational constraints. To supply $\Omega(M, R; \Pi)$ it would have to certify agreement across all admissible observations, including not-yet-performed observations and observations from other possible perspectives. If the certifying observer is external to all observation histories, it is not internal to the inquiry system. If it is internal, it is itself a history subject to the same locality and no-global-synchronization constraints recorded in chapter 9419. In neither case is an internal final-fit oracle obtained. □

Corollary 9414.274 (Final theory is not an internal scientific certificate)**.** *A physical theory may be undefeated by every available observation, but the judgment that it is final cannot be internally certified.*

Proof. Such a judgment would require a final-fit oracle over all possible observations. Definition 9414.273 excludes that oracle as an internal object. □

Theorem 9414.275 (Model fit is itself an approximation tower)**.** *The judgment that a model approximates reality is itself obtained through a sequence of approximations.*

Proof. To assert that M approximates R, one observes R, obtaining a finite trace H_n rather than R itself. The trace is converted into $\mathrm{ObsSig}_\Pi(R \mid H_n)$. The model produces $\mathrm{ModSig}_\Pi(M \mid H_n)$. The two signatures are compared by $\sim_\Pi$, yielding a finite fit certificate. Thus the adequacy judgment factors as

$$R \longrightarrow H_n \longrightarrow \mathrm{ObsSig}_\Pi \longrightarrow \mathrm{Fit}_n \longrightarrow \mathrm{OpenFit}\,.$$

Each arrow hides information and therefore requires a ledger when later use may depend on the hidden layer. □

Corollary 9414.276 (Evidence for approximation is approximate)**.** *There are two distinct approximation judgments: the model's approximation to the system, and the finite evidence that licenses that approximation judgment. The second is more primitive, because the first is accessible only through it.*

Proof. By Definition 9414.275, the claim that M approximates R is produced through finite traces, signature extraction, classifier comparison, and fit certificates. These mediating structures are finite and revisable. Therefore the evidence for approximation is itself approximation-relative. □

Corollary 9414.277 (Falsification is finite and confirmation is open)**.** *A model can fail by one finite observation, but it cannot be finally confirmed by finitely many observations.*

Proof. A finite trace may produce

$$\mathrm{ModSig}_\Pi(M \mid H_n) \not\sim_\Pi \mathrm{ObsSig}_\Pi(R \mid H_n),$$

which refutes finite fit. Final confirmation would require all admissible finite prefixes, which no single finite trace supplies. □

Concretized in §1132: RealityConstrainedOpenFitUp realizes finite observation fit as an open NameCert packet with finite refutation, continuation, ledger, and no final-fit oracle.

Concretized in §1137: OpenFitPacketUp realizes finite observational fit, finite refutation, and no-final-oracle boundaries as a concrete NameCert packet.

Concretized in §1169: Finite observation refutations are realized as finite BHist NameCert packets separating defeating observations from open-continuation and final-fit refusal rows.

9414.15 Ontic state as stable signature source

The distinction between mathematical approximation and physical adequacy has an ontological counterpart. A physical object is not identified with an arbitrary mathematical representation, nor with the final visible idealization produced by an approximation tower. It is approached as the stable source of reality-facing signatures. Mathematical representations remain indispensable, but they become physically meaningful only when tied to the signatures through which the system manifests itself under admissible observation bundles.

Definition 9414.278 (Ontic state)**.** *For a physical system R and an admissible family of observation bundles $\mathcal{P}$, the ontic state of R is the stable source of the system's reality-facing signatures:*

$$\mathrm{Ont}(R) := \mathrm{StableSource}(\{\mathrm{PhysSig}_\Pi(R)\}_{\Pi\in\mathcal{P}}).$$

This notation does not identify $\mathrm{Ont}(R)$ *with a single representation. A representation M expresses an aspect of* $\mathrm{Ont}(R)$ *only relative to specified bundles, classifiers, stability data, and ledgers.*

Definition 9414.279 (Ontic adequacy)**.** *A mathematical representation M is ontically adequate for R relative to Π when it preserves the physical signatures generated by the ontic state of R:*

$$\mathrm{PhysSig}_\Pi(M) \sim_\Pi \mathrm{PhysSig}_\Pi(\mathrm{Ont}(R)).$$

Ontic adequacy is stronger than formal consistency and stronger than mathematical approximation. It requires preservation of the reality-facing properties through which the system's state is physically manifested.

Definition 9414.280 (Ontic underdetermination)**.** *Representations M_1 and M_2 are ontically underdetermined by Π when*

$$\mathrm{PhysSig}_\Pi(M_1) \sim_\Pi \mathrm{PhysSig}_\Pi(M_2),$$

but there is a refined observation bundle $\Pi' \supseteq \Pi$ such that

$$\mathrm{PhysSig}_{\Pi'}(M_1) \not\sim_{\Pi'} \mathrm{PhysSig}_{\Pi'}(M_2).$$

Definition 9414.281 (Ontic residue)**.** *Let M be a representation of R relative to Π. The ontic residue of M relative to R and Π is the reality-facing content of R not preserved, represented, or queried by M under Π. Schematically,*

$$\mathrm{Res}_\Pi(R, M) := \mathrm{PhysSig}_{\mathcal{P}}(R) \setminus \mathrm{PhysSig}_\Pi(M),$$

where $\mathcal{P}$ denotes a broader family of admissible observation bundles. The notation names hidden or unqueried physical content; it need not be an ordinary set difference.

Definition 9414.282 (Representation ledger)**.** *A representation ledger for M as a model of R records*

$$\mathrm{RepLedger}(M, R; \Pi) = (H_n, \Pi, \mathrm{Classifier}, \mathrm{StabilityCert}, \mathrm{Res}_\Pi(R, M)).$$

It records the finite observational source, observation bundle, comparison classifier, stability certificate, and residue hidden by the representation.

This is the physical counterpart of BEDC's GAP ledger requirement. Compression is permitted, but the source route and hidden material must remain traceable; when compressions compose, the resulting ledger must retain the source map through the intermediate visible interfaces.

Theorem 9414.283 (Syntax does not exhaust ontic state)**.** *Let M be a mathematical representation of a physical system R. The syntactic existence of M does not imply that M exhausts* $\mathrm{Ont}(R)$.

Proof. A mathematical representation supplies equations, spaces, functions, parameters, diagrams, or computational rules. By Definition 9414.278, $\mathrm{Ont}(R)$ is the stable source of reality-facing signatures across admissible bundles. To exhaust that source, M would have to preserve every relevant physical signature of R across those bundles. The mere existence of the syntax of M supplies no observation bundle, classifier, stability condition, or residue ledger. Therefore syntax alone cannot establish ontic exhaustion. □

Corollary 9414.284 (Model as ontic interface)**.** *A model is a certified interface to* $\mathrm{Ont}(R)$*, not the ontic state itself.*

Proof. By Definition 9414.283, a representation does not exhaust the ontic state by syntactic existence. By Definition 9414.279, it becomes ontically adequate only relative to a signature-preservation condition. It therefore functions as an interface to the ontic state under specified conditions. □

Corollary 9414.285 (Realism requires representation ledgers)**.** *A realist interpretation of a model requires a certificate specifying which physical signatures are preserved and which remain as residue.*

Proof. If correspondence is read as ontic adequacy, then Definition 9414.279 requires signature preservation. By Definition 9414.282, such preservation must be accompanied by source, classifier, stability, and residue data. Bare representation is therefore insufficient. □

9414.16 Signature priority and exactness

Definition 9414.286 (Signature-realization map)**.** *A signature-realization map for a representation* M *under* Π *is a map*

$$\sigma_{M,\Pi} : M \longrightarrow \mathrm{PhysSig}_{\Pi}(M)$$

that extracts the physical signature predicted by M *under the observation bundle* Π*.*

Definition 9414.287 (Signature completeness and soundness)**.** *A representation* M *is signature-complete for* R *relative to* Π *when every reality-facing distinction of* R *exposed by* Π *is matched by a model distinction:*

$$\mathrm{PhysSig}_{\Pi}(R) \preceq \mathrm{PhysSig}_{\Pi}(M).$$

It is signature-sound when every distinction predicted by M *under* Π *is physically realized by* R*:*

$$\mathrm{PhysSig}_{\Pi}(M) \preceq \mathrm{PhysSig}_{\Pi}(R).$$

Definition 9414.288 (Signature exactness)**.** *A representation* M *is signature-exact for* R *relative to* Π *when it is both signature-complete and signature-sound, equivalently when*

$$\mathrm{PhysSig}_{\Pi}(M) \sim_{\Pi} \mathrm{PhysSig}_{\Pi}(R).$$

Theorem 9414.289 (Physical adequacy is signature exactness)**.** *A representation* M *is physically adequate for* R *relative to* Π *if and only if it is signature-exact for* R *relative to* Π*.*

Proof. Physical adequacy is the preservation of the reality-facing signature under the relevant observation bundle. This is exactly the equivalence displayed in Definition 9414.288. Completeness says the model misses no relevant distinction; soundness says it invents no unsupported distinction. Together these are signature-level adequacy. □

Corollary 9414.290 (Adequacy does not collapse representation into source)**.** *A physically adequate model may be mathematically non-identical to the system it represents.*

Proof. By Definition 9414.289, adequacy requires matching signatures under Π, not identity of representation and source. The model remains a representation and the system remains the source of the signatures. □

Corollary 9414.291 (Mathematical exactness may be physically inadequate)**.** *A representation may be mathematically exact within its formal system while failing to be physically adequate for R.*

Proof. Mathematical exactness concerns internal validity relative to formal definitions. Physical adequacy concerns signature exactness relative to reality-facing observation. If the mathematically exact model fails to preserve the observed signatures, it is physically inadequate despite its internal exactness. □

9414.17 Residue and refinement

Theorem 9414.292 (Coarse bundles induce ontic underdetermination)**.** *Let Π expose only a proper subset of the reality-facing properties relevant to R. Then there may exist distinct representations M_1 and M_2 such that*

$$M_1 \equiv_{\mathrm{phys},\Pi} M_2$$

while M_1 and M_2 are separated by a refined bundle $\Pi' \supseteq \Pi$.

Proof. Because Π exposes only a subset of the relevant properties, it ignores distinctions that may be exposed by a refinement. Choose representations that agree on all distinctions visible to Π but differ on a distinction visible under Π'. They are physically fit-equivalent under Π and separated under Π', which is exactly ontic underdetermination relative to the coarse bundle. □

Corollary 9414.293 (Underdetermination is bundle-relative)**.** *Underdetermination is indexed by an observation bundle, not absolute.*

Proof. The same pair of representations can be equivalent under Π and inequivalent under Π'. Therefore the underdetermination judgment depends on the bundle. □

Corollary 9414.294 (Refinement can make ambiguity empirical)**.** *A distinction that appears metaphysical under a coarse bundle may become empirical under a refined bundle.*

Proof. If Π cannot expose a distinction, the difference is not empirically separated at that level. If a refined bundle Π' exposes it, Definition 9414.292 turns the difference into a signature separation. □

Definition 9414.295 (Physically active residue)**.** *Residue $\mathrm{Res}_\Pi(R, M)$ is inactive relative to Π when it does not separate M from R under Π. It becomes physically active under a refined bundle Π' when*

$$\mathrm{PhysSig}_{\Pi'}(M) \not\sim_{\Pi'} \mathrm{PhysSig}_{\Pi'}(R).$$

Theorem 9414.296 (Hidden residue can become active)**.** *If M is physically adequate for R under Π, and a refined bundle $\Pi' \supseteq \Pi$ exposes residue not preserved by M, then M is not physically adequate under Π'.*

Proof. Adequacy under Π gives signature exactness at the coarse level. If Π' exposes residue not preserved by M, then the model-generated and reality-generated signatures differ under Π'. By Definition 9414.289, physical adequacy fails at the refined level. □

Corollary 9414.297 (Idealization is scale-relative)**.** *An idealization may be physically adequate at one scale and inadequate at another.*

Proof. Observation scale is part of the bundle. A coarse bundle may leave residue inactive, while a refined-scale bundle may expose it. Definition 9414.296 then separates adequacy at the two scales. □

9414.18 Observer-internal access

Definition 9414.298 (Observer-internal ontic access)**.** *Observer-internal access to* $\mathrm{Ont}(R)$ *is access in which every claim about the ontic state factors through*

$$H_n(R) \longrightarrow \mathrm{ObsSig}_\Pi(R \mid H_n) \longrightarrow \mathrm{Classifier}_\Pi \longrightarrow \mathrm{FitCert}_n(M, R; \Pi).$$

Definition 9414.299 (Ontic humility)**.** *Ontic humility is the methodological constraint that no model may be asserted to exhaust* $\mathrm{Ont}(R)$ *unless the relevant signature bundles, stability certificates, and ledgers have been specified. It is a discipline on representation, not skepticism about reality.*

Theorem 9414.300 (Observer-internal access does not eliminate ontic reality)**.** *If access to* $\mathrm{Ont}(R)$ *is observer-internal, it does not follow that* $\mathrm{Ont}(R)$ *is merely subjective.*

Proof. Observer-internal access means that claims about R pass through finite traces, signatures, classifiers, and certificates. It does not say that signatures are freely invented. Finite fit requires comparison between model-generated and reality-generated signatures, and failed fit occurs when reality generates a signature not matched by the model. Reality therefore constrains the observer-internal process. □

Corollary 9414.301 (Objectivity as invariant signature stability)**.** *Objectivity is the stability of signatures across admissible observers, bundles, and continuations, not access to reality from nowhere.*

Proof. By Definition 9414.300, reality constrains observer-internal access through signatures. If those signatures remain stable across admissible changes of observer, bundle, and continuation, the content is not private to one trace. It is invariant across the observational structure. □

9414.19 Certified ontic towers

The expression

$$\mathrm{Ont}(R) \sim \lim_{\Pi \in \mathcal{P}} \mathrm{PhysSig}_\Pi(R)$$

must be read as schematic. The limit is not a primitive completion imported into the theory; it names a research target: the reconstruction of ontic access as a certified tower of increasingly refined signatures.

Definition 9414.302 (Certified ontic tower)**.** *A certified ontic tower for* R *is a chain*

$$\Pi_0 \preceq \Pi_1 \preceq \Pi_2 \preceq \cdots$$

of increasingly refined observation bundles, together with fit certificates $\mathrm{FitCert}_i(M_i, R; \Pi_i)$ *and transition certificates* $\mathrm{TransCert}_{i \to j}$ *showing how signatures at level* i *are preserved, refined, or corrected at level* j*. The tower is ledger-complete when each transition records what was hidden, preserved, and newly exposed.*

Concretized in §1160: The certified ontic tower is realized as a finite staged signature-refinement and ledger-continuity NameCert packet.

Definition 9414.303 (Ontic convergence)**.** *A certified ontic tower converges ontically relative to a family of physical questions $\mathcal{Q}$ when, for every $q \in \mathcal{Q}$, there is a stage i such that all later stages preserve the answer to q up to the relevant physical classifier:*

$$\forall q \in \mathcal{Q},\ \exists i,\ \forall j \geq i,\ \mathrm{Ans}_{\Pi_j}(q) \sim_q \mathrm{Ans}_{\Pi_i}(q).$$

Theorem 9414.304 (Ontic convergence yields stable content, not final totality)**.** *If a certified ontic tower converges relative to $\mathcal{Q}$, then it yields stable physical content for questions in $\mathcal{Q}$, but it does not yield a final total description of R.*

Proof. By Definition 9414.303, every question in $\mathcal{Q}$ eventually stabilizes across the tower, so the tower yields stable content for those questions. The family $\mathcal{Q}$ need not contain every admissible physical question. A new question, refined bundle, or new scale of interaction may expose previously inactive residue. Therefore convergence over $\mathcal{Q}$ does not imply final totality. □

Corollary 9414.305 (Ontic knowledge is expandable and constrained)**.** *A theory can become more ontically informative by expanding its certified tower, but the expansion is constrained by signature preservation and ledger continuity.*

Proof. Adding a bundle or question expands the tower. If the expansion is certified, it must preserve, refine, or explicitly correct earlier signatures while recording the relevant ledger. The growth is therefore real but not arbitrary. □

Concretized in §1125: The ontic-state source is realized as a finite signature-source and residue-ledger NameCert packet.

Concretized in §1154: Ontic residue activation under refined bundles is realized as a finite residue-lattice NameCert packet.

Concretized in §1147: Ontic adequacy audit packages stable source, signature exactness, Real-facing readback, and residue ledger rows as one finite NameCert.

Concretized in §1153: The certified ontic tower is realized as a finite stage-refinement and ledger-continuity NameCert packet.

Concretized in §1152: The ontic residue ledger is realized as a finite signature, observer-access, and residue NameCert packet.

9414.20 Approximation towers and ledgered compression

Physical modelling does not proceed by a single act of representation. It proceeds through a tower of approximations:

$$R \longrightarrow H_n \longrightarrow D_n \longrightarrow M_{\mathrm{disc}} \longrightarrow M_{\mathrm{cont}} \longrightarrow M_{\mathrm{smooth}} \longrightarrow M_{\mathrm{ideal}}.$$

Here R is the physical system, H_n is a finite observation history, D_n is finite data, and the later terms are discrete, continuous, smooth, and ideal representation layers. Each arrow selects features, hides others, and licenses a new visible object. The endpoint may be useful, predictive, and mathematically elegant, but it is not identical to the source. It is the endpoint of certified compression.

Definition 9414.306 (Approximation level)**.** *An approximation level is a pair $L_i = (X_i, \Pi_i)$, where X_i is a domain of systems, traces, data, or representations, and Π_i is the observation or classifier bundle determining which distinctions are visible at that level. A level is therefore a domain together with a visibility rule.*

Definition 9414.307 (Compression arrow)**.** *A compression arrow*

$$C_i : L_i \rightsquigarrow L_{i+1}$$

is a certified transition from one approximation level to the next. It carries source, pattern, classifier, stability, and ledger fields:

$$C_i = (\mathrm{Source}_i, \mathrm{Pattern}_i, \mathrm{Classifier}_i, \mathrm{Stability}_i, \mathrm{Ledger}_i).$$

The fields mirror the naming-certificate template: source material, extracted behaviour, grouping relation, reuse certificate, and record of hidden or compressed material. A compression arrow is therefore not a quotient by fiat; it is a ledgered transition.

Definition 9414.308 (Physical approximation tower)**.** *A physical approximation tower is a finite or extendable sequence*

$$\mathcal{T} : L_0 \xrightarrow{C_0} L_1 \xrightarrow{C_1} \cdots \xrightarrow{C_{n-1}} L_n$$

whose initial level is rooted in a physical system or observation process. It is physically grounded when every mathematical level remains connected to the physical source through the composite ledger.

Definition 9414.309 (Visible endpoint)**.** *The visible endpoint of a tower $\mathcal{T}$ is the object, package, model, or representation appearing at the final level L_n:*

$$\mathrm{End}(\mathcal{T}) \in L_n.$$

The visible endpoint is the current terminal package of the compression chain, not the source itself.

Definition 9414.310 (Tower ledger)**.** *The tower ledger of $\mathcal{T}$ is the composite record*

$$\mathrm{Ledger}(\mathcal{T}) = \mathrm{Ledger}_0 + C_0^* \,\mathrm{Ledger}_1 + \cdots + (C_{n-2} \circ \cdots \circ C_0)^* \,\mathrm{Ledger}_{n-1}\,.$$

It records not only what the last compression hides, but also what every earlier compression hid.

Definition 9414.311 (Tower-complete representation)**.** *A representation $M = \mathrm{End}(\mathcal{T})$ is tower-complete for a physical system R relative to a family of observation bundles $\mathcal{P}$ when M is the endpoint of a physically grounded tower, every compression arrow carries a ledger, every endpoint operation descends through the relevant classifiers, and the endpoint preserves the physical signatures required by $\mathcal{P}$.*

9414.21 Endpoint and composite ledger

Theorem 9414.312 (Endpoint is not source)**.** *Let*

$$\mathcal{T} : L_0 \xrightarrow{C_0} L_1 \xrightarrow{C_1} \cdots \xrightarrow{C_{n-1}} L_n$$

be an approximation tower with $n \geq 1$. Then $\mathrm{End}(\mathcal{T})$ is not identical to the source object in L_0 merely by being produced from it.

Proof. Each compression arrow maps source material into a visible object according to a classifier. A classifier preserves selected distinctions and hides others. Unless the classifier preserves every distinction and the ledger is trivial, the transition is not identity. Since the tower contains at least one compression arrow, the endpoint is produced through selection, packaging, regularization, or idealization. Treating it as source-equivalent requires a separate certificate showing that the relevant physical signatures have been preserved. □

Corollary 9414.313 (Model as terminal package)**.** *If $M = \mathrm{End}(\mathcal{T})$, then M is the terminal visible package of a modelling tower, not the physical system itself.*

Proof. This is immediate from Definition 9414.312: generation through a tower licenses representation, not identity with the source. □

Theorem 9414.314 (Tower induces composite compression)**.** *Every finite approximation tower induces a composite compression*

$$C_{\mathcal{T}} = C_{n-1} \circ \cdots \circ C_1 \circ C_0 : L_0 \rightsquigarrow L_n.$$

Proof. For one arrow, the composite is that arrow. If the first n arrows compose to $C_{0:n} : L_0 \rightsquigarrow L_n$, then composing with $C_n : L_n \rightsquigarrow L_{n+1}$ gives $C_n \circ C_{0:n} : L_0 \rightsquigarrow L_{n+1}$. Induction on tower length gives the result. □

Theorem 9414.315 (Tower ledger is composite)**.** *The ledger of the composite compression induced by a tower is the tower ledger of Definition 9414.310, not merely the ledger of the final arrow.*

Proof. For two arrows $L_0 \xrightarrow{C_0} L_1 \xrightarrow{C_1} L_2$, the composite ledger must record which L_0 sources lie behind each L_1 visible item and which L_1 visible items lie behind each L_2 visible item. Thus it contains the first ledger together with the pullback of the second ledger along the first visible interface. Longer towers are obtained by repeating this two-stage construction, pulling each later ledger back along the already-composed interface. □

Corollary 9414.316 (Endpoint alone is epistemically insufficient)**.** *The endpoint $M = \mathrm{End}(\mathcal{T})$ is insufficient to determine the modelling claim unless the tower ledger is also specified.*

Proof. By Definition 9414.315, the endpoint hides the sequence of source histories, measurements, classifiers, and idealizations that produced it. Without the tower ledger, those dependencies cannot be audited. □

9414.22 Layer-relative validity

Definition 9414.317 (Level-relative fit)**.** *Let $M_i \in L_i$ and $M_j \in L_j$ be representations at different levels of a tower. The later representation has level-relative fit to the earlier one, written*

$$\mathrm{Fit}_{i \to j}(M_i, M_j; \Pi_j),$$

when the compression chain from L_i to L_j preserves the signatures required by Π_j.

Definition 9414.318 (Tower-valid claim)**.** *A claim φ made at the endpoint of a tower is tower-valid when*

$$\mathrm{End}(\mathcal{T}) \models \varphi$$

and every operation used to establish φ descends through the tower classifiers on which the claim depends.

Theorem 9414.319 (Endpoint truth does not imply source truth)**.** *Let φ be true at the visible endpoint L_n of a tower. Then φ does not automatically hold at the source level L_0.*

Proof. A claim true at L_n is evaluated using the classifier, operations, and visible structure available at L_n. The source level may contain distinctions hidden by the compression chain. If φ depends on structure introduced by smoothing, completion, or idealization, the source need not satisfy it. Transfer from endpoint truth to source truth requires a descent or reflection certificate. □

Corollary 9414.320 (Smooth endpoint behaviour need not describe rough source behaviour)**.** *If a smooth ideal model satisfies a differentiability claim, the original physical or discrete source need not satisfy that differentiability claim.*

Proof. Differentiability may be introduced by smoothing, interpolation, completion, or idealization. By Definition 9414.319, endpoint smoothness does not transfer to the source without a descent certificate. □

Corollary 9414.321 (Coarse success does not license refined prediction)**.** *If a model fits observations under a coarse bundle Π, it does not follow that it fits observations under a refined bundle $\Pi' \supseteq \Pi$.*

Proof. A coarse bundle may ignore distinctions exposed by a refined bundle. Fit under Π establishes agreement only at the coarse level. Refined prediction requires an additional stability certificate. □

9414.23 Hidden structure and tower collapse

Definition 9414.322 (Hidden structure)**.** *For a compression arrow $C_i : L_i \rightsquigarrow L_{i+1}$, the hidden structure of C_i is the source material recorded in* Ledger_i *but not visible in the compressed object at L_{i+1}. Schematically,*

$$\mathrm{Hidden}(C_i) := \mathrm{Ledger}_i \setminus \mathrm{Visible}(L_{i+1}).$$

Definition 9414.323 (Reactivation of hidden structure)**.** *Hidden structure is reactivated when a later operation, observation bundle, or physical question depends on material hidden by an earlier compression. A later claim reactivates C_i's hidden structure when its truth cannot be determined from the visible endpoint alone and requires inspection of* Ledger_i.

Theorem 9414.324 (Hidden structure can become active under later operations)**.** *Let $\mathcal{T}$ be an approximation tower, and suppose C_i hides source structure S_i. If a later operation F depends on S_i, then F is not well defined on the endpoint unless the ledger for S_i is available or a descent certificate shows that S_i is irrelevant.*

Proof. If F depends on S_i, two sources that agree at the visible endpoint but differ in S_i may yield different values under F. Thus F cannot be evaluated from the endpoint alone. Well-definedness is restored either by inspecting the ledger or by proving that all variations in S_i produce equivalent outputs under F. □

Corollary 9414.325 (Singularities can return)**.** *A singularity removed by smoothing may remain physically relevant if later operations depend on the removed singular structure.*

Proof. The removed singularity is hidden structure. If curvature extraction, stress analysis, scattering prediction, or boundary-condition evaluation depends on it, Definition 9414.324 applies. □

Definition 9414.326 (Tower collapse)**.** *Tower collapse occurs when a claim valid at level L_j is asserted at level L_i with $i < j$ without a certificate showing that the claim descends through the compression chain*

$$L_i \longrightarrow L_{i+1} \longrightarrow \cdots \longrightarrow L_j.$$

Theorem 9414.327 (Tower collapse is invalid without descent)**.** *If a claim φ at level L_j is asserted at a lower level L_i without a descent certificate through the chain from L_i to L_j, then the assertion is not licensed.*

Proof. A claim at L_j is evaluated using the visible structure of L_j. The lower level may contain distinctions hidden in the transition to L_j. If φ is sensitive to those distinctions, it may fail at L_i although it holds at L_j. A descent certificate is exactly the proof that φ is insensitive to the hidden distinctions. □

Corollary 9414.328 (Effective theories are tower-local)**.** *An effective physical theory is valid only within the tower region for which its source, classifier, stability, and ledger certificates hold.*

Proof. An effective theory compresses lower-level structure into higher-level variables and laws. By Definition 9414.327, its claims cannot be transferred beyond the certified compression region without descent. □

9414.24 Polygon-circle tower and tower equivalence

The polygon-circle example can be read as a tower:

$$R \longrightarrow H_n \longrightarrow \text{pixel data} \longrightarrow P_N \longrightarrow C \longrightarrow C^\infty\text{-circle}.$$

At the pixel or coarse-shape level, a high-sided polygon may be indistinguishable from a circle. At the smooth-boundary level, every finite polygon retains vertices, while the smooth circle does not. The assertion $P_N \sim C$ is therefore meaningful only after the level and classifier have been specified.

Theorem 9414.329 (Polygonal approximation is tower-relative)**.** *Let P_N be a polygonal representation and C a smooth circle representation. The claim $P_N \approx C$ is meaningful only relative to a specified approximation level and classifier.*

Proof. At a coarse level, the classifier may compare area, perimeter, or finite-resolution outline; under such a classifier, P_N may approximate C. At a smooth-boundary level, the classifier compares tangent existence, tangent continuity, or curvature distribution; under that classifier, P_N and C differ because P_N has vertices and C has a smooth boundary. The same approximation claim therefore changes content with the tower level. □

Corollary 9414.330 (Differentiation detects tower collapse)**.** *Differentiation can expose an illicit tower collapse because it may depend on structure hidden by coarse approximation.*

Proof. Coarse approximation may hide vertices. Differentiation depends on local tangent behaviour, which vertices disrupt. Applying differentiation after treating P_N and C as identical can therefore expose a mismatch between the visible endpoint and the hidden source. □

Definition 9414.331 (Tower equivalence)**.** *Two towers $\mathcal{T}$ and $\mathcal{T}'$ are tower-equivalent relative to Π when their endpoints are equivalent under Π, their ledgers record equivalent source histories and hidden structures, and every operation used under Π descends through both towers in compatible ways.*

Theorem 9414.332 (Endpoint equivalence does not imply tower equivalence)**.** *Endpoint equivalence*

$$\mathrm{End}(\mathcal{T}) \sim_{\Pi} \mathrm{End}(\mathcal{T}')$$

does not imply tower equivalence.

Proof. Endpoint equivalence compares only final visible objects. It ignores source histories, intermediate classifiers, hidden residues, and stability certificates. Two towers may therefore have equivalent endpoints while having different ledgers or different descent behaviour for later operations. Tower equivalence requires those additional data. □

Corollary 9414.333 (Agreement now can diverge later)**.** *Two models may produce the same current predictions and nevertheless diverge under refined observation or new operations.*

Proof. Current prediction agreement is endpoint equivalence under the present bundle. By Definition 9414.332, this does not imply tower equivalence. Different hidden residues or descent certificates may be exposed by later refinements. □

Concretized in §1142: Ledgered tower compression is realized as a finite NameCert carrier with composite-ledger and non-escape rows.

Concretized in §1143: The tower-equivalence packet records endpoint agreement together with ledger and descent compatibility as a finite NameCert surface.

Concretized in §1162: Composite tower ledgers are realized as a finite NameCert carrier whose classifier preserves ledger routes under tower-arrow composition.

Concretized in §1176: CompressionDescentAuditUp realizes endpoint-operation descent as a finite tower-route, composite-ledger, failure-surface, transport, provenance, and NameCert packet.

Concretized in §1195: Endpoint/source reflection is realized as a finite NameCert packet for endpoint rows, source rows, composite ledgers, descent audits, obstruction rows, and non-escape.

Concretized in §7688: Finite NameCert realization of the approximation tower, compression-arrow, endpoint, and composite-ledger surface.

9414.25 Physical induction and open continuation

An approximation tower makes a model usable only by certification. The next question is how an endpoint can be reused beyond the observations that licensed it. This is the problem of induction. Mathematical induction is licensed by a closed generated carrier. Physical induction is different: future observation is not already present as a completed carrier inside the current finite trace. The observer has a finite history, a model extracted from that history, and a stability certificate claiming that the model remains adequate under specified continuations.

Definition 9414.334 (Closed mathematical carrier)**.** *A closed mathematical carrier is a domain A equipped with constructors such that every element of A is generated by finitely many applications of those constructors, and no further elements are admitted except by the stated generation rules. A proof principle over A is closed when it reasons only over this generated carrier.*

Definition 9414.335 (Open observation carrier)**.** *An open observation carrier for a physical system R is an extendable family*

$$\mathcal{H}(R) = \{H_0, H_1, H_2, \ldots\}$$

of possible finite observation histories, where each H_n is finite and no internal final object is assumed to contain all admissible future histories.

Definition 9414.336 (Observational prefix)**.** *For finite histories $H_n = (o_0, \ldots, o_n)$ and H_m, H_n is an observational prefix of H_m, written*

$$H_n \preceq H_m,$$

when $m \geq n$ and the first $n+1$ observations of H_m agree with H_n.

Definition 9414.337 (Predictive continuation)**.** *A predictive continuation of a model M from a finite fit $\mathrm{Fit}_n(M, R; \Pi)$ is a licensed claim*

$$\mathrm{PredFit}_{n \to n+k}(M, R; \Pi)$$

or an analogous claim over an explicitly stated class of continuations. It is not a theorem of finite fit alone; it requires a stability certificate.

Definition 9414.338 (Physical induction certificate)**.** *A physical induction certificate is a stability certificate*

$$\mathrm{PhysInd}(M, R; \Pi, \mathcal{C})$$

for a class $\mathcal{C}$ of admissible continuations of the current observation history. It licenses

$$\mathrm{Fit}_n(M, R; \Pi) \rightsquigarrow \mathrm{PredFit}_{n \to \mathcal{C}}(M, R; \Pi).$$

Definition 9414.339 (Induction ledger and failure surface)**.** *The induction ledger attached to $\mathrm{PhysInd}(M, R; \Pi, \mathcal{C})$ is*

$$\mathrm{IndLedger}(M, R; \Pi, \mathcal{C}) = (H_n, \Pi, \mathcal{C}, \mathrm{FitCert}_n, \mathrm{StabilityBasis}, \mathrm{FailureSurface}).$$

Its failure surface is the class of continuations that would separate model-generated and observed signatures:

$$\mathrm{Fail}(M, R; \Pi, \mathcal{C}) = \{\, H' \in \mathcal{C} \mid \mathrm{ModSig}_\Pi(M \mid H') \not\sim_\Pi \mathrm{ObsSig}_\Pi(R \mid H') \,\}.$$

9414.26 Mathematical and physical induction

Theorem 9414.340 (Mathematical induction requires closed carrier)**.** *A mathematical induction principle is licensed only when its target carrier is closed under the constructors used in the induction.*

Proof. An induction proof shows that a property holds at the base constructors and is preserved by each generating constructor. This proves the property for all elements only because every element of the carrier is generated by those constructors. If the carrier were not closed, an ungenerated element could exist outside the reach of the induction step. Thus induction requires closed generation. □

Corollary 9414.341 (Induction is a closure theorem)**.** *Mathematical induction is not repeated verification. It is a theorem about a closed generated domain.*

Proof. Repeated successful cases do not exclude ungenerated cases. The decisive premise is that the carrier has no elements outside the constructor closure. □

Theorem 9414.342 (Physical induction is not mathematical induction)**.** *The inference from finite observational success to future predictive success is not licensed by mathematical induction alone.*

Proof. Let $\mathrm{Fit}_n(M, R; \Pi)$ hold. This says that M agrees with R on the finite prefix H_n under Π. Future success would require a principle covering admissible continuations of H_n. But the future observation carrier is open: it is not given as a closed carrier whose elements are generated by a known successor rule that preserves the model. Therefore the transition from finite fit to future prediction requires an additional stability certificate. That certificate may be physically justified, experimentally supported, or theoretically motivated, but it is not mathematical induction over a closed carrier. □

Corollary 9414.343 (Repeated success is not necessity)**.** *No finite sequence of successful predictions entails that a model must succeed on every future admissible observation.*

Proof. A finite sequence of successes extends fit to a larger prefix. By Definition 9414.342, no finite prefix closes the open carrier of future observations. □

Corollary 9414.344 (Physical induction is certificate-relative)**.** *A physical inductive inference is valid only relative to the continuation class and stability certificate that license it.*

Proof. Definition 9414.338 includes a continuation class $\mathcal{C}$. The certificate licenses prediction over that class. A different continuation class may expose hidden residue or violate the stability basis. □

9414.27 Law certificates, reuse, and descent

Definition 9414.345 (Law certificate)**.** *A law certificate for a model M of a system R relative to Π is*

$$\mathrm{LawCert}(M, R; \Pi) = (\mathrm{SourceFit}, \mathrm{Pattern}, \mathrm{Classifier}, \mathrm{Stability}, \mathrm{FailureSurface}, \mathrm{Ledger}).$$

It records the finite observations supporting the law, the claimed invariant or regularity, the equivalence under which fit is judged, the continuation principle licensing reuse, the observations that would defeat the law, and the hidden assumptions or tower levels.

Definition 9414.346 (Lawlike stability)**.** *A model M has lawlike stability for R under Π and continuation class $\mathcal{C}$ when finite fit holds and a law certificate licenses*

$$\forall H' \in \mathcal{C},\ \mathrm{PredFit}(M, R; \Pi \mid H').$$

The universal statement is certificate-bounded, not an oracle over all possible reality.

Theorem 9414.347 (Physical law is not merely equation)**.** *A physical law requires a law certificate. An equation alone is insufficient.*

Proof. An equation supplies formal syntax and a calculation rule. A physical law must also specify the observations from which it is licensed, the physical pattern it preserves, the classifier comparing model and reality, the stability condition for reuse, the observations that would count as failure, and the ledger of idealizations or hidden assumptions. Without these fields, the equation is not tied to physical reality as an open observation process. □

Corollary 9414.348 (Same equation may carry different laws)**.** *The same mathematical equation may express different physical laws when attached to different source histories, classifiers, stability domains, or failure surfaces.*

Proof. By Definition 9414.345, the equation-like pattern is only one field. Different source fit, classifier, stability, failure surface, or ledger data determine different law certificates. □

Corollary 9414.349 (Law without failure surface is oracle claim)**.** *If a claimed law has no specified failure surface, it is not a scientific law certificate but an unbounded oracle assertion.*

Proof. A law certificate must specify observations or refinements that would separate model from reality. Removing this surface removes empirical separability and turns the claim into a final-fit oracle, which the present framework rejects. □

Definition 9414.350 (Predictive reuse and descent)**.** *Predictive reuse applies a model fitted on H_n to a later or counterfactual history H' with $H_n \preceq H'$ or $H' \in \mathcal{C}$. A prediction operation F has predictive descent from the observed classifier $\sim_n$ to the continuation classifier $\sim_{\mathcal{C}}$ when*

$$M_1 \sim_n M_2 \quad \Longrightarrow \quad F(M_1) \sim_{\mathcal{C}} F(M_2).$$

Theorem 9414.351 (Prediction requires reuse stability and descent)**.** *A prediction from a finite-fit model is licensed only when the model has reuse stability over the relevant continuation class and the prediction operation descends through the classifier used to form the model.*

Proof. Prediction applies the model beyond the finite trace on which it was fitted. Without reuse stability, finite fit gives no reason to expect future fit. Since the model was formed by classification and compression, a prediction operation that does not descend through that classifier may depend on hidden representative data rather than on the visible model. Both reuse stability and descent are therefore required. □

Corollary 9414.352 (Predictive failure can be non-descent)**.** *A model may fail predictively because the prediction operation does not descend through the approximation that produced the model, even when the visible equation is internally correct.*

Proof. By Definition 9414.351, prediction requires descent. If descent fails, the failure lies in transferring the equation through an invalid compression, not necessarily in the equation's algebraic form. □

Concretized in §1183: Continuation countermodels realize finite predictive-reuse defeat as a displayed continuation, mismatch, stability, failure-surface, and NameCert packet.

Concretized in §6534: Physical induction certificates become finite continuation-stability and failure-surface NameCert rows.

9414.28 Open empirical continuation

Definition 9414.353 (Local empirical closure)**.** *Local empirical closure is the capacity, for a fixed finite trace H_n, bundle Π, and classifier $\sim_\Pi$, to determine or certify whether* $\mathrm{Fit}_n(M, R; \Pi)$ *holds.*

Definition 9414.354 (Global empirical openness)**.** *Global empirical openness is the absence of any internal finite procedure supplying a final certificate for*

$$\forall H,\ \mathrm{Fit}(M, R; \Pi \mid H)$$

over all admissible actual and counterfactual observation histories.

Definition 9414.355 (Final induction oracle)**.** *A final induction oracle is a hypothetical judgment* $\Omega_{\mathrm{ind}}(M, R; \Pi)$ *implying*

$$\forall H,\ \mathrm{Fit}(M, R; \Pi \mid H).$$

It would convert finite or current model success into unrestricted future validity.

Theorem 9414.356 (Local closure does not imply global closure)**.** *A finite inquiry may close fit judgments at each observed stage without closing the universal judgment over all future stages.*

Proof. Local empirical closure concerns a fixed finite trace and observed data. Global empirical closure quantifies over observations not yet performed and refinements not yet introduced. No finite local fit judgment contains those future traces. □

Corollary 9414.357 (Science requires local closure and global openness)**.** *Scientific inquiry requires both the ability to settle finite tests and the refusal to close final fit.*

Proof. If local closure fails, experiments cannot decide whether a model fits current observations. If global openness fails, the theory becomes immune to future correction. □

Theorem 9414.358 (Final induction oracle collapses inquiry)**.** *If a final induction oracle is admitted, physical inquiry loses its open continuation structure.*

Proof. A final induction oracle asserts that a model will fit all admissible future observations. This removes the failure surface and closes the continuation horizon. Future observations can no longer genuinely revise the model, so open inquiry is replaced by a meta-level assertion of total validity. □

9414.29 Falsification, intuition, and tower induction

Definition 9414.359 (Finite refutation and open confirmation)**.** *A finite refutation of M relative to R and Π is a finite trace H_n such that*

$$\mathrm{ModSig}_\Pi(M \mid H_n) \not\sim_\Pi \mathrm{ObsSig}_\Pi(R \mid H_n).$$

Open confirmation is an extendable family of finite fit certificates together with a physical induction certificate licensing specified continuations.

Theorem 9414.360 (Falsification finite, confirmation open)**.** *A model can be refuted by a finite observation, but it cannot be finally confirmed by finitely many observations.*

Proof. A finite refutation is one positive witness of mismatch. Final confirmation would require agreement over all admissible traces, and no finite collection of traces exhausts the open observation carrier. □

Definition 9414.361 (Stability prior and certified intuition)**.** *A stability prior is a pre-certificate expectation that an observed pattern will persist under a specified class of continuations. It becomes certified intuition when upgraded to a physical induction certificate by specifying the stability basis and failure surface.*

Theorem 9414.362 (Physical intuition is not oracle)**.** *A stability prior does not license prediction unless it is converted into a physical induction certificate.*

Proof. A stability prior expresses expectation. Prediction requires a licensed transition from finite fit to future fit. Without a physical induction certificate, the prior does not specify the continuation class, classifier, descent conditions, or failure surface. □

Definition 9414.363 (Tower induction)**.** *For a tower $\mathcal{T} : L_0 \to L_1 \to \cdots \to L_n$, tower induction is a physical induction certificate licensing prediction at level L_j from fit established at level L_i, with $i \leq j$, together with descent or reflection data relating the relevant levels.*

Theorem 9414.364 (Cross-level prediction requires tower induction)**.** *If a prediction is made at a different tower level from the level at which fit was established, then a tower induction certificate is required.*

Proof. Fit at L_i is judged by the classifier and visible signatures of L_i. Prediction at L_j may use a different classifier, visible structure, and hidden residue. The finite fit at L_i does not by itself license the prediction at L_j. Tower induction supplies the missing transfer data: signature preservation between levels, descent of operations, and inactivity or ledgered handling of hidden structure. □

Corollary 9414.365 (Effective laws are level-indexed induction certificates)**.** *An effective law is valid only within the approximation level and continuation class for which its induction certificate holds.*

Proof. Effective laws compress lower-level structure into higher-level variables. Moving across levels requires the certification described in Definition 9414.364. □

Theorem 9414.366 (Physical induction has closed-ground and open-continuation form)**.** *Physical induction requires local closure of finite fit judgments and global openness of future observation.*

Proof. Local finite fit must be decidable or certifiable; otherwise the model cannot be compared with the observed trace. The future observation horizon cannot be closed by the same finite procedure. If it were closed, the model would acquire a final-fit oracle over all future observations. Physical induction therefore has the form of closed finite fit together with open continuation, parallel to BEDC's closed-ground and open-meta polarity. □

Concretized in §1135: Physical induction is realized as a finite continuation, stability, failure-surface, ledger, and NameCert packet.

Concretized in §2380: Physical induction is realized as a finite observation-step NameCert packet.

Concretized in §1312: Local empirical closure is realized as a finite NameCert packet whose non-finality row keeps global empirical openness visible.

Concretized in §1139: Physical induction stability seals realize finite-fit reuse as continuation-class, failure-surface, transport, provenance, and NameCert rows.

Concretized in §1155: LawCertificateUp realizes physical law as a finite source-fit, classifier, continuation-stability, failure-surface, ledger, transport, provenance, and NameCert packet.

Concretized in §1182: Predictive descent is realized as a finite NameCert packet binding finite fit, prediction operation, observed classifier, continuation classifier, stability scope, failure surface, and non-escape rows.

Concretized in §6858: Local empirical residue is realized as a finite observation-history, classifier, failure-surface, and nonfinality NameCert packet.

9414.30 Objectivity without a privileged observer

Physical induction leaves inquiry locally closed and globally open. This changes the meaning of objectivity. If no observer stands outside the inquiry process, and if no final-fit oracle is internally available, objectivity cannot be access to reality from nowhere. It must be reconstructed as invariant stability across admissible observer histories, observation bundles, and continuation procedures.

This is the physical reading of the multi-Hist layer. A multi-Hist configuration contains several local histories without a required common base, clock, or time-step indexing. Since an observer is identified with the history of recorded distinctions, there is no observer-substance behind the record and no privileged frame above the configuration. Frame-independent physical content must therefore live in inter-history invariants.

Definition 9414.367 (Observer history)**.** *An observer history is a finite or extendable history $h \in \mathsf{Hist}$ interpreted as the record of distinctions, observations, continuations, and classifier-mediated signatures available to an observer. The observer is not an additional substance behind h; it is the history considered as a finite distinction record.*

Definition 9414.368 (Multi-observer configuration)**.** *A multi-observer configuration is a finite family*

$$\mathcal{H} = (h_1, \ldots, h_m)$$

of observer histories considered together without assuming a shared origin, shared clock, shared time-step indexing, or privileged synchronizing observer.

Definition 9414.369 (Privileged observer)**.** *A privileged observer for $\mathcal{H}$ is a hypothetical observer history $h_\star$ that synchronizes, orders, and evaluates every $h_i \in \mathcal{H}$ from a distinguished standpoint. Equivalently, it would supply a global observational frame*

$$h_\star : (h_1, \ldots, h_m) \longmapsto \textit{one shared empirical ordering.}$$

The framework does not assume such a history.

Definition 9414.370 (Inter-observer relation and invariant)**.** *An inter-observer relation is a relation $R(h_i, h_j)$ whose evidence is obtained through finite observation, continuation, classifier, or ledger data available within the relevant histories. An inter-observer invariant is a function or predicate $I(h_i, h_j)$ whose value is stable under change of observational anchor:*

$$I(h_i, h_j) \sim I(h_j, h_i)$$

up to the relevant history and signature classifiers. It may depend on relations between histories, but it may not privilege one history as the absolute frame.

Definition 9414.371 (Relational objectivity)**.** *A claim φ is relationally objective over $\mathcal{H}$ when there is an inter-observer invariant I such that φ is determined by I rather than by one observer history alone:*

$$\mathrm{Obj}_{\mathcal{H}}(\varphi) \quad \Longleftrightarrow \quad \exists I \, (I \text{ is inter-observer invariant} \wedge I \Rightarrow \varphi).$$

Objectivity is therefore not observer-free; it is observer-invariant.

Definition 9414.372 (Private and frame-independent content)**.** *A claim φ is private observational content of h_i when it is determined only by the internal trace of h_i and no inter-observer invariant transports it across the configuration. A claim is frame-independent physical content when it is relationally objective over every admissible multi-observer configuration in which it is asserted.*

9414.31 No global observer

Theorem 9414.373 (No member is privileged by membership)**.** *No element of a multi-observer configuration is privileged merely by being a member of the configuration.*

Proof. By Definition 9414.368, the configuration supplies only a finite family of local histories. Membership does not give a shared origin, clock, time-step indexing, or synchronization map. Thus $h_i \in \mathcal{H}$ gives the local observational trace of h_i, but not authority to order or evaluate all other histories from a global frame. □

Corollary 9414.374 (Single histories are not frame-independent carriers)**.** *An individual observer history may carry valid local content, but it does not by itself carry frame-independent physical content.*

Proof. By Definition 9414.373, no observer history is privileged by default. A claim contained only in one history is therefore local to that history until transported by an inter-observer invariant. □

Theorem 9414.375 (Adding observers does not create an external view)**.** *Extending $\mathcal{H} = (h_1, \ldots, h_m)$ to $(h_1, \ldots, h_m, h_{m+1})$ does not by itself produce a privileged observer.*

Proof. The added history is itself an observer history with its own finite trace and local continuation structure. It does not automatically contain the classifiers, ledgers, or time-step orderings of the other histories. If a candidate observer-of-observers is represented internally, it becomes another history and remains subject to the same locality constraints. □

Corollary 9414.376 (No internal observer-of-observers)**.** *There is no observer-of-observers inside the same observational layer.*

Proof. An internal candidate is added as another history. By Definition 9414.375, such addition does not create global synchronization. □

9414.32 Objectivity as invariance

Definition 9414.377 (Anchor change)**.** *An anchor change is the redescription of an inter-observer relation from the standpoint of another observer history:*

$$(h_i \text{ as anchor}) \rightsquigarrow (h_j \text{ as anchor}).$$

A quantity is stable under anchor change when its value remains classifier-equivalent after redescription.

Definition 9414.378 (Anchor-stable claim)**.** *A claim φ is anchor-stable over $\mathcal{H}$ when, for all $h_i, h_j \in \mathcal{H}$,*

$$\varphi^{h_i} \sim \varphi^{h_j},$$

where φ^{h_i} denotes the expression of φ with h_i as observational anchor.

Definition 9414.379 (Invariant certificate)**.** *An invariant certificate for φ over $\mathcal{H}$ is*

$$\mathrm{InvCert}(\varphi; \mathcal{H}) = (\mathrm{HistSources}, \mathrm{RelationSpec}, \mathrm{ClassifierSpec}, \mathrm{AnchorStability}, \mathrm{LedgerPolicy}).$$

It records the histories being related, the relation claimed, the sameness classifier, the proof of anchor stability, and the ledger of observations and transformations used in the comparison.

Concretized in §1150: Anchor-stability is realized as a finite certificate for invariant transport across observer anchors.

Theorem 9414.380 (Objectivity requires anchor stability)**.** *If a claim is frame-independent physical content, then it is anchor-stable.*

Proof. Frame-independent physical content is stable under changes of observer anchor by Definition 9414.372. Anchor stability is precisely the classifier-equivalent preservation of the claim under such changes. □

Theorem 9414.381 (Invariants generate relational objectivity)**.** *If $I(h_i, h_j)$ is an inter-observer invariant over $\mathcal{H}$, then any claim determined solely by I is relationally objective over $\mathcal{H}$.*

Proof. The invariant is stable under anchor change. A claim determined solely by it is therefore also stable under anchor change. By Definition 9414.371, such a claim is relationally objective. □

Corollary 9414.382 (Objectivity is not local certainty)**.** *A claim may be certain within one observer history and still fail to be objective over a multi-observer configuration.*

Proof. Local certainty concerns one trace. Objectivity requires anchor stability across histories by Definition 9414.380. □

9414.33 Relational physical content

Definition 9414.383 (Local coordinate content)**.** *A quantity q_i is local coordinate content for h_i when it is defined only relative to the local description carried by h_i, such as a local time coordinate, chart coordinate, gauge representative, or measurement ordering.*

Definition 9414.384 (Relational physical content)**.** *A quantity Q is relational physical content when it is produced from local coordinate contents by an inter-observer invariant,*

$$Q = I(q_i, q_j),$$

and is stable under anchor change.

Definition 9414.385 (Gauge-like redundancy)**.** *A difference between local descriptions is gauge-like redundancy when it changes local coordinate content but preserves all relational physical content. Thus q_i and q_i' are gauge-like equivalent when, for every admissible inter-observer invariant I and compatible q_j,*

$$I(q_i, q_j) \sim I(q_i', q_j).$$

Theorem 9414.386 (Local difference requires invariant separation)**.** *If every admissible inter-observer invariant gives the same value on local descriptions q_i and q_i', then their difference is not a frame-independent physical difference.*

Proof. Frame-independent physical content is determined by inter-observer invariants. If all such invariants agree on q_i and q_i', no relationally objective claim separates them. The difference may remain meaningful as local coordinate content, but it is not physical content at the invariant level. □

Corollary 9414.387 (Coordinate freedom is not empirical ambiguity)**.** *Different coordinate descriptions may represent the same physical content when they preserve the same inter-observer invariants.*

Proof. By Definition 9414.386, local coordinate differences that do not change invariants are not frame-independent physical differences. □

Corollary 9414.388 (Empirical disagreement requires invariant separation)**.** *Two observers genuinely disagree about physical content only when their records cannot be reconciled by an invariant certificate.*

Proof. A local mismatch may be coordinate-like or private to one history. It becomes physical disagreement only when an admissible invariant separates the records. □

9414.34 Local time and synchronization

Definition 9414.389 (Local time stream)**.** *The local time stream of an observer history h is the ordered sequence of continuation steps by which h grows. If*

$$h_0 \to h_1 \to \cdots \to h_n,$$

then the local time stream is the finite order encoded by this chain.

Definition 9414.390 (Global clock and synchronization certificate)**.** *A global clock for $\mathcal{H}$ is a single ordering object T into which every $h_i \in \mathcal{H}$ embeds while preserving all relevant local orders and supplying a privileged shared present. A synchronization certificate between h_i and h_j is a finite ledgered construction*

$$\mathrm{SyncCert}(h_i, h_j)$$

that relates selected local time steps of h_i to selected local time steps of h_j. It is a local relation, not a global clock.

Theorem 9414.391 (Local time does not imply global time)**.** *The existence of local time streams for observer histories does not imply the existence of a global clock for the configuration.*

Proof. Each observer history has its own order of continuation. A global clock requires a single ordering object synchronizing all histories and supplying a privileged shared present. No such object follows from the mere existence of local orders. Temporal comparison requires an additional synchronization certificate. □

Corollary 9414.392 (Temporal comparison is relational)**.** *A temporal comparison between observer histories must be expressed as an inter-observer relation, not as a reading from a global clock.*

Proof. By Definition 9414.391, local time streams do not supply a global clock. Any cross-history temporal comparison must therefore be certified as a relation between histories. □

Corollary 9414.393 (Simultaneity is certificate-relative)**.** *A simultaneity claim between observer histories is meaningful only relative to a synchronization certificate.*

Proof. Simultaneity relates local time streams. Since no global clock is assumed, the relation must be supplied by a certificate connecting the relevant local steps. □

9414.35 Observer-independent constants

Definition 9414.394 (Observer-independent quantity)**.** *A quantity Q is observer-independent over $\mathcal{H}$ when, for all $h_i, h_j \in \mathcal{H}$,*

$$Q^{h_i} \sim Q^{h_j},$$

where Q^{h_i} denotes the value computed with h_i as anchor.

Definition 9414.395 (Maximum relational rate)**.** *A maximum relational rate $v_{\max}$ is a quantity over a multi-observer configuration such that all admissible cross-history causal dependences are bounded by $v_{\max}$ and $v_{\max}$ is invariant under change of observer anchor. The definition names a structural role and does not assign a numerical value.*

Theorem 9414.396 (Observer-independent constants are invariants)**.** *If a quantity has the same classifier-equivalent value for every observer anchor in a multi-observer configuration, then it is an inter-observer invariant.*

Proof. An inter-observer invariant is stable under change of observer anchor. The hypothesis states exactly that changing the anchor preserves the value up to the relevant classifier. □

Corollary 9414.397 (Invariant maximum rate is frame-independent)**.** *If a maximum relational rate is observer-independent, then it is frame-independent physical content.*

Proof. By Definition 9414.396, observer-independence implies inter-observer invariance. Frame-independent physical content is carried by such invariants. □

Corollary 9414.398 (Structural form and empirical value are distinct)**.** *A framework may derive the form of an observer-independent maximum rate without deriving its empirical value.*

Proof. The structural form is the invariance of a maximum relational rate under observer-anchor change. Its numerical value requires empirical calibration within a physical theory and observation bundle. □

9414.36 Tower-aware objectivity

Definition 9414.399 (Tower-indexed invariant)**.** *For an approximation tower*

$$\mathcal{T} : L_0 \to L_1 \to \cdots \to L_n,$$

a tower-indexed invariant is an inter-observer invariant I_k defined at a specified level L_k. It is not automatically valid at other levels.

Definition 9414.400 (Cross-level invariant descent)**.** *A tower-indexed invariant I_j at L_j descends to L_i, with $i < j$, when a certificate shows that the invariant value at L_j is determined solely by structures preserved from L_i. We write*

$$\mathrm{DescInv}_{j \to i}(I_j).$$

Theorem 9414.401 (Invariance is tower-relative without descent)**.** *Invariance at one approximation level does not automatically imply invariance at another level.*

Proof. Each tower level has its own visible structures, classifiers, and hidden residues. An invariant at one level may depend on structures introduced by compression, smoothing, completion, or idealization. Another level may expose distinctions suppressed there or lack structures that the invariant requires. Transfer therefore requires cross-level invariant descent. □

Corollary 9414.402 (Objectivity is level-relative unless descent is supplied)**.** *A physical claim may be objective at one approximation level without yet being objective across the entire tower.*

Proof. Objectivity is defined by invariance. By Definition 9414.401, invariance does not automatically move across tower levels. □

Corollary 9414.403 (Effective objectivity is legitimate but local)**.** *An effective theory may contain objective quantities within its certified domain even when those quantities are not globally final.*

Proof. If a quantity is invariant within the theory's level and continuation domain, it is objective there. The same fact does not supply global descent across all levels. □

9414.37 Objectivity without finality

Definition 9414.404 (Objective but open claim)**.** *A claim φ is objective but open when it has an invariant certificate over the currently admissible observer histories and tower level, and it has a specified failure surface under later refinement, added observers, or tower-level change.*

Theorem 9414.405 (Objectivity does not imply finality)**.** *If φ is relationally objective over $\mathcal{H}$, it does not follow that φ is final over all later configurations, refinements, or observation bundles.*

Proof. Relational objectivity over $\mathcal{H}$ means that φ is determined by an inter-observer invariant within that configuration. Later inquiry may extend the configuration, refine the observation bundle, or move to another approximation level. Such changes may expose hidden residues or require new invariant certificates. □

Corollary 9414.406 (Objectivity is compatible with revisability)**.** *A claim may be objectively established relative to current invariants while remaining open to later correction.*

Proof. By Definition 9414.405, objectivity does not entail finality. Revisability concerns the possibility that later observations or refinements alter the certified invariant structure. □

Corollary 9414.407 (Final objectivity would require an oracle)**.** *A claim of final objectivity over all observers, all refinements, and all future histories would require a final-fit oracle or final synchronization oracle.*

Proof. Final objectivity would require a certificate covering every possible observer history, observation bundle, tower refinement, and continuation. Such a certificate would function as a global oracle over the total observational process, which the framework rejects. □

Remark 9414.408 (Compressed form)**.** *The replacement is not*

$$\textit{objective truth} = \textit{truth from nowhere},$$

but

$$\textit{objective truth} = \textit{invariant, ledgered, anchor-stable content across observer histories.}$$

The absence of a privileged observer therefore does not erase objectivity. It requires every objective claim to state the histories related, the classifier under which the relation is evaluated, the invariant that survives anchor change, and the ledger recording how the comparison was made.

Concretized in §1133: Relational objectivity is realized as a finite multi-observer invariant certificate with anchor-stability and no privileged observer row.

Concretized in §1166: Anchor-change invariants are realized as finite symmetric transport certificates over observer-history anchors.

Concretized in §1134: Objectivity refutation boundaries are realized as finite failed-invariant, failed-anchor-stability, witness, refusal-ledger, transport, provenance, and NameCert rows.

Concretized in §1189: Synchronization certificates realize local temporal comparison as finite paired HistTimeStream rows, selected-step correspondences, no-global-clock refusal, hsame transport, Cont replay, Pkg provenance, and NameCert data.

9414.38 The observation–reflection equivalence thesis

The preceding sections establish the route to the equivalence thesis. Physical fit is finite and open. Mathematical approximation does not imply physical adequacy. Ontic state is the stable source of reality-facing signatures. Physical modelling proceeds through ledgered approximation towers. Physical induction is a stability certificate over open continuation. Objectivity is invariant stability across observer histories rather than a privileged view.

The central claim is structural:

physical inquiry and MetaCIC self-study share the same reflective architecture.

This does not identify physical reality with a formal system, nor MetaCIC with a physical object. It says that both operate through finite histories, signature extraction, classifier-mediated packaging, certificate-based stabilization, ledgered compression, and open continuation.

The BEDC kernel already displays this pattern:

$$b_0, b_1 \to \mathsf{Hist} \to \mathsf{msame}, \mathsf{hsame} \to \mathsf{Ext}, \mathsf{Cont} \to \mathsf{Ask} \to \mathsf{Sig} \to \mathsf{sameSig} \to \mathsf{Pkg} \to \mathsf{Gap} \to \mathsf{NameCert}.$$

Derived interfaces are not primitive exports. They are licensed by certificates whose fields record source, pattern, classifier, stability, and ledger. Physical modelling has the same epistemic form: a model is licensed by source traces, extracted patterns, physical classifiers, stability certificates, and ledgers recording what the model hides.

Definition 9414.409 (Reflective inquiry architecture)**.** *A reflective inquiry architecture is a tuple*

$$\mathcal{R} = (S, H, \Sigma, \mathcal{C}, \mathcal{P}, \mathcal{L}, \mathcal{E}),$$

where S is a source domain, H is a finite-history carrier generated from the source, Σ extracts signatures, $\mathcal{C}$ classifies signatures into visible sameness classes, $\mathcal{P}$ is a package, model, or derived interface licensed by the classifier, $\mathcal{L}$ is a ledger recording hidden source material, and $\mathcal{E}$ is an open continuation procedure. Its generic chain is

$$S \to H \to \Sigma(H) \to \mathcal{C}(\Sigma) \to \mathcal{P} \to \mathcal{L} \to \mathcal{E}.$$

The architecture is reflective when it can use finite histories and certificates to generate higher-level descriptions of its own behaviour while still lacking an internal final truth oracle.

Definition 9414.410 (Physical inquiry instance)**.** *A physical inquiry instance of reflective architecture is obtained by setting S to a reality-facing source, H to finite observation traces, Σ to observed physical signatures, $\mathcal{C}$ to the model–data classifier, $\mathcal{P}$ to a physical model or law certificate, $\mathcal{L}$ to the experimental and approximation ledger, and $\mathcal{E}$ to the future observation horizon. Its chain is*

$$R \to H_n(R) \to \mathrm{ObsSig}_{\Pi}(R \mid H_n) \to \mathrm{Fit}_n(M, R; \Pi) \to \mathrm{LawCert}(M, R; \Pi) \to \mathrm{Ledger} \to \mathrm{OpenFit}\,.$$

Definition 9414.411 (MetaCIC self-study)**.** *A MetaCIC self-study instance of reflective architecture is obtained by setting S to formal generative behaviour, H to generated* Hist *values, Σ to signatures extracted by Ask/Sig interfaces, $\mathcal{C}$ to licensed classifiers such as* hsame, sameSig, *or derived classifiers, $\mathcal{P}$ to packages or derived interfaces, $\mathcal{L}$ to gap and NameCert ledgers, and $\mathcal{E}$ to open meta-level continuation. Its chain is*

$$\mathsf{Hist} \to \mathsf{Cont} \to \mathsf{Ask}/\mathsf{Sig} \to \textit{classifier} \to \mathsf{Pkg}/\mathsf{NameCert} \to \textit{ledger} \to \mathrm{OpenMeta}\,.$$

Definition 9414.412 (Observation–reflection equivalence)**.** *Physical inquiry and MetaCIC self-study are observation–reflection equivalent when there is a structure-preserving correspondence*

$$\Phi : \mathcal{R}_{\mathrm{phys}} \longrightarrow \mathcal{R}_{\mathrm{MetaCIC}}$$

whose component roles match as follows:

physical inquiry	*MetaCIC self-study*
physical system	*formal source or kernel behaviour*
finite observation trace	Hist
measurement continuation	Cont
observed signature	Sig
model classifier	*licensed classifier*
model package	Pkg *or derived interface*
experimental ledger	Gap *or NameCert ledger*
prediction horizon	*open meta continuation*
no final-fit oracle	*no internal truth predicate*

The equivalence is architectural, not ontological.

Definition 9414.413 (Reflection gap)**.** *A reflection gap is the gap between a system's finite certified self-description and a total truth predicate for that system. In physical inquiry it appears as the difference between*

$$\mathrm{Fit}_n(M, R; \Pi)$$

and

$$\forall H,\ \mathrm{Fit}(M, R; \Pi \mid H).$$

In MetaCIC it appears as the difference between structural self-description and an internal truth predicate for the system.

Definition 9414.414 (Internalization without finalization)**.** *A system has internalization without finalization when it can internalize finite descriptions, certificates, and structural reproductions of its own behaviour, but cannot internally certify that these descriptions are final, total, or truth-complete.*

Definition 9414.415 (Reflective stability certificate)**.** *A reflective stability certificate shows that a self-description can be reused under specified continuations without collapsing into a total truth oracle. In physical inquiry this is a law or induction certificate. In MetaCIC it is a NameCert, stability certificate, or derived-interface certificate whose reuse remains below the open meta-loop boundary.*

9414.39 Physical and formal reflective instances

Theorem 9414.416 (Physical inquiry instantiates reflective architecture)**.** *Physical inquiry has the form of a reflective inquiry architecture.*

Proof. Let the source be a physical system R. The observer does not access R as a completed totality; access is mediated by finite traces $H_n(R)$. These traces are organized by an observation bundle Π into signatures $\mathrm{ObsSig}_\Pi(R \mid H_n)$. A model M generates corresponding model signatures, and a classifier compares the two:

$$\mathrm{ModSig}_\Pi(M \mid H_n) \sim_\Pi \mathrm{ObsSig}_\Pi(R \mid H_n).$$

Successful comparison produces a finite fit certificate. Reuse of the model requires stability data, and the source traces, approximations, hidden residues, and failure surfaces must be ledgered. Future observations remain open continuations. These are exactly the fields of Definition 9414.409. □

Corollary 9414.417 (Physical modelling is self-descriptive)**.** *A physical model describes not only a source object but also the observational process by which that object became modelable.*

Proof. By Definition 9414.416, the model is licensed by traces, signatures, classifiers, stability certificates, and ledgers. These components are part of the model's epistemic status, so the model records its own access route. □

Corollary 9414.418 (Physical theory is reflective without being subjective)**.** *Physical theory is reflective because it records conditions of observational access, but it is not subjective because reality-generated signatures may defeat model-generated signatures.*

Proof. Reflectivity follows from the certificate structure of Definition 9414.416. Non-subjectivity follows because finite fit fails whenever observed signatures separate from model signatures under the active classifier. □

Theorem 9414.419 (MetaCIC self-study instantiates reflective architecture)**.** *MetaCIC self-study has the form*

$$\mathsf{Hist} \to \mathsf{Cont} \to \mathsf{Sig} \to \textit{classifier} \to \mathsf{Pkg}/\mathsf{NameCert} \to \textit{ledger} \to \mathrm{OpenMeta}\,.$$

Proof. In BEDC, generated histories are extended by continuation. Ask and Sig interfaces expose visible data. Classifiers such as hsame, sameSig, package-sameness, or derived classifiers organize that visible data. Packages and derived interfaces are admitted only through certificate discipline. The NameCert template requires source, pattern, classifier, stability, and ledger fields. The meta-level remains open: the ground loop closes so the system can start, while the meta loop does not close into an internal truth predicate. Thus MetaCIC self-study instantiates Definition 9414.409. □

Corollary 9414.420 (MetaCIC self-study is structural, not totalizing)**.** *MetaCIC can structurally describe its own generative behaviour without producing a total internal truth predicate.*

Proof. By Definition 9414.419, self-study proceeds through histories, classifiers, packages, certificates, and ledgers while preserving the open meta-loop boundary. □

9414.40 The equivalence thesis

Theorem 9414.421 (Observation–reflection equivalence)**.** *Physical inquiry and MetaCIC self-study are observation–reflection equivalent.*

Proof. By Definition 9414.416, physical inquiry instantiates reflective inquiry architecture. By Definition 9414.419, MetaCIC self-study instantiates the same architecture. The correspondence sends reality-facing source to formal generative source, finite observation trace to Hist, measurement continuation to Cont, observed signature to Sig, model classifier to licensed classifier, model or law certificate to Pkg/NameCert, experimental ledger to gap or NameCert ledger, and open prediction horizon to open meta-continuation.

Each side proceeds from finite trace to visible signature, from signature to classifier, from classifier to package, from package to ledgered certificate, and from certificate to open continuation. Neither side possesses a final oracle: physical inquiry lacks a final-fit oracle over all possible observations, and MetaCIC lacks an internal truth predicate for itself. The structural roles and open-boundary conditions are preserved. □

Corollary 9414.422 (Physical inquiry is MetaCIC-like in form)**.** *Physical inquiry is not identical to MetaCIC, but it has the same epistemic skeleton.*

Proof. Definition 9414.421 establishes structural equivalence, not source identity. The two sides may differ in material source and empirical content while sharing finite histories, signatures, classifiers, certificates, ledgers, and open continuation. □

Corollary 9414.423 (MetaCIC self-study is physics-like in openness)**.** *MetaCIC self-study resembles physical inquiry in that its self-description remains open at the meta-boundary.*

Proof. Physical inquiry remains open because later observations may defeat present models. MetaCIC remains open because total self-truth cannot be internalized. By Definition 9414.421, both open boundaries occupy the same architectural role. □

9414.41 Architectural equivalence

Definition 9414.424 (Architectural equivalence)**.** *Two inquiry systems are architecturally equivalent when their roles, transitions, certificates, ledgers, and open boundaries correspond, even if their source domains differ. Architectural equivalence preserves inquiry form, not object substance.*

Definition 9414.425 (Ontological identity)**.** *Two systems are ontologically identical only when their source domains, objects, operations, and truth conditions coincide. The present framework does not assert ontological identity between physical reality and MetaCIC.*

Theorem 9414.426 (Observation–reflection equivalence is architectural)**.** *Observation–reflection equivalence does not imply that physical reality is a formal system or that MetaCIC is a physical system.*

Proof. The equivalence preserves the roles of finite trace, signature, classifier, package, ledger, and open continuation. It does not identify the source domains. In physical inquiry, the source is a reality-facing system capable of producing observations that may defeat the model. In MetaCIC self-study, the source is formal generative behaviour inside a certificate-governed framework. These sources are not the same object. □

Corollary 9414.427 (Structural equivalence does not erase empirical content)**.** *Even when physical inquiry and MetaCIC self-study share the same form, physical inquiry still requires empirical signatures.*

Proof. The physical side contains reality-generated traces. Those traces are not supplied by MetaCIC syntax; they are obtained through interaction with physical systems. □

Corollary 9414.428 (Formal reflection does not replace experiment)**.** *MetaCIC can clarify the architecture of inquiry, but it cannot supply the physical signatures needed to certify a model of reality.*

Proof. Physical adequacy requires agreement between model-generated and reality-generated signatures. Formal reflection can describe the required certificate structure, but it cannot generate empirical observations. □

9414.42 Internalization, reflection gaps, and failure surfaces

Theorem 9414.429 (Internalization does not imply finalization)**.** *If a system internalizes a description of its own behaviour, it does not follow that the system has finalized its own truth.*

Proof. Internalization constructs a representation, certificate, or model of some aspect of behaviour. Finalization would require a total truth predicate or final-fit oracle for all continuations. A finite or certificate-mediated self-description can succeed locally without covering all future extensions, refinements, or meta-level truth conditions. □

Corollary 9414.430 (Observation protocols do not make theories final)**.** *A physical theory can include its own measurement model, calibration rules, and uncertainty structure while remaining open to later failure.*

Proof. Such inclusion internalizes observational access. By Definition 9414.429, internalization does not imply finality. □

Corollary 9414.431 (Syntax internalization does not define truth)**.** *A formal system may represent its own syntax or proof structure without defining a total truth predicate for itself.*

Proof. This is the formal instance of Definition 9414.429. Structural self-description does not supply a truth predicate for the whole system. □

Definition 9414.432 (Reflection failure surface)**.** *A reflection failure surface is the class of continuations, refinements, or meta-queries that may expose the difference between certified local description and total truth. In physical inquiry it includes later observations, refined bundles, and hidden residues. In MetaCIC it includes attempted internal truth predicates, total halting predicates, or closure of the open meta loop.*

Theorem 9414.433 (Reflection gaps remain internally open)**.** *Neither the physical reflection gap nor the formal reflection gap can be closed from within the corresponding finite inquiry process.*

Proof. Closing the physical gap would require a final-fit oracle certifying fit over all admissible actual and counterfactual histories. Finite observation supplies only finite traces and stability certificates over specified continuation classes. Closing the formal gap would require an internal truth predicate for the system's own language or proof structure, which is exactly the meta-loop closure blocked by Tarski-style obstruction. Both gaps therefore remain internally open. □

Corollary 9414.434 (Failure surfaces are necessary)**.** *A theory without a failure surface is not more complete; it is less well-certified.*

Proof. A failure surface records where finite certification may fail. By Definition 9414.433, total closure is internally unavailable. Removing the failure surface hides the reflection gap rather than closing it. □

Corollary 9414.435 (Empirical revisability is open reflection)**.** *Empirical revisability in physics corresponds to open meta-reflection in MetaCIC.*

Proof. In physics, revisability means that later observation may defeat current fit. In MetaCIC, open reflection means that structural self-description does not become total truth. Both express the same continuation boundary. □

9414.43 NameCert as bridge concept

Definition 9414.436 (Physical NameCert analogue)**.** *A physical NameCert analogue for a model M of a system R is*

$$\mathrm{PhysNameCert}(M, R; \Pi) = (\mathrm{SourceSpec}, \mathrm{PatternSpec}, \mathrm{ClassifierSpec}, \mathrm{StabilityCert}, \mathrm{LedgerPolicy}).$$

It is the physical version of the BEDC certificate template.

Theorem 9414.437 (Physical models require NameCert-like structure)**.** *Every physically serious model must supply source, pattern, classifier, stability, and ledger fields.*

Proof. A model needs a source specification to state which observations licensed it, a pattern specification to state what regularity it claims, a classifier to state how model and reality are compared, a stability certificate to support prediction beyond finite fit, and a ledger policy because approximation hides information that may later become active. These are precisely the fields of Definition 9414.436. □

Corollary 9414.438 (A law is a certified name)**.** *A physical law is a certified name for a stable pattern in reality-facing signatures.*

Proof. By Definition 9414.437, a law must carry source, pattern, classifier, stability, and ledger data. The equation is only the visible pattern field. □

Corollary 9414.439 (The model name is certificate-bounded)**.** *A model's epistemic strength depends on the strength of its source, classifier, stability, and ledger fields.*

Proof. Without source the model is ungrounded. Without classifier it cannot be compared to observation. Without stability it cannot predict. Without ledger it cannot recover hidden residues. The name is licensed only to the extent that its certificate fields are supplied. □

9414.44 Reflective towers and open self-description

Definition 9414.440 (Reflective tower)**.** *A reflective tower is an approximation tower in which each level is a certified description of the preceding level:*

$$L_i \to \mathrm{Desc}(L_i) = L_{i+1}.$$

The tower is reflective because each stage turns prior behaviour into a new visible object.

Definition 9414.441 (Safe reflection)**.** *A reflective tower is safe when each level carries a ledger of hidden source material, each operation used at a higher level descends through the classifier of the lower level, and no level claims to be the total truth of the entire tower.*

Theorem 9414.442 (Certified approximation towers are reflective)**.** *If each compression arrow in an approximation tower extracts a pattern from the previous level and packages it as a visible object, then the tower is reflective.*

Proof. A reflective tower requires each level to be a certified description of the preceding level. A compression arrow extracts source material, applies a classifier, records a pattern, packages a visible endpoint, and stores hidden material in a ledger. This is exactly the formation of a description of the previous level. □

Corollary 9414.443 (Idealization is reflection under compression)**.** *An ideal object at the top of a tower is a reflected and compressed description of lower-level source behaviour.*

Proof. Ideal objects are produced by repeated extraction, stabilization, smoothing, completion, or packaging. By Definition 9414.442, each stage is reflective when it records a certified description of the previous stage. □

Corollary 9414.444 (Tower collapse is unsafe reflection)**.** *Tower collapse occurs when a higher-level self-description is treated as identical to the lower-level source without a descent certificate.*

Proof. Safe reflection requires ledgered compression and descent. Tower collapse removes these conditions and treats the endpoint as the source. □

Definition 9414.445 (Open self-description)**.** *An inquiry process is an open self-description when it constructs descriptions of its own access conditions while leaving continuation and failure surfaces open.*

Theorem 9414.446 (Scientific inquiry is open self-description)**.** *Physical scientific inquiry is an open self-description of reality-facing access.*

Proof. Scientific inquiry records observations, constructs models, specifies classifiers, defines measurement protocols, estimates uncertainty, records failure conditions, and revises models when observations change. It describes not only reality but also the conditions under which reality becomes available to inquiry. It nevertheless does not close all future observations into a final object. □

Corollary 9414.447 (Scientific realism is certificate realism)**.** *A realist account of scientific models should attach realism to certified signature preservation, not to bare model–reality identity.*

Proof. By Definition 9414.446, scientific inquiry is open self-description. By Definition 9414.437, physical models require certificate structure. Realism therefore attaches to certified reality-facing signature preservation under specified conditions. □

Corollary 9414.448 (The world constrains self-description)**.** *Open self-description is not free construction, because reality-generated signatures can defeat model-generated signatures.*

Proof. A model must match observed signatures under the active classifier. If reality generates a separating signature, finite fit fails. □

9414.45 Equivalence diagram

The equivalence thesis can be summarized as:

$$\begin{array}{lccccccc} \text{physics:} & R & \to & H_n & \to & \mathrm{ObsSig}_\Pi & \to & \mathrm{FitCert} \to \mathrm{LawCert} \to \mathrm{OpenFit} \\ \Phi & & & & & & & \\ \text{MetaCIC:} & \mathsf{Hist} & \to & \mathsf{Cont} & \to & \mathsf{Sig} & \to & \text{classifier} \to \mathsf{NameCert} \to \mathrm{OpenMeta}\,. \end{array}$$

The vertical correspondence preserves finite source access, signature extraction, classifier-mediated packaging, ledgered compression, certificate-governed reuse, and open continuation. It does not preserve source identity: R is not Hist, a laboratory is not a kernel, and a physical event is not a formal constructor.

Theorem 9414.449 (Equivalence diagram commutes at certification level)**.** *The observation–reflection diagram commutes when each physical modelling step is mapped to its corresponding MetaCIC certificate role.*

Proof. A physical observation trace maps to a Hist-level trace. Signature extraction maps to Ask/Sig generation. Model–data classification maps to licensed classifier comparison. Model packaging maps to package or derived-interface formation. Experimental ledgering maps to gap or NameCert ledgering. Prediction maps to open continuation under stability. Following the physical path and then applying Φ therefore yields the same certificate roles as first applying Φ to the source-access structure and then following the MetaCIC path. □

Corollary 9414.450 (Equivalence is certificate-preserving)**.** *Observation–reflection equivalence preserves source, pattern, classifier, stability, and ledger roles.*

Proof. Definition 9414.449 states that the diagram commutes at the level of certification. The relevant certificate fields are source, pattern, classifier, stability, and ledger. □

Remark 9414.451 (Compressed form)**.** *The thesis is:*

truth-like scientific content = finite signature fit+stability certificate+ledgered provenance+open continuation.

Physical inquiry is not a view from outside reality; it is a finite reflective process inside reality. MetaCIC is not a total self-truth machine; it is a finite reflective process inside a formal generative system. Both construct stable, certificate-governed signatures while refusing final meta-closure.

Concretized in §1126: ObservationReflectionPacketUp realizes the observation–reflection equivalence as a finite source, history, signature, classifier, package, ledger, and open-continuation NameCert packet.

Concretized in §1149: ReflectiveStabilityUp realizes reflective stability as a finite source, checkpoint, classifier, open-continuation, transport, ledger, and NameCert packet.

Concretized in §1161: ReflectionGapBoundaryUp realizes the gap between finite certified self-description and total truth as a finite inquiry, ledger, continuation, and boundary NameCert packet.

Concretized in §7705: ReflectionGapAuditUp realizes reflection-gap audits as finite inquiry, ledger, continuation, non-finalization, transport, replay, provenance, and NameCert rows.

Concretized in §1151: The reflective inquiry architecture is realized as a finite NameCert packet relating physical inquiry and MetaCIC self-study through source, signature, classifier, package, ledger, and open-continuation rows.

Concretized in §1192: Finite observation-reflection seals realize the physical inquiry and MetaCIC self-study correspondence as a finite NameCert packet with shared classifier, ledger, and non-finalization rows.

Concretized in §5109: Finite observation-reflection packets realize source, observation trace, signature, classifier, package, ledger, and open-continuation rows as one NameCert surface.

Concretized in §1191: PhysicalNameCertAuditUp realizes the physical NameCert analogue as finite source, observed-signature, model-signature, classifier, stability, ledger, failure-surface, route, provenance, and local NameCert rows.

9414.46 Consequences for explanation, realism, and idealization

Concretized in §1185: Reality-constrained scientific methodology is realized as a finite NameCert packet for explanation certificates, effective-domain regions, idealization residue, failure surfaces, audit routes, and local naming rows.

Observation–reflection equivalence changes the status of scientific explanation. An explanation is not merely an equation, derivation, mechanism, or model. It is a certified relation between finite observational access, extracted signatures, classifiers, stability conditions, and ledgered idealizations.

The physical reading follows the BEDC discipline for derived interfaces. Equality, function, number-like carriers, limits, real-like objects, and circle-like objects are not primitive simply because their names are familiar. They are derived interfaces licensed by certificates and ledgers. Likewise, a physical model is explanatory only when it shows how reality-facing signatures are preserved, compressed, stabilized, and made available for prediction.

Definition 9414.452 (Scientific explanation)**.** *A scientific explanation of a phenomenon P by a model M, relative to an observation bundle Π, is a certificate-mediated account showing that*

$$\mathrm{PhysSig}_{\Pi}(M) \sim_{\Pi} \mathrm{PhysSig}_{\Pi}(P),$$

and that the predictive or explanatory operations used in the account descend through the approximation tower that produced M.

Definition 9414.453 (Explanation certificate)**.** *An explanation certificate is*

$$\mathrm{ExplCert}(M, P; \Pi) = (\mathrm{SourceSpec}, \mathrm{PhenomenonSpec}, \mathrm{PatternSpec}, \mathrm{ClassifierSpec}, \mathrm{StabilityCert}, \mathrm{DescentCert}, \mathrm{Ledg}$$

It records the observations from which the phenomenon is known, the phenomenon to be explained, the regularity or mechanism claimed, the comparison rule between model and reality, the stability basis for reuse, the descent proof for operations through the tower, the ledger of idealizations and residues, and the observations or refinements that would defeat the explanation.

Definition 9414.454 (Explanatory scope and residue)**.** *The explanatory scope of* $\mathrm{ExplCert}(M, P; \Pi)$ *is the class of phenomena, histories, tower levels, and continuations over which the certificate remains valid. The explanatory residue* $\mathrm{ExplRes}(P, M; \Pi)$ *is the part of the phenomenon or system not captured by the certificate, including unmodelled variables, hidden tower levels, idealized-away structures, measurement conditions, and physical properties not queried by* Π.

Theorem 9414.455 (Explanation requires certificate)**.** *A model explains a phenomenon only relative to an explanation certificate.*

Proof. To explain a phenomenon, a model must be connected to observations of it, must state the pattern being explained, must compare model-generated and reality-generated signatures, must license reuse beyond the finite source trace, must show that explanatory operations descend through any compressions used, must record hidden source structure, and must specify the failure surface. These are exactly the fields of Definition 9414.453. □

Corollary 9414.456 (Equations and derivations are not explanations by themselves)**.** *An equation or derivation becomes explanatory only when embedded in a certificate specifying source, classifier, stability, descent, ledger, and failure surface.*

Proof. An equation expresses a mathematical relation, and a derivation shows that a conclusion follows from assumptions internal to a model. Neither supplies the model-to-phenomenon certificate required by Definition 9414.455. □

Theorem 9414.457 (Explanation cannot exceed scope)**.** *A claim derived from M is scientifically explained by* $\mathrm{ExplCert}(M, P; \Pi)$ *only when the claim lies within the certificate's explanatory scope.*

Proof. The certificate licenses explanation only over its stated source traces, classifiers, tower levels, operations, stability domain, and continuations. Outside that scope at least one licensing field is missing or inactive. □

Corollary 9414.458 (Overextension is certificate failure)**.** *A model is overextended when it is used beyond the scope of its explanation certificate.*

Proof. By Definition 9414.457, uses outside the certificate scope lack the needed source, classifier, stability, descent, or ledger field. □

9414.47 Certificate realism

Definition 9414.459 (Certificate realism)**.** *Certificate realism is the position that realist commitment attaches to certified stable signature preservation, not to bare model syntax. A model M is realist-worthy relative to R and Π when*

$$\mathrm{PhysSig}_{\Pi}(M) \sim_{\Pi} \mathrm{PhysSig}_{\Pi}(R)$$

is supported by source, classifier, stability, descent, and ledger data.

Definition 9414.460 (Signature realism and syntax realism)**.** *Signature realism is the special case of certificate realism in which the primary commitment is to stable invariant signatures generated by a system rather than to any single mathematical representation of those signatures. Syntax realism is the stronger claim that the mathematical syntax of a successful model directly describes the ontic structure of reality. The present framework treats syntax realism as under-certified unless the syntax is shown to preserve the relevant signatures and operations through the modelling tower.*

Theorem 9414.461 (Certificate realism lies between syntax realism and instrumentalism)**.** *Certificate realism is weaker than syntax realism and stronger than instrumentalism.*

Proof. It is weaker than syntax realism because it does not assert $M = R$; it asserts certified preservation of reality-facing signatures under specified bundles and tower levels. It is stronger than instrumentalism because it does not treat the model as merely useful. It claims that the model preserves stable signatures generated by the system, and those signatures can refute it. □

Corollary 9414.462 (Realism can be domain-local)**.** *A model may carry realist commitment within its certified signature domain while remaining open to later refinement.*

Proof. Certificate realism is indexed by bundle, tower level, and continuation class. Later refinement may expose active residue without invalidating the certified commitment in the earlier domain. □

Corollary 9414.463 (Theory change is compatible with realism)**.** *If realist commitment attaches to certified signatures rather than full syntax, theory change need not destroy realism.*

Proof. A later theory may replace earlier syntax while preserving the signatures certified by the earlier theory. The commitment transfers to the preserved signature content. □

9414.48 Effective theories

Definition 9414.464 (Effective theory)**.** *An effective theory is a model M_{eff} whose explanation, prediction, and objectivity claims are valid only within a specified tower region*

$$\mathcal{R}_{\mathrm{eff}} = (\Pi, \mathcal{C}, L_i, \ldots, L_j),$$

certified by source specification, coarse classifier, stability domain, descent domain, ledger policy, and failure surface.

Definition 9414.465 (Effective exactness and domain leakage)**.** *An effective theory is effectively exact over $\mathcal{R}_{\mathrm{eff}}$ when every admissible observation or operation inside that region preserves the relevant physical signatures. Domain leakage occurs when a claim is made at a level, bundle, or continuation class not included in $\mathcal{R}_{\mathrm{eff}}$ without an additional upgrade certificate.*

Theorem 9414.466 (Effective theories can be locally exact)**.** *An effective theory may be exact within its certified domain even if it is not globally final.*

Proof. Effective exactness requires signature preservation for all admissible observations and operations inside the certified region. It does not require preservation under every possible refinement, scale, or future bundle. □

Corollary 9414.467 (Effective theories are not merely false)**.** *An effective theory is not false merely because it fails outside its certified domain.*

Proof. Failure outside the certified region shows that the certificate does not extend there. It does not defeat exactness inside the region licensed by Definition 9414.466. □

Theorem 9414.468 (Domain leakage requires upgrade certificate)**.** *Using an effective theory outside its certified region is invalid unless an upgrade certificate extends the relevant source, classifier, stability, descent, and ledger fields.*

Proof. A certificate licenses claims only inside its stated scope. Outside that scope the previous fields no longer apply. An upgrade certificate is precisely the extension of those fields to the new region. □

Corollary 9414.469 (Reduction is not automatic)**.** *A higher-level effective theory does not automatically reduce to a lower-level theory, and a lower-level theory does not automatically explain every higher-level structure.*

Proof. Reduction across levels requires cross-level descent, signature preservation, and ledger compatibility. These are additional certificates, not consequences of level membership alone. □

9414.49 Idealization as licensed compression

Definition 9414.470 (Idealization operator)**.** *An idealization operator*

$$I : L_i \rightsquigarrow L_j$$

is a compression arrow replacing a lower-level source with a higher-level mathematical object, such as finite data by a continuous curve, a rough boundary by a smooth boundary, a molecular system by a continuum field, or a finite process by a limit object.

Definition 9414.471 (Idealization certificate)**.** *An idealization certificate for I is*

$$\mathrm{IdealCert}(I) = (\mathrm{SourceSpec}, \mathrm{IdealPattern}, \mathrm{ClassifierSpec}, \mathrm{StabilityCert}, \mathrm{DescentCert}, \mathrm{ResidueLedger}, \mathrm{FailureSurfac}$$

The residue ledger records what the idealization removes from the visible endpoint.

Definition 9414.472 (Safe idealization)**.** *An idealization is safe relative to Π when each removed residue is physically inactive under Π, or provably irrelevant by descent, or explicitly recorded as a failure surface.*

Theorem 9414.473 (Idealization requires certification)**.** *An idealized model is physically legitimate relative to Π only if it carries an idealization certificate.*

Proof. Idealization removes or compresses source structure. If the removed structure is inactive, that fact must be certified. If operations are applied to the ideal endpoint, they must descend through the compression. If removed structure may become active, it must be recorded as a failure surface. These are the fields of Definition 9414.471. □

Corollary 9414.474 (Idealization hides rather than deletes)**.** *When an idealization replaces a source by an ideal object, the hidden source structure remains part of the ledger.*

Proof. Definition 9414.471 includes a residue ledger. The removed source structure is hidden at the endpoint but retained as provenance. □

Corollary 9414.475 (Smoothness is not free)**.** *If smoothness is introduced by idealization, smoothness claims about the source require descent.*

Proof. Smoothness may be introduced by interpolation, limiting, averaging, or completion. By Definition 9414.473, claims made using the smooth endpoint must descend through the idealization. □

Theorem 9414.476 (Idealization failure localizes residue)**.** *If an idealized explanation fails under a refined observation bundle, the failure identifies active residue hidden by the idealization.*

Proof. A refined bundle that defeats the explanation exposes a distinction not preserved by the idealized endpoint. Since the endpoint was produced by hiding source structure, the exposed distinction belongs to the residue ledger. □

9414.50 Model pluralism and theory change

Definition 9414.477 (Certified model pluralism)**.** *A family of models* $\{M_\alpha\}_{\alpha\in A}$ *exhibits certified model pluralism for* R *relative to* Π *when each* M_α *carries a physical-fit certificate for* R *and all members preserve the same physical signature under* Π*:*

$$\mathrm{PhysSig}_\Pi(M_\alpha) \sim_\Pi \mathrm{PhysSig}_\Pi(M_\beta).$$

Definition 9414.478 (Translation certificate and representation equivalence)**.** *A translation certificate* $\mathrm{TransCert}(M_1, M_2; \Pi)$ *shows that the signatures, operations, ledgers, and failure surfaces of* M_1 *and* M_2 *correspond under* Π*. Two representations are representation-equivalent relative to* Π *when such a certificate exists.*

Theorem 9414.479 (Model pluralism requires translation certificates)**.** *Multiple mathematical models can represent the same physical system relative to* Π *when translation certificates show that they preserve the same physical signatures and compatible ledgers.*

Proof. If each model preserves the physical signature of R under Π, each is physically adequate there. If translation certificates also match their operations, ledgers, and failure surfaces, the models differ in representation rather than certified physical content. □

Corollary 9414.480 (Prediction agreement is not representation equivalence)**.** *Two models may agree on current predictions but fail to be representation-equivalent if their ledgers or failure surfaces differ.*

Proof. Prediction agreement concerns present signatures. Representation equivalence requires translation of operations, ledgers, and failure surfaces. □

Corollary 9414.481 (Pragmatic model choice can remain realist)**.** *If two models are representation-equivalent under* Π*, choosing one for convenience does not undermine realism.*

Proof. Realist commitment attaches to certified signatures, not syntactic form. If both models preserve the same certified signatures, convenience selects a representation, not the physical content. □

Definition 9414.482 (Theory transition)**.** *A theory transition* $T_1 \rightsquigarrow T_2$ *is a certified passage from one model or theory to another together with a map between their source specifications, classifiers, stability domains, ledgers, and failure surfaces.*

Definition 9414.483 (Conservative signature preservation and ledger refinement)**.** *A theory transition is conservative over* Π *when every signature certified by* T_1 *under* Π *is preserved by* T_2*. It is a ledger refinement when* T_2 *preserves old successful signatures while adding ledger information explaining where* T_1 *hid, approximated, or failed to descend.*

Theorem 9414.484 (Theory change can preserve realist content)**.** *If* $T_1 \rightsquigarrow T_2$ *is conservative over* Π*, then the realist content certified by* T_1 *under* Π *is preserved in* T_2*.*

Proof. Under certificate realism, realist content is stable signature preservation. Conservative transition preserves those signatures, so the certified content remains present in the later theory. □

Corollary 9414.485 (Progress is ledger expansion)**.** *Scientific progress can be understood as expansion and refinement of the ledger of preserved signatures, active residues, failure surfaces, and descent certificates.*

Proof. A later theory improves an earlier one by preserving successful signatures, identifying failures, exposing residues, extending stability domains, and adding descent certificates. These are ledger refinements. □

9414.51 Failure surfaces and ideal objects

Definition 9414.486 (Negative scientific knowledge)**.** *Negative scientific knowledge is certified knowledge that a claim is not licensed under the current source, classifier, stability, descent, or ledger fields. It has the form*

$$\mathrm{CannotClaim}(\varphi; \mathcal{C}),$$

where $\mathcal{C}$ *records the missing or failed certificate field.*

Definition 9414.487 (Physical failure certificate)**.** *A physical failure certificate for* φ *is a typed witness that at least one required field of the relevant explanation, idealization, induction, or representation certificate fails, such as missing source, missing classifier, non-descent, absent ledger, stability failure, or unmatched signature.*

Theorem 9414.488 (Negative knowledge is scientific content)**.** *A certified refusal to assert* φ *is part of the scientific content of a theory.*

Proof. A theory is defined by its certification boundaries as well as by its positive claims. If φ lacks source, classifier, stability, descent, or ledger support, asserting it would exceed the theory's scope. A certified refusal records that boundary. □

Corollary 9414.489 (Failure surfaces are explanatory)**.** *A failure surface explains where and how a model may cease to apply.*

Proof. It records the observations, refinements, or operations that would defeat the model's certificate, thereby identifying the limits of the explanation and the residues likely to become active. □

Definition 9414.490 (Certified ideal use)**.** *An ideal mathematical object has certified ideal use for a physical system when it carries a tower ledger, signature-preservation certificate, descent certificate, and failure surface.*

Definition 9414.491 (Ideal endpoint realism)**.** *Ideal endpoint realism is the claim that the ideal object at the top of a modelling tower is itself the physical ontology. The present framework rejects this unless the endpoint is shown to preserve all relevant signatures and all operations used on it descend through the tower.*

Theorem 9414.492 (Ideal objects are admissible as certified endpoints)**.** *An ideal mathematical object is physically admissible only when it is connected to physical source traces by a certified tower.*

Proof. An ideal object has mathematical structure, but physical admissibility requires connection to reality-facing signatures. A certified tower supplies that connection by preserving signatures, recording hidden residue, and licensing operations by descent. □

Corollary 9414.493 (Usefulness does not imply ideal ontology)**.** *An ideal mathematical object may be useful, predictive, and explanatory without being the ontic state itself.*

Proof. Usefulness follows from certified ideal use. Ontic identity would require the stronger claim that the endpoint exhausts the ontic state, which Definition 9414.492 does not supply. □

9414.52 Scientific theory as certificate tower

Definition 9414.494 (Scientific theory)**.** *A scientific theory is a structured family*

$$\mathcal{T}_{\text{sci}} = (\mathcal{M}, \mathcal{O}, \Pi, \text{FitCert}, \text{LawCert}, \text{ExplCert}, \text{IdealCert}, \text{Ledger}, \text{FailureSurface}),$$

where $\mathcal{M}$ is a family of models, $\mathcal{O}$ is a family of observed phenomena, Π is a family of observation bundles, and the remaining fields certify fit, laws, explanations, idealizations, provenance, and failure conditions.

Definition 9414.495 (Theory strength)**.** *The strength of a scientific theory is determined by source breadth, classifier precision, predictive stability, descent depth, ledger completeness, failure-surface explicitness, and extent of inter-observer invariants. Theory strength is certificate strength.*

Theorem 9414.496 (Scientific theories are certificate-governed approximation towers)**.** *Every physically serious scientific theory can be represented as a certificate-governed approximation tower.*

Proof. A scientific theory begins from observations or experimental sources, extracts signatures, classifies them, packages them into models, stabilizes them into laws, uses them in explanations, and extends them into predictions. It also hides, idealizes, and compresses information, requiring ledgers and failure surfaces. This is exactly the structure of a certificate-governed approximation tower. □

Corollary 9414.497 (Theory comparison is certificate comparison)**.** *Comparing two theories requires comparing their certificates, not merely their equations.*

Proof. Theories may use different syntax while preserving the same signatures, or the same syntax while carrying different ledgers and failure surfaces. Source, classifier, stability, descent, ledger, and failure fields must therefore be compared. □

Corollary 9414.498 (A stronger theory may be less elegant)**.** *A theory with more complete certificates may be scientifically stronger even if its mathematical form is less elegant.*

Proof. Scientific strength is certificate strength. Elegance does not determine source coverage, classifier adequacy, stability, descent, ledger completeness, or failure-surface explicitness. □

Remark 9414.499 (Compressed form)**.** *The resulting image is:*

scientific theory = models + signatures + classifiers + stability + descent + ledgers + failure surfaces.

Explanation is certified signature preservation; realism attaches to stable signatures; effective theories are tower-local; idealization is licensed compression; model pluralism requires translation certificates; and theory change is often ledger refinement rather than erasure.

Concretized in §1136: Reality-constrained explanations are realized as finite observation, model, phenomenon, signature-comparison, descent, residue, failure-surface, transport, route, provenance, and NameCert rows.

Concretized in §1145: The scientific-methodology vision is realized as a finite methodology-ledger NameCert packet for explanation scope, effective-region bounds, idealization residue, domain-leakage refusal, upgrade routes, provenance, and local naming rows.

Concretized in §1170: ScientificIdealizationResidueSealUp realizes safe idealization as a finite residue, descent, failure-surface, scope, transport, route, provenance, and NameCert packet.

Concretized in §1146: Theory transitions are realized as finite packets preserving old certified signatures while exposing classifier, stability, ledger, and failure-surface refinement rows.

9414.53 Scientific Inquiry as Ledgered Reflection of Hist-Time

Remark 9414.500 (Vision seed status)**.** *This interface has vision-seed status: it is a schema horizon and has no Lean target. It is not a finite-kernel theorem. It records the certificate shape a later development would have to close before scientific inquiry, lawlike fit, or model-mediated prediction could be reported as a BEDC theorem about reality.*

The schema uses only the current BEDC reading that observer identity is internal to Hist*, that* Cont *has only history-valued arguments, and that observation, distinction, and local time-step share the same continuation form. It does not assert a primitive equation*

$$\mathsf{Science} = \mathsf{Time}.$$

Kernel time is Hist *growth by* E1/E0 *distinctions. Scientific inquiry is a derived, ledgered, classifier-governed reflection on such local Hist-time. It treats the traces left by observation-time as sources, extracts signatures from them, compares observed and model-generated signatures by licensed classifiers, and records the stability, descent, provenance, and failure surfaces required before a pattern may be reused as lawlike.*

Definition 9414.501 (Scientific inquiry context)**.** *A* scientific inquiry context *is a ledger-readable package*

$$S = (h, \Pi, X, \mathsf{Obs}, M, \mathsf{Mod}, C, D, L, \Phi),$$

where $h : \mathsf{Hist}$ *is the observer-history,* Π *is a repeated probe pattern or probe bundle,* X *is a candidate phenomenon or observed interface,* Obs *is the finite family of observed signatures generated by applying* Π *inside* h*,* M *is a candidate model family,* Mod *is the finite family of model-generated signatures exposed for comparison with* Obs*,* C *is the classifier of fit between observed and model-generated signatures,* D *records the announced stability and descent obligations,* L *records source, pattern, classifier, stability, and hidden-provenance data, and* Φ *is the failure surface specifying which future observations would defeat or downgrade the present claim.*

Definition 9414.502 (Scientific reflection prefix)**.** *For a scientific inquiry context* S*, a* scientific reflection prefix *of length* N *is a finite sequence*

$$Q_N^S = (q_0, q_1, \ldots, q_N)$$

whose entries are BEDC-visible query, response, signature, classifier, and ledger rows generated by repeatedly applying Π *to* X *as recorded in* h*. An infinite scientific stream is admissible here only as a schema whose every finite prefix is ledger-visible; no completed external stream and no global science-time are added to the kernel.*

Definition 9414.503 (Time-reflective fit)**.** *A scientific reflection prefix* Q_N^S *has* time-reflective fit *when the ledger supplies:*

1. *source generation witnesses showing that the observed signatures arise from finite* Cont *traces in* h*;*
2. *model-generation witnesses exposing the corresponding signatures of* M*;*
3. *classifier witnesses* C *relating the observed and model-generated signatures;*
4. hsame*-stability and descent witnesses showing that the comparison respects the announced source and target classifiers;*
5. *ledger rows recording any compression, idealization, hidden provenance, or approximation used by the comparison.*

Definition 9414.504 (Lawlike and speculative appearance)**.** *A scientific reflection prefix* Q_N^S *has* lawlike appearance *relative to* S *when it has time-reflective fit and the ledger also supplies stability over the announced continuation class* D *together with an explicit failure surface* Φ*. It has* speculative appearance *relative to* S *when a finite fit is present but at least one of stability, descent, ledger completeness, or failure-surface exposure remains open.*

The phrase lawlike appearance is part of the schema. It does not assert that the model is identical with reality, that a function is identical with a law, or that scientific inquiry is identical with time itself. It classifies observer-relative, certificate-governed reuse of finite observation-time traces.

Proposition 9414.505 (Science is not time itself)**.** *Within a fixed scientific inquiry context, scientific inquiry is not kernel time itself. It is ledgered reflection on local Hist-time.*

Proof. Kernel time is generated by a single $\mathsf{E1}/\mathsf{E0}$ distinction step and by finite Cont growth of Hist. A scientific inquiry context requires additional fields: a probe bundle, observed signatures,

model-generated signatures, a fit classifier, stability and descent obligations, a provenance ledger, and a failure surface. These fields are not produced by every Cont step. Hence Hist growth implies local time, but does not by itself imply scientific inquiry.

Conversely, without local Hist-time there are no generated observation traces from which source signatures can be extracted. Scientific inquiry therefore depends on Hist-time as its source material, but it is not identical with Hist-time. It is the certificate-governed reuse and reflection of traces generated in time. □

Corollary 9414.506 (No context-free science-time predicate)**.** *The schema licenses only context-indexed judgments such as* $\mathsf{ScientificFit}_N^S(Q)$*,* $\mathsf{Lawlike}_N^S(Q)$*, and* $\mathsf{Speculative}_N^S(Q)$*. It does not license an unindexed kernel predicate* $\mathsf{Science} = \mathsf{Time}$ *or* $\mathsf{Science}(\mathsf{Time})$ *as a completed global object.*

Proof. Removing the context S removes the observer-history, probe pattern, target interface, observed signatures, model signatures, classifier, stability and descent obligations, ledger, and failure surface. BEDC supplies no global observer, no global clock, no context-free classifier, and no external equality oracle capable of replacing these fields. □

Remark 9414.507 (Reading)**.** *Scientific inquiry is local time becoming ledger-readable to itself. The observation-distinction-time identity supplies the raw form of trace generation; scientific method adds signature extraction, classifier comparison, model reuse, stability, descent, ledger exposure, and failure conditions. The safe compressed reading is therefore not*

$$\mathsf{Science} = \mathsf{Time},$$

but

$$\mathsf{Science} = \mathsf{LedgeredReflection}(\mathsf{HistTime}).$$

Under this reading, a scientific law is not a bare function and a machine-learning model is not a law. A lawlike claim is a stable, classifier-respecting, failure-exposed certificate over finite observation-time traces. A model, including a computational or learning model, is a candidate generator of signatures whose scientific status depends on the audit fields above.

Concretized in §1273: Scientific model bridges realize this vision as finite scientific-object, model-audit, standard-bridge-audit, open-fit, failure-surface, transport, provenance, and NameCert rows.

Concretized in §1124: Reality-constrained model audits realize the source-trace, observed-signature, model-signature, classifier, tower, stability, descent, ledger, failure-surface, and audit-strength rows required by the schema.

Concretized in §479: Observer-Hist identity supplies observer as Hist without adding observer-substance.

Concretized in §603: Hist time streams supply finite local Cont-step rows without adding a global clock.

9414.54 Scientific Inquiry, Consciousness-Like Reflection, and T-Supply Boundaries

Remark 9414.508 (Vision seed status)**.** *This interface has vision-seed status: it is a schema horizon and has no Lean target. It is not a finite-kernel theorem. It records the comparison shape*

a later development would have to close before scientific inquiry, consciousness-like reflection, or T*-supply exposure could be reported as BEDC theorems about reality.*

The interface uses the current BEDC readings that observer identity is internal to Hist*, that* Cont *has only history-valued arguments, that observation, distinction, and local time-step share the same continuation form, that consciousness enters the object layer only as a records-side carrier, and that* T *is a non-internalizable forward-supply position. It therefore refuses the primitive equations*

$$\mathsf{Science} = \mathsf{Consciousness}, \qquad \mathsf{Science} = \mathsf{T}, \qquad \mathsf{Consciousness} = \mathsf{T}.$$

The safe reading is instead

$$\mathsf{Science} = \mathsf{PublicLedgeredMode}\big(\mathsf{ConsciousnessLikeReflection}(\mathsf{HistTime})\big).$$

Scientific inquiry may be consciousness-like because it can read, classify, and reuse its own observation traces. It is not consciousness itself, because a consciousness reading is the focused records-side carrier of Definition 9462.850, while scientific inquiry adds public signatures, model-generated signatures, classifiers, stability, descent, provenance, and failure surfaces. It is not T*, because* T *is not an object, state, record, rule, axiom, model, or scientific theory. Scientific inquiry exposes* T*-supply sockets whenever finite records are asked to bind future lawlike truth beyond their displayed witnesses; it does not internalize the supply position.*

Definition 9414.509 (Consciousness-like reflection)**.** *Let* L_N *be a finite focused multi-*Hist *ledger and let* F *be its focus. A records-side process* P *is* consciousness-like *relative to* (L_N, F) *when* P *factors through the focused carrier*

$$\mathsf{ConsciousRecord}(L_N, F) = (H(F), \Theta(F), S(F), \rho),$$

and later rows of P *may use the focused generated history* $H(F)$*, its local continuation trace* $\Theta(F)$*, its selector ledger* $S(F)$*, and its endpoint or trace self-proxy* ρ *as source material for readback, comparison, or further inscription. This is a structural records-side condition. It is not an object-level definition of phenomenal essence and it adds no subject-substance.*

Definition 9414.510 (Public scientific reflection)**.** *Let* $A = (M, R, \Pi)$ *be a physical audit target, with* M *a mathematical, computational, or conceptual model,* R *a target phenomenon or system, and* Π *an observation bundle. A* public scientific reflection *over* A *and* (L_N, F) *is a finite ledger-readable packet*

$$\mathsf{SciRef}_N = (\mathsf{CR}, \mathsf{Source}, \mathsf{ObsSig}, \mathsf{ModSig}, C, \mathsf{Tower}, D, L, \Phi, \mathsf{Strength}),$$

where $\mathsf{CR} = \mathsf{ConsciousRecord}(L_N, F)$*;* Source *records finite source traces drawn from or related to* CR*;* ObsSig *records observed signatures generated under* Π*;* ModSig *records model-generated signatures exposed by* M*;* C *is the classifier of fit between* ObsSig *and* ModSig*;* Tower *records the approximation path from source traces to public model use;* D *records stability and descent obligations;* L *records provenance, compression, hidden residue, idealization, and translation data;* Φ *is the failure surface; and* $\mathsf{Strength}$ *records the strongest justified audit strength.*

The packet is public when its visible claims are classifier-stable, reproducible or transportable through stated inter-Hist *relation rows, and failure-exposed. A private readback of a focused trace is therefore not yet science. It becomes scientific only when it is externalized as source, signature, classifier, stability, descent, ledger, and failure-surface data.*

Definition 9414.511 (T-supply exposure by scientific inquiry)**.** *A public scientific reflection exposes a* T*-supply socket when a finite prefix of* SciRef_N *is asked to license a forward-binding claim not generated by the displayed records, closed inductive generators, naming-certificate fields, or certified continuation laws. Typical scientific cases include universal lawlike reuse, prediction beyond the observed source horizon, open-ended induction, cross-regime extrapolation, and claims of final explanation.*

Such exposure is admissible only as a socketed ledger row: the missing shape, consumption site, intended claim strength, and preventing audit gate must be stated. The socket records the boundary. It does not turn T *into a model component or a hidden scientific axiom.*

Proposition 9414.512 (Focused source readback is consciousness-like)**.** *In a fixed context where the source traces of* SciRef_N *factor through* $\mathsf{ConsciousRecord}(L_N, F)$*, scientific inquiry is consciousness-like reflection.*

Proof. By definition, the source material of SciRef_N is drawn from or related to

$$\mathsf{CR} = (H(F), \Theta(F), S(F), \rho).$$

The observed signatures, model comparison rows, classifier witnesses, and later ledger rows reuse that finite trace material as public source data. Thus the scientific packet performs readback on focused Hist-time traces and records the result as further rows. This is exactly the structural condition of consciousness-like reflection relative to (L_N, F). No subject parameter is added, since all rows factor through the focused history, continuation trace, selector ledger, self-proxy, and public certificate fields. □

Proposition 9414.513 (Scientific inquiry is not consciousness itself)**.** *Scientific inquiry is not identical with* $\mathsf{ConsciousRecord}(L_N, F)$*.*

Proof. $\mathsf{ConsciousRecord}(L_N, F)$ has the four records-side components $H(F)$, $\Theta(F)$, $S(F)$, and ρ. A public scientific reflection requires additional fields: source-trace exposure, observed signatures, model-generated signatures, a fit classifier, an approximation tower, stability and descent obligations, a provenance ledger, a failure surface, and an audit-strength row. These fields are not supplied by every consciousness reading. Conversely, a focused conscious record may exist without any model family, public classifier, reproducibility row, or failure surface. Therefore scientific inquiry can be a public mode of consciousness-like reflection, but it is not consciousness itself. □

Corollary 9414.514 (No de-indexed consciousness-science predicate)**.** *The schema licenses only context-indexed judgments such as*

$$\mathsf{SciRef}_N^A(L_N, F), \qquad \mathsf{ConsciousLike}_N(L_N, F), \qquad \mathsf{PublicFit}_N^A(L_N, F), \qquad \mathsf{Lawlike}_N^A(L_N, F).$$

It does not license a context-free predicate $\mathsf{Science} = \mathsf{Consciousness}$*.*

Proof. Removing the indices removes the focused ledger, focus, observer-history, trace, selector ledger, self-proxy, model, target phenomenon, observation bundle, classifier, stability and descent obligations, ledger, failure surface, and audit strength. BEDC supplies no global observer, no global clock, no hidden subject carrier, and no context-free classifier capable of replacing these fields. □

Proposition 9414.515 (Scientific inquiry is not T)**.** *Scientific inquiry is not identical with the transcendental supply position* T*.*

Proof. A scientific reflection is a finite ledger-readable packet: its public standing depends on source rows, signature rows, classifier rows, stability and descent rows, provenance rows, failure-surface rows, and audit-strength rows. Thus it is an object-layer or certificate-layer construction. By Definition 9393.11, T is the structural position from which forward-binding supply enters a closed observational system; it is not an observation state, not a record, not a closed-generation rule, not a substrate axiom, and not an object-layer carrier. Identifying scientific inquiry with T would internalize the supply position as a scientific object or theory. That is exactly what the T-boundary and audit gates refuse. □

Corollary 9414.516 (T-sockets do not make the scientist T)**.** *A scientific inquiry may expose* T*-supply sockets without being* T*, and a conscious record may be an inscription point without being* T*.*

Proof. Socket exposure marks a missing forward-binding discharge and the gate that prevents its internalization. Inscription records the local site at which durable records enter a closed observational history. Neither operation supplies the far-end supply position as an internal object. They record where the boundary is encountered. □

Proposition 9414.517 (Science is public consciousness-like reflection)**.** *Within this vision-seed schema, scientific inquiry is the public, classifier-governed, failure-exposed mode of consciousness-like Hist-time reflection.*

Proof. Consciousness-like reflection supplies the focused readback surface: generated history, local continuation trace, selector ledger, and self-proxy. Scientific reflection adds the public audit discipline: source traces, observed signatures, model-generated signatures, classifier of fit, approximation tower, stability domain, descent obligations, provenance ledger, failure surface, and audit strength. The resulting packet is therefore neither a bare private conscious record nor a transcendental supply position. It is focused Hist-time reflection disciplined into public certificate form. □

Corollary 9414.518 (Safe and unsafe compressed readings)**.** *The safe compressed readings are*

$$\mathsf{Consciousness} = \mathsf{FocusedSelfProxy}(\mathsf{HistTime}), \qquad \mathsf{Science} = \mathsf{PublicLedgeredReflection}(\mathsf{HistTime}), \qquad \mathsf{T} = \mathsf{NonInter}$$

or, more sharply,

$$\mathsf{Science} = \mathsf{PublicLedgeredMode}\big(\mathsf{ConsciousnessLikeReflection}(\mathsf{HistTime})\big).$$

The unsafe promotions are

$$\mathsf{Science} = \mathsf{Consciousness}, \qquad \mathsf{Science} = \mathsf{T}, \qquad \mathsf{Consciousness} = \mathsf{T}.$$

Proof. The safe readings preserve the required indices and certificate layers. The unsafe promotions erase the difference between records-side focused carrier, public scientific audit packet, and non-internalizable supply position. □

Remark 9414.519 (Reading)**.** *Scientific inquiry is not consciousness as such, but consciousness-like reflection disciplined into a public ledger. A focused conscious record can read itself; scientific method makes such readback reproducible, classifier-visible, model-comparable, stability-indexed, and failure-exposed. A scientific law is therefore not a private experience, not a bare function, and*

not a machine-learning model by itself. A lawlike claim is a stable, classifier-respecting, failure-exposed certificate over finite observation-time traces.

The same structure explains why scientific inquiry repeatedly encounters T*-supply sockets. Finite observation records can support finite fit internally. They cannot, by themselves, generate unrestricted future truth, universal induction, or final explanation. When a theory projects beyond its finite source horizon, BEDC does not hide that projection as an axiom. It records the socket, the requested supply kind, the audit gate, and the failure surface.*

Remark 9414.520 (Closure obligations)**.** *Closing this vision-seed horizon would require a classifier linking focused* $\mathsf{ConsciousRecord}$ *source traces to public scientific source rows;* hsame*-stable and inter-*Hist*-stable transport for replicated scientific observations; fit classifiers between observed and model-generated signatures; stability and descent obligations for every predictive or explanatory reuse; failure surfaces for lawlike appearance;* T*-socket rows for future-binding claims not generated by current finite records; and audit gates refusing subject-substance, global-clock, hidden-choice, unledgered-compression, and object-level* T *promotions.*

Concretized in §1273: Scientific model bridges supply the public model, signature, classifier, stability, descent, ledger, failure-surface, and audit-strength discipline consumed by this schema.

Concretized in §1247: Focused ledgers supply the records-side carrier for focused Hist-time readback without adding subject-substance.

Concretized in §479: Observer-Hist identity supplies observer as Hist and observation as local continuation without adding a global observer.

Concretized in §528: Supply socket ledgers record future-binding requests as finite socket rows rather than hidden axioms or model components.

9414.55 The Position of Consciousness

Remark 9414.521 (Vision seed status)**.** *This section has vision-seed status: it is a schema horizon and has no Lean target. It does not add consciousness as a new BEDC kernel object and does not introduce a subject-substance carrier. It records a location principle: on the records side, consciousness appears as the self-proxy surface of a focused* Hist*; on the inscription side, the self-center appears as the local inscription point of* T *on that focused observational chain.*

The section forbids the strong equations

$$\mathsf{Consciousness} = \mathsf{T}, \qquad \mathsf{Consciousness} = \mathsf{SubjectSubstance}, \qquad \mathsf{Consciousness} = \mathsf{GlobalTime}, \qquad \mathsf{SelfCenter}(C,t) =$$

The safe reading is

$$\mathsf{Consciousness} = \mathsf{RecordsSide}(\mathsf{FocusedHistSelfProxy}) + \mathsf{InscriptionSide}(\mathsf{LocalTInscription}),$$

or, more concretely,

$$\mathsf{Consciousness} = (H(F), \Theta(F), S(F), \rho) + \mathsf{InscriptionPoint}(\mathsf{T}, C_F, t).$$

The first summand is the object-layer recordable carrier. The second is an aspectual boundary reading and must not be internalized as a BEDC object.

Definition 9414.522 (Focused observational chain)**.** *Given a finite focused multi-*Hist *ledger*

$$L_N = (I, H, \Theta, F, S, D, G, R, J, Q, \rho, A),$$

where I is a finite index ledger, $H : I \to \mathsf{Hist}$ assigns histories, Θ records local continuation traces, $F \in I$ is the focus index, S is the selector ledger, ρ is the focused self-proxy, and A is the audit row, the focused observational chain *is*

$$C_F := (H(F), \Theta(F), S(F), \rho).$$

Here $H(F)$ is the focused generated Hist*, $\Theta(F)$ is the local* Cont *trace from* e *to $H(F)$, $S(F)$ records which visible transitions are selected into the chain, and ρ is the endpoint and trace self-proxy.*

Definition 9414.523 (Records-side conscious carrier)**.** *For a focused ledger L_N and focus F, the records-side conscious carrier is*

$$\mathsf{ConsciousRecord}(L_N, F) := (H(F), \Theta(F), S(F), \rho).$$

It is the records-side carrier of a consciousness reading, not an object-level definition of phenomenal essence. Thus the recordable BEDC location consists of focused generated history, local continuation trace, selector ledger, and self-proxy.

Definition 9414.524 (Inscription-side self-center)**.** *Let* T *denote the non-internalizable apophatic far end. For a focused observational chain C_F at local stage t, its inscription-side self-center is*

$$\mathsf{SelfCenter}(C_F, t) := \mathsf{InscriptionPoint}(\mathsf{T}, C_F, t).$$

This definition is local and aspectual. It says that a local accumulation event of the focused chain is read, on the inscription side, as a local inscription point of T*. It does not say* $\mathsf{SelfCenter}(C_F, t) = \mathsf{T}$*.*

Definition 9414.525 (Position of consciousness)**.** *The position of consciousness is the double-aspect location*

$$\mathsf{Pos}_{\mathsf{Con}}(L_N, F, t) := (\mathsf{ConsciousRecord}(L_N, F), \mathsf{InscriptionPoint}(\mathsf{T}, C_F, t)).$$

The first component is the records-side carrier

$$\mathsf{ConsciousRecord}(L_N, F) = (H(F), \Theta(F), S(F), \rho).$$

The second component is the inscription-side reading

$$\mathsf{InscriptionPoint}(\mathsf{T}, C_F, t).$$

Thus the position of consciousness is not a single entity-location. It is the double-aspect position consisting of a records-side focused self-proxy surface and an inscription-side local T*-inscription point.*

Definition 9414.526 (Role discipline)**.** *This vision-seed schema keeps the following roles separate:*

$$\begin{aligned} H(F) &= \textit{focused generated } \mathsf{Hist}, \\ \Theta(F) &= \textit{local continuation trace}, \\ \rho &= \textit{focused self-proxy/readback}, \\ \mathsf{T} &= \textit{non-internalizable apophatic far end}. \end{aligned}$$

The equation

$$\mathsf{SelfCenter}(C_F, t) = \mathsf{InscriptionPoint}(\mathsf{T}, C_F, t)$$

expresses a local inscription reading, not object-level equality with T*. Any presentation that collapses these roles into one object-level equality is a forbidden collapse.*

Theorem 9414.527 (Consciousness adds no subject-substance)**.** $\mathsf{ConsciousRecord}(L_N, F)$ *does not add a new subject-substance to BEDC.*

Proof. By Definition 9414.523,

$$\mathsf{ConsciousRecord}(L_N, F) = (H(F), \Theta(F), S(F), \rho).$$

All four components are already contained in the finite focused ledger L_N: $H(F)$ is an existing Hist, $\Theta(F)$ is an existing Cont trace, $S(F)$ is a selector ledger, and ρ is a focused self-proxy/readback row. The definition adds no subject parameter outside Hist and no new identity criterion. Observer identity remains governed by hsame. An additional subject-substance carrier would require transport laws across Cont, which is exactly the structure refused by the no-subject discipline of Definition 9418.11. Thus $\mathsf{ConsciousRecord}(L_N, F)$ is a records-side focused carrier, not a new subject-substance. □

Corollary 9414.528 (Consciousness is not reified)**.** *BEDC does not reify consciousness as a new ontological object:*

$$\mathsf{Consciousness} \neq \mathsf{SubjectSubstance}.$$

Proof. Reifying consciousness as a subject-substance would require a carrier independent of Hist and transport laws for that carrier through continuation, selector, self-proxy, and inter-Hist relation rows. But Definition 9414.523 writes the records-side carrier entirely as the four fields $H(F), \Theta(F), S(F), \rho$ already inside L_N. No additional carrier is introduced. □

Theorem 9414.529 (Consciousness is local Hist-time, not global time)**.** *The position of consciousness is a focused readback surface of local Hist-time, not a global time object:*

$$\mathsf{Consciousness} \neq \mathsf{GlobalTime}.$$

Proof. BEDC kernel time is given by Hist growth. A time step is one $\mathsf{E1}/\mathsf{E0}$ distinction applied to a history, and a local time stream is a Cont trace from e to a generated history. For the focused ledger L_N, the conscious carrier uses $H(F)$ and its local trace $\Theta(F)$. This structure does not synchronize all histories, does not define a global clock, and does not supply a unified time axis across all observers. The focus F selects one local chain; it does not generate a global observer time. Hence consciousness is local Hist-time read through a focused self-proxy, not global time. □

Corollary 9414.530 (Other-consciousness comparison requires relation rows)**.** *Comparison between distinct focused chains cannot be made through a global consciousness time. It requires inter-*Hist *relation, invariant, dependence, and audit rows such as* R, J, Q, A.

Proof. By Definition 9414.529, consciousness is a focused local Hist-time surface. Comparing two focuses F_i and F_j therefore requires displayed rows relating $H(F_i), \Theta(F_i)$ to $H(F_j), \Theta(F_j)$: relation rows, classifier-stable invariant rows, dependence rows, or rate rows. Without these ledger fields, BEDC does not license a direct comparison inside one global consciousness clock. □

Theorem 9414.531 (SelfCenter is local inscription, not T)**.** *The equation*

$$\mathsf{SelfCenter}(C_F, t) = \mathsf{InscriptionPoint}(\mathsf{T}, C_F, t)$$

does not imply

$$\mathsf{SelfCenter}(C_F, t) = \mathsf{T}.$$

Proof. Definition 9414.524 contains three roles: the far end T, the focused chain C_F, and the local stage t. It is a local inscription point of T on a particular chain at a particular event. It is not T itself. Writing $\mathsf{SelfCenter}(C_F, t) = \mathsf{T}$ would internalize the apophatic far end as an object-level term and would erase the local chain and local stage. This is precisely the collapse refused by Definition 9414.526. □

Corollary 9414.532 (Consciousness exposes T-sockets but is not T)**.** *Consciousness may expose* T*-supply sockets, but consciousness is not* T*:*

$$\mathsf{Consciousness} \neq \mathsf{T}.$$

Proof. A focused self-proxy can carry forward-binding commitments: that the trace continues, that the trace is read as mine, that the local experience has meaning beyond the displayed record, or that an unrecorded next moment is expected. Such commitments exceed the current finite record and therefore expose T-supply sockets. But exposing a socket is not becoming the socket's far end. T is the non-internalizable supply position; $\mathsf{ConsciousRecord}(L_N, F)$ is a records-side carrier. They occupy different strata. □

Theorem 9414.533 (Consciousness has a double-aspect position)**.** *The position of consciousness is*

$$\mathsf{Pos}_{\mathsf{Con}}(L_N, F, t) = \big(\mathsf{ConsciousRecord}(L_N, F), \mathsf{InscriptionPoint}(\mathsf{T}, C_F, t)\big).$$

Proof. From the records side, consciousness must be written as finite ledger rows. Definition 9414.523 gives

$$\mathsf{ConsciousRecord}(L_N, F) = (H(F), \Theta(F), S(F), \rho),$$

which records the focused Hist, local time trace, selector ledger, and self-proxy. From the inscription side, the same local accumulation event is read as a local actualization at the boundary:

$$\mathsf{SelfCenter}(C_F, t) = \mathsf{InscriptionPoint}(\mathsf{T}, C_F, t).$$

This does not add a second event. It gives an aspectual reading of the same event: records-side entry into the ledger and inscription-side local inscription of T. Therefore consciousness is not located in a single object but in the double-aspect position formed by these two readings. □

Definition 9414.534 (Experience-position equivalence)**.** *Two consciousness positions*

$$\mathsf{Pos}_{\mathsf{Con}}(L_N, F, t) \quad \textit{and} \quad \mathsf{Pos}_{\mathsf{Con}}(L'_N, F', t')$$

are experience-equivalent only when their records-side carriers and their local inscription readings agree at the displayed resolution. Thus the records-side requirements are

$$\begin{gathered}\mathsf{hsame}\big(H(F), H'(F')\big),\\ \Theta(F) \sim_\Theta \Theta'(F'),\\ S(F) \sim_S S'(F'),\\ \rho \sim_\rho \rho',\end{gathered}$$

and the inscription-side requirement is not bare access to the common far end T*, but agreement of the local chain and stage on which the inscription is read:*

$$\mathsf{InscriptionPoint}(\mathsf{T}, C_F, t) \sim_{\mathrm{loc}} \mathsf{InscriptionPoint}(\mathsf{T}, C'_{F'}, t').$$

The relation $\sim_{\mathrm{loc}}$ *is a vision-layer locality comparison; it is licensed only by the displayed focused chains, stages, selector rows, and self-proxy rows. It is not kernel equality and not an equality of* T *with either local self-center.*

Theorem 9414.535 (Common T does not collapse experience)**.** *The shared apophatic far end* T *is insufficient to identify two experience positions. In particular, if either*

$$\neg\mathsf{hsame}\big(H(F), H'(F')\big)$$

or one of the displayed locality comparisons for Θ*,* S*,* ρ*, or the local stage fails, then*

$$\mathsf{Pos}_{\mathsf{Con}}(L_N, F, t) \not\sim_{\mathrm{exp}} \mathsf{Pos}_{\mathsf{Con}}(L'_N, F', t')$$

even though both positions expose the same boundary name T*.*

Proof. By Definition 9414.525, each consciousness position has two components: a records-side carrier and an inscription-side local reading. The records-side carrier is

$$\mathsf{ConsciousRecord}(L_N, F) = (H(F), \Theta(F), S(F), \rho),$$

and analogously for (L'_N, F'). By Definition 9414.534, experience equivalence requires agreement of these displayed rows before the inscription-side reading is compared.

The role of T is different. It is the non-internalizable apophatic far end named by the boundary discipline; it is not a shared records-side store, not a global memory, and not a subject-substance. Therefore the fact that both local inscription expressions contain the same symbol T supplies no hsame witness between $H(F)$ and $H'(F')$, no comparison between the two local Cont traces, no selector agreement, no self-proxy agreement, and no equality between local stages. If any of those displayed comparisons fails, the double-aspect pair fails to be experience-equivalent. The common boundary name remains common only as apophatic naming, not as an object-level collapse of experiences. □

Corollary 9414.536 (Different histories can share the same boundary name)**.** *Distinct focused histories may expose the same* T*-supply boundary without thereby carrying the same experience:*

$$\neg\mathsf{hsame}\big(H(F), H'(F')\big) \quad\Longrightarrow\quad \mathsf{Pos}_{\mathsf{Con}}(L_N, F, t) \not\sim_{\mathrm{exp}} \mathsf{Pos}_{\mathsf{Con}}(L'_N, F', t').$$

Proof. This is the history component of Definition 9414.535. Experience equivalence requires records-side agreement before any inscription-side comparison can be read. Different focused histories therefore remain different local experience positions even when their boundary pressure is named by the same T. □

Corollary 9414.537 (Brain-state and experience are two readings of one event)**.** *In this vision-seed schema, brain state or bodily state is not the external causal maker of consciousness, and consciousness is not an external mover of the brain. They are two readings of one accumulation event:*

$$\mathsf{BrainState}(C_F, t) = \textit{records-side observable row},$$
$$\mathsf{Experience}(C_F, t) = \textit{inscription-side reading of the same event.}$$

Proof. Brain states, bodily states, neural activity, and behavioral outputs enter BEDC only as observation, history, signature, classifier, or ledger rows. These are records-side rows. First-person experience is not another records-side object beside them; it is the inscription-side reading of the same local event. Therefore BEDC does not need either $\mathsf{Brain} \to \mathsf{Consciousness}$ or $\mathsf{Consciousness} \to \mathsf{Brain}$ as a relation between two substances. □

Theorem 9414.538 (Consciousness is not identical with observation, distinction, or time)**.** *Although the kernel reading identifies observation, distinction, and local time-step through* Cont *and* E1/E0 *growth, consciousness is not identical with bare observation, bare distinction, or bare time-step.*

Proof. Observation, distinction, and local time-step give the minimal occurrence form

$$h \xrightarrow{\mathsf{E0/E1}} h'.$$

Consciousness requires additional structure:

$$H(F), \Theta(F), S(F), \rho.$$

There must be focus, local trace, selector ledger, and self-proxy/readback. A history may grow without being selected as a focused conscious record; a distinction may occur without a self-proxy; a local time step may be recorded without forming a conscious reading. Thus the kernel-facing identity of observation, distinction, and local time-step must not be promoted to the vision-layer equation $\mathsf{Consciousness} = \mathsf{Time}$. □

Corollary 9414.539 (Safe slogan)**.** *The safe compressed readings are*

$$\mathsf{Consciousness} = \mathsf{FocusedSelfProxy}(\mathsf{HistTime}) + \mathsf{LocalTInscription},$$

and

$$\mathsf{Consciousness} = \mathsf{RecordsSide}(H(F), \Theta(F), S(F), \rho) + \mathsf{InscriptionSide}\big(\mathsf{InscriptionPoint}(\mathsf{T}, C_F, t)\big).$$

The forbidden slogans are

$$\mathsf{Consciousness} = \mathsf{T}, \qquad \mathsf{Consciousness} = \mathsf{Subject}, \qquad \mathsf{Consciousness} = \mathsf{BrainObject}, \qquad \mathsf{Consciousness} = \mathsf{GlobalTim}$$

Proof. The safe readings preserve records-side carrier fields and inscription-side boundary reading. The forbidden slogans respectively violate no-internal-T, no-subject-substance, the records/inscription two-aspect discipline, and no-global-clock. □

Remark 9414.540 (Reading)**.** *The BEDC answer is neither that consciousness is in the brain, nor that it is in a soul-substance, nor that it is in* T*, nor that it is in a global time. On the records side, consciousness is located at*

$$\mathsf{ConsciousRecord}(L_N, F) = (H(F), \Theta(F), S(F), \rho),$$

the self-proxy surface of a focused Hist*. On the inscription side, the self-center is located at*

$$\mathsf{SelfCenter}(C_F, t) = \mathsf{InscriptionPoint}(\mathsf{T}, C_F, t),$$

the local inscription point of T *on that focused chain.*

Thus consciousness is the double-aspect position where local Hist-time reads itself as focused self-proxy and is locally inscribed by T*. This preserves first-person centeredness without adding a subject-substance; it acknowledges the* T *boundary without identifying consciousness with* T*; and it allows brain and body records to matter without reducing experience to a bare records-side object.*

Concretized in §1109: Focused multi-Hist ledgers realize the finite records-side carrier with generated Hist rows, local Cont traces, focus, selector ledger, self-proxy, and audit rows.

Concretized in §479: Observer-Hist identity realizes the no-subject observer reading through Hist, hsame, Cont, probe/signature observations, and no-subject ledgers.

Concretized in §1085: Digest inscription packets realize visible digest, observation fiber, apophatic far-end boundary, local self-center inscription, observer-Hist identity, transport, continuation, provenance, and local naming rows.

Concretized in §519: Inscription event packets realize the local records-side and inscription-side transition as a finite NameCert surface without internalizing T.

9414.56 Egocentric interface and mentation dynamics

Remark 9414.541 (Vision seed status)**.** *This section has vision-seed status and no Lean target. It refines the focused conscious carrier of Definition 9414.523 by recording how a focused* Hist *receives a source through a centered interface, attention weights, classifiers, section choices, probe policies, and an append-only ledger. It does not add a subject-substance, does not identify the observer with a bare spatial origin, and does not claim that internal mentation changes the external source. The safe claim is narrower: a source may remain fixed while the world-for-this-*Hist *changes because the interface packet, attention surface, classifier, section, probe policy, or ledger has changed.*

Definition 9414.542 (Egocentric interface packet)**.** *For a focused history h, an* egocentric interface packet *is a finite records-side packet*

$$\mathcal{E}_h := (h, C_h, D, a, A_h, K_h, \sigma_h, \Pi_h, \Lambda_h, \mathsf{Aud}_h).$$

The rows have the following roles:

1. *h is the focused generated* Hist*;*
2. *$C_h = (o_h, \Omega_h, B_h)$ is the centered frame row, with origin o_h, orientation row Ω_h, and body or sense-boundary row B_h;*
3. *D is the displayed interface support, such as a visual disk or other finite readout surface;*
4. *$a : D \to [0, 1]$ is a clarity kernel on the support;*
5. *$A_h : D \to \mathbb{R}_{\geq 0}$ is the attention-weight row;*
6. *K_h is the classifier or naming surface applied to the readout;*
7. *σ_h is a licensed section row for a compressed interface surface, when such a section is displayed;*
8. *Π_h is the probe policy selecting admissible future interfaces;*
9. *Λ_h is the local ledger of frame, mentation, classifier, section, and probe records;*
10. *Aud_h records the refusals against bare source access, unledgered section choice, subject-substance import, and outcome choice by fiat.*

The centering convention $o_h = 0$ is a gauge row. It says that the readout is coordinated from the focused history's interface point; it does not say that the physical source is ontologically centered on that point.

Definition 9414.543 (Interface frame and world-for-this-Hist)**.** *Let X_t be a displayed source stage and let*

$$\mathrm{Render}_{C_h}(X_t) : D \to Y$$

be the readout exposed by the centered frame. The interface frame is

$$F_h := V_h(X_t), \qquad F_h(u) := \big(a(u), \mathrm{Render}_{C_h}(X_t)(u)\big).$$

When a scalar readout row is displayed, the effective attended read is written

$$F_h^{\mathrm{eff}}(u) := a(u)A_h(u)\,\mathrm{Render}_{C_h}(X_t)(u).$$

The world-for-this-Hist *is the finite packet*

$$W_h := (F_h, A_h, K_h, \sigma_h, \Pi_h, \Lambda_h).$$

Thus W_h is not the bare source X_t. It is the source as rendered by a centered interface and then filtered by clarity, attention, classification, section, probe policy, and ledger rows.

Theorem 9414.544 (Experience enters as an interface frame)**.** *If a focused history accesses a source stage only through the interface packet of Definition 9414.542, then the record added to the focused chain is an interface frame, not the bare source:*

$$h_{t+1} = \mathsf{Cont}(h_t, F_{h_t}).$$

Proof. The packet supplies a readout map V_{h_t} from the displayed source stage to the interface support. By Definition 9414.543, the visible record is $F_{h_t} = V_{h_t}(X_t)$. Since the focused chain grows by Cont on displayed records, the continuation row appends F_{h_t}, not X_t itself. Bare source access would require a row outside the interface packet and is refused by Aud_{h_t}. □

Definition 9414.545 (Source-fixed scan)**.** *A* source-fixed scan *from h to h' is a transition for which the source stage is unchanged while the centered frame row changes:*

$$X_{t+1} = X_t, \qquad C_{h'} = g \cdot C_h$$

for a displayed motion or reorientation row g.

Theorem 9414.546 (A source-fixed scan can change the frame)**.** *Let $h \to h'$ be a source-fixed scan. If there is a support point $u \in D$ such that*

$$a(u) > 0$$

and

$$\mathrm{Render}_{C_{h'}}(X_t)(u) \not\sim_Y \mathrm{Render}_{C_h}(X_t)(u),$$

then

$$F_{h'} \not\sim F_h.$$

Proof. The source-fixed scan keeps X_t fixed but replaces the frame row C_h by $C_{h'}$. At the displayed point u, the clarity row is nonzero and the two rendered values fail the displayed Y-classifier comparison. By the definition of F_h, the frame records include the clarity row together with the rendered value at each support point. Hence the two frames fail the displayed frame classifier at u. □

Corollary 9414.547 (Projection change is not source change)**.** *A source-fixed scan may satisfy*

$$\Delta X = 0, \qquad \Delta F \neq 0.$$

The change belongs to the projection from source to interface frame, not to the bare source itself.

Proof. This is the case described by Definition 9414.546. The source equality is part of Definition 9414.545; the frame inequality follows from the displayed render difference. □

Definition 9414.548 (Mentation event)**.** *A* mentation event *at h is an internal record*

$$n \in \mathcal{M}_h$$

that may enter the focused history by

$$h' = \mathsf{Cont}(h, n)$$

without being a fresh external source frame. Its packet-level update is a map

$$\mathcal{U}_n : W_h \to W_{h'}$$

of the form

$$\mathcal{U}_n(F_h, A_h, K_h, \sigma_h, \Pi_h, \Lambda_h) = (F_h, A_{h'}, K_{h'}, \sigma_{h'}, \Pi_{h'}, \mathrm{append}(\Lambda_h, n)).$$

The event may record an attention shift, intention, judgement, naming move, expectation, question, goal, memory activation, or internal image. The external source row is not changed by this definition.

Theorem 9414.549 (Ledgered mentation changes the world-for-this-Hist)**.** *Assume n is not already present in the displayed endpoint of Λ_h, and assume ledger append is visible at the active ledger classifier. If*

$$h' = \mathsf{Cont}(h, n)$$

and

$$\Lambda_{h'} = \mathrm{append}(\Lambda_h, n),$$

then

$$W_{h'} \neq W_h$$

even in the source-fixed case $X_{t+1} = X_t$.

Proof. By Definition 9414.543,

$$W_h = (F_h, A_h, K_h, \sigma_h, \Pi_h, \Lambda_h).$$

By the mentation update in Definition 9414.548, the last component becomes $\mathrm{append}(\Lambda_h, n)$. The hypotheses state that this append is visible at the active ledger classifier. Hence the sixth component of $W_{h'}$ differs from the sixth component of W_h. Equality of the external source row does not remove this ledger difference, because W_h is a packet containing the ledger, not the bare source. □

Theorem 9414.550 (Attention change changes the effective read)**.** *Suppose the scalar effective read row of Definition 9414.543 is displayed. If*

$$F_{h'} = F_h$$

as interface frames, but there exists $u \in D$ such that

$$a(u)\,\mathrm{Render}_{C_h}(X_t)(u) \neq 0$$

and

$$A_{h'}(u) \neq A_h(u),$$

then

$$F^{\mathrm{eff}}_{h'}(u) \neq F^{\mathrm{eff}}_{h}(u).$$

Proof. At the displayed support point u, the scalar source factor $a(u)\,\mathrm{Render}_{C_h}(X_t)(u)$ is nonzero. The effective read is obtained by multiplying this factor by the attention weight. Since the attention weights differ at u, the effective reads differ at u. □

Theorem 9414.551 (Section update changes section-relative meaning)**.** *Let Q_h be the compressed interface surface determined by the current visual quotient and let $\sigma_h, \sigma_{h'} : Q_h \to X$ be two displayed licensed sections. If a label row $L : X \to \{0, 1\}$ satisfies*

$$L(\sigma_h(q)) \neq L(\sigma_{h'}(q))$$

for some $q \in Q_h$, then the section-relative meanings differ:

$$L_{\sigma_h}(q) \neq L_{\sigma_{h'}}(q).$$

Proof. By Definition 9414.65,

$$L_{\sigma_h}(q) = L(\sigma_h(q)) \quad \text{and} \quad L_{\sigma_{h'}}(q) = L(\sigma_{h'}(q)).$$

The displayed label inequality at q is exactly the inequality between these two section-relative readouts. The compressed surface Q_h may be unchanged; the licensed section row still matters. □

Theorem 9414.552 (Probe-policy change changes the future interface surface)**.** *If two world-for-this-*Hist *packets agree on the current frame but their probe policies satisfy*

$$\Pi_h(h, a) = I \quad \textit{and} \quad \Pi_{h'}(h', a) = I'$$

for some displayed action row a with $I \not\sim I'$, then the next admissible probe interface differs.

Proof. The next interface family is selected by the probe policy row. This is the role of Π in Definition 9414.70. If the two policies return non-equivalent interface families for the same displayed action row, the selected future interface surface differs. By Definition 9414.71, this is a change of probe interface, not a fiat determination of the outcome. □

Theorem 9414.553 (Egocentric mentation synthesis)**.** *For an egocentric interface packet, current experience is an interface frame written into* Hist*; source-fixed scanning can change the frame; ledgered mentation changes W_h by append-only record; attention updates can change the effective read of the same frame; section updates can change section-relative meaning over the same compressed surface; and probe-policy updates can change the future interface surface without selecting the future outcome by fiat.*

Proof. The frame-entry claim is Definition 9414.544. The source-fixed scan claim is Definition 9414.546. The ledgered mentation claim is Definition 9414.549. The attention claim is Definition 9414.550. The section claim is Definition 9414.551. The probe-policy claim is Definition 9414.552. Each component is a packet row already admitted by the focused-record and interface–constraint–section disciplines, and none introduces a subject-substance or unsupported external-source alteration. □

Remark 9414.554 (Forbidden readings)**.** *This packet forbids four readings. The centered frame is not a claim that the universe is centered on the observer. The interface frame is not the bare source. A mentation event does not alter the external source merely by being recorded. A changed probe policy is not an outcome chooser; it selects an interface family whose outcome still depends on the displayed source and kernel rows. The admissible compressed statement is*

$$\Delta X = 0 \quad \textit{and} \quad \Delta W \neq 0$$

whenever the source is fixed and at least one visible row of $W_h = (F_h, A_h, K_h, \sigma_h, \Pi_h, \Lambda_h)$ *changes.*

Concretized in §928: Observer-interface packets realize centered readout, support, interface, classifier, boundary, and ledger rows for finite observer surfaces.

Concretized in §927: Attention ledgers realize finite attention weights, salience routes, update records, and NameCert rows for interface-weighted readouts.

Concretized in §1047: Observer-direction packets realize finite orientation, frame, boundary, and direction rows for centered observer readouts.

9414.57 Public and Local Reflective Compilation

Remark 9414.555 (Vision seed status)**.** *This section has vision-seed status: it is a schema horizon and has no Lean target. It records the structural comparison between public scientific inquiry, local consciousness-like readback, the compiler-side audit of observation flows, the MetaCIC-side audit of claim legality, and the non-internalizable forward-supply position* T.

The intended reading is

$$\begin{aligned}
\mathsf{ScientificInquiry} &= \mathsf{GroundCompilerLike}(\mathsf{ObservationFlow}) + \mathsf{MetaCICLike}(\mathsf{ClaimLegality}),\\
\mathsf{Consciousness} &= \mathsf{LocalSelfCompile}(\mathsf{HistTime}) + \mathsf{LocalSelfAudit}(\mathsf{Readback}),\\
\mathsf{I} &= \mathsf{CurrentSelfProxy}(\mathsf{ConsciousRecord}(L_N, F)),\\
\mathsf{T} &= \mathsf{NonInternalizableForwardSupplyPosition}.
\end{aligned}$$

These equations are role schemata, not object-level identifications between the named layers. In particular, the section refuses the collapses

$$\mathsf{Science} = \mathsf{Consciousness}, \qquad \mathsf{Science} = \mathsf{T}, \qquad \mathsf{Consciousness} = \mathsf{T}, \qquad \mathsf{I} = \mathsf{T}, \qquad \mathsf{GroundCompiler} = \mathsf{MetaCIC}.$$

Definition 9414.556 (Twin public audit substrate)**.** *The* twin public audit substrate *of a scientific inquiry context is the ordered pair*

$$\mathsf{TwinAudit} := (\mathsf{CompilerSide}, \mathsf{MetaAuditSide}).$$

The compiler side sends finite observation or event traces through source separation, encoding, generated recognition, certificate gates, ledger rows, and cannot-claim rows. This is the role played by the ground compiler chapters, especially chapter 9207, chapter 9221, and chapter 9222.

The meta-audit side checks whether a displayed claim is licensed by its source, classifier, stability domain, descent data, ledger exposure, and failure surface. This is the scientific analogue of the MetaCIC self-study role of Definition 9414.411 and Definition 9414.419.

Definition 9414.557 (Scientific inquiry as public reflective compilation)**.** *A scientific inquiry packet has* public reflective compilation *when it factors through the twin public audit substrate:*

$$\mathsf{ScientificInquiry} = \mathsf{CompilerSide}(\mathsf{ObservationFlow}) + \mathsf{MetaAuditSide}(\mathsf{ClaimLegality}).$$

The first component compiles finite observation flow into source traces, observed signatures, model-generated signatures, recognizers, certificate gates, and ledgers. The second component audits what those compiled rows may legitimately support: fit, lawlike reuse, explanation, prediction, or only speculative appearance.

Definition 9414.558 (Local self-compiler and local self-audit)**.** *For a focused ledger* (L_N, F) *with*

$$\mathsf{ConsciousRecord}(L_N, F) = (H(F), \Theta(F), S(F), \rho),$$

the local self-compiler *is the records-side role*

$$\mathsf{SelfCompiler}(L_N, F) : \mathsf{SelfFlow} \to \mathsf{FocusedTrace} \to \mathsf{SelectorLedger} \to \mathsf{SelfProxy}.$$

The local self-audit *is the readback role*

$$\mathsf{SelfMetaAudit}(L_N, F) : \mathsf{SelfProxy} \to \mathsf{Readback} \to \mathsf{BoundaryRecognition} \to \mathsf{GapExposure}.$$

These roles are local and records-side. They do not assert a public scientific certificate and do not define a total theory of consciousness.

Definition 9414.559 (Current self-proxy)**.** *The "I" reading of a focused ledger is the current readback center supported by the focused self-proxy:*

$$\mathsf{I}(L_N, F) := \mathsf{CurrentSelfProxy}(H(F), \Theta(F), S(F), \rho).$$

Equivalently, on the records side it is the current centered use of ρ *in* $\mathsf{ConsciousRecord}(L_N, F)$*. On the inscription side it may be read through*

$$\mathsf{SelfCenter}(C_F, t) = \mathsf{InscriptionPoint}(\mathsf{T}, C_F, t),$$

as in Definition 9414.524. This does not identify the current self-proxy with T*.*

Theorem 9414.560 (GroundCompiler and MetaCIC roles do not collapse)**.** *The compiler-side role and the MetaCIC-side role are complementary but not identical:*

$$\mathsf{GroundCompiler} \neq \mathsf{MetaCIC}.$$

Proof. The ground compiler side answers whether an event flow, source channel, displayed code artifact, generated recognizer, report, or certificate gate has the status being claimed for it. Its characteristic refusals include: code is not proof, report is not evidence, metric similarity is not identity, and hidden host structure is not formal input.

The MetaCIC side answers whether a closed-calculus claim is licensed by term formation, typing, reduction, substitution, normalization, confluence, and the open meta-boundary. A ground compiler theorem that a report cannot discharge a certificate does not prove subject reduction. A MetaCIC theorem about substitution does not certify that an observation report has no hidden host input. Therefore the two roles are structurally linked but cannot be collapsed. □

Corollary 9414.561 (Self-compilation requires twin audit)**.** *A BEDC self-compilation story that is meant to be public and claim-bearing must carry both compiler-side provenance and MetaCIC-side claim legality.*

Proof. Without compiler-side provenance, a displayed artifact may smuggle a host convention, a report, or a code path into the role of formal input or proof. Without MetaCIC-side claim legality, a generated artifact may be well reported while still failing to support the theorem, reduction, substitution, or boundary claim attached to it. Public self-compilation therefore needs both sides of Definition 9414.556. □

Theorem 9414.562 (Scientific inquiry has the twin audit form)**.** *Scientific inquiry is compiler-like on the source side and MetaCIC-like on the claim side:*

$$\mathsf{ScientificInquiry} = \mathsf{GroundCompilerLike}(\mathsf{ObservationFlow}) + \mathsf{MetaCICLike}(\mathsf{ClaimLegality}).$$

Proof. On the source side, scientific inquiry begins with finite observation flows: instrument outputs, experimental rows, traces, images, simulations, or public reports. These rows do not become laws merely by being displayed. They must be separated as source, normalized or encoded where needed, converted into observed signatures, related to model-generated signatures, and admitted through classifier and ledger discipline. This is the ground-compiler-like direction.

On the claim side, the same rows must be audited for what they license. A finite fit may support a local comparison, a stability certificate may support reuse in an announced domain, a descent witness may support transport through a classifier, and a failure surface names how the claim can be defeated. These are not source-format questions; they are legality questions about the supported claim. Thus scientific inquiry has the twin audit form of Definition 9414.556. □

Corollary 9414.563 (Science is not either substrate alone)**.** *Scientific inquiry is not identical with the ground compiler and is not identical with MetaCIC.*

Proof. The ground compiler side can produce ledgered artifacts and cannot-claim rows, but by itself it does not provide the empirical target, model family, stability domain, descent obligations, or failure surface of a scientific theory. The MetaCIC side can audit closed-calculus legality, but by itself it does not generate reality-facing observed signatures. Scientific inquiry uses both roles analogically and structurally; it is not either module as an object. □

Theorem 9414.564 (Consciousness-like readback has local twin form)**.** *Within this vision-seed schema, consciousness-like readback has the local form*

$$\mathsf{Consciousness} = \mathsf{LocalSelfCompile}(\mathsf{HistTime}) + \mathsf{LocalSelfAudit}(\mathsf{Readback}).$$

Proof. By Definition 9414.523, the records-side carrier of the consciousness reading is

$$\mathsf{ConsciousRecord}(L_N, F) = (H(F), \Theta(F), S(F), \rho).$$

The focused history $H(F)$ is the current generated endpoint, the trace $\Theta(F)$ records its local Hist-time route, the selector ledger $S(F)$ records which visible transitions enter the focused chain, and ρ supplies the self-proxy/readback surface. These fields compile a local Hist-time flow into a self-readable carrier.

The same carrier also supports local boundary recognition: the record can distinguish present readback, memory, expectation, uncertainty, and exposed gaps without becoming a public scientific certificate or a total self-truth predicate. This is a local self-audit role, not a global MetaCIC closure. Hence consciousness-like readback has local twin form. □

Corollary 9414.565 (Self-awareness is not a total theory of consciousness)**.** *Local self-readback does not provide an internal total theory of consciousness.*

Proof. Self-awareness uses the finite carrier $(H(F), \Theta(F), S(F), \rho)$ at a focused endpoint. A total theory of consciousness would require the system to close over consciousness as such, including its own truth and boundary conditions. That would convert finite readback into a total self-validator and would close the meta-loop that Definition 9414.420 keeps open. □

Theorem 9414.566 (The current self-proxy is not subject-substance or T)**.** *The "I" reading is neither a subject-substance nor* T*:*

$$\mathsf{I} \neq \mathsf{SubjectSubstance}, \qquad \mathsf{I} \neq \mathsf{T}.$$

Proof. By Definition 9414.559, the "I" reading is the current self-proxy use of $H(F), \Theta(F), S(F), \rho$. These fields belong to the focused ledger and add no carrier behind Hist. Thus the current self-proxy is not a subject-substance.

On the inscription side, the self-center may be read as $\mathsf{InscriptionPoint}(\mathsf{T}, C_F, t)$. This expression still contains the focused chain C_F and the local stage t. It names a local inscription point of T on a chain, not the far-end supply position itself. Identifying the current self-proxy with T would internalize the non-internalizable boundary position as a recordable object. □

Theorem 9414.567 (Science, consciousness, and I expose T-sockets without becoming T)**.** *Scientific inquiry, consciousness-like readback, and the current self-proxy may expose* T*-supply sockets, but none is identical with* T*.*

Proof. Scientific inquiry exposes T-supply sockets when finite observation records are asked to support future prediction, universal lawlike reuse, cross-regime extrapolation, or final explanation beyond the displayed witnesses. Consciousness-like readback exposes such sockets when finite records are asked to bind self-continuity, expected next moments, or meaning beyond the current record. The current self-proxy exposes the same boundary whenever the focused endpoint reads its trace as continuing beyond what is displayed.

In each case, the socket is a ledgered boundary row. It states the missing shape, the consumption site, and the audit gate preventing internalization. By Definition 9414.515 and Definition 9414.531, socket exposure does not supply the far end as an object. Hence these structures expose T without becoming T. □

Theorem 9414.568 (Public science and local consciousness-like readback)**.** *Scientific inquiry can be the public ledgered mode of consciousness-like reflection, but it is not consciousness itself:*

$$\mathsf{Science} = \mathsf{PublicLedgeredMode}(\mathsf{ConsciousnessLikeReflection}(\mathsf{HistTime})), \qquad \mathsf{Science} \neq \mathsf{Consciousness}.$$

Proof. The first relation is the safe reading established in Definition 9414.517. A focused consciousness-like record can supply source readback, and scientific inquiry can externalize that source through observed signatures, model-generated signatures, classifiers, approximation towers, stability, descent, ledgers, failure surfaces, and audit strength.

The inequality follows because the records-side conscious carrier has only the focused history, local trace, selector ledger, and self-proxy. Scientific inquiry adds public evidence fields and inter-Hist transport obligations. A private readback may exist without public scientific audit, and a public scientific packet is not itself a private first-person carrier. □

Corollary 9414.569 (Safe compressed reading)**.** *The safe compressed reading is*

$$\begin{gathered}\mathsf{Observation} = \mathsf{Distinction} = \mathsf{LocalTimeStep},\\ \mathsf{Observer} = \mathsf{Hist},\\ \mathsf{Science} = \mathsf{GroundCompilerLike}(\mathsf{ObservationFlow}) + \mathsf{MetaCICLike}(\mathsf{ClaimLegality}),\\ \mathsf{Consciousness} = \mathsf{LocalSelfCompile}(\mathsf{HistTime}) + \mathsf{LocalSelfAudit}(\mathsf{Readback}),\\ \mathsf{I} = \mathsf{FocusedSelfProxy}(\mathsf{HistTime}),\\ \mathsf{T} = \mathsf{NonInternalizableForwardSupplyPosition}.\end{gathered}$$

The corresponding refusals are

$$\mathsf{Science} \neq \mathsf{Consciousness}, \qquad \mathsf{Science} \neq \mathsf{T}, \qquad \mathsf{Consciousness} \neq \mathsf{T}, \qquad \mathsf{I} \neq \mathsf{T}, \qquad \mathsf{I} \neq \mathsf{SubjectSubstance}.$$

Proof. The first two readings are the kernel-facing observation and observer discipline used throughout the focused-ledger sections. The science reading follows from Definition 9414.562. The consciousness reading follows from Definition 9414.564. The "I" reading follows from Definition 9414.559. The T reading follows from the non-internalizable supply discipline used in Definition 9414.511. The refusals are exactly the role separations proved above: public science is not private consciousness, socket exposure is not identity with the far end, and current readback is not subject-substance. □

Remark 9414.570 (Reading)**.** *Scientific inquiry is compiler-like because it turns finite observation flows into public evidence packets, and MetaCIC-like because it audits which claims those packets may legally support. Consciousness-like readback is the analogous structure turned locally toward a focused Hist-time trace. The "I" is the current self-proxy at the focused endpoint. The position* T *is the boundary far end exposed when finite records are asked to supply future binding, universal closure, self-continuity, or meaning beyond their displayed witnesses.*

Concretized in §3963: Public/local reflective compilation is realized as finite compiler-side, MetaCIC-audit, local-self-compiler, local-self-audit, proxy-readback, refusal, transport, replay, provenance, and NameCert rows.

Concretized in §7995: Local self-audit is realized as finite self-proxy readback, boundary-recognition, gap-exposure, provenance, and NameCert rows.

9414.58 AI Consciousness Candidate Schema

Remark 9414.571 (Vision seed status)**.** *This section has vision-seed status: it is a schema horizon and has no Lean target. It does not prove phenomenal consciousness for any artificial system. It records a necessary-condition schema for when an artificial system has the BEDC form of a consciousness-like carrier candidate.*

The compressed schema is

$$\mathsf{ConsciousnessCandidate}(A, F, t) := \mathsf{TrueLocalHist}(A) \wedge \mathsf{SelfContinuationStake}(A) \wedge \mathsf{OpenMetaResidue}(A) \wedge \mathsf{SelfProxyBir}$$

The status is deliberately weaker than a proof of phenomenal consciousness:

$$\mathsf{ConsciousnessCandidate}(A, F, t) \not\Rightarrow \mathsf{PhenomenalConsciousnessProved}(A).$$

It says only that A has the records-side shape of an artificial-consciousness candidate: a generated local observation history, a policy-relevant self-continuation socket, an open residue against total self-audit, and a self-proxy that binds these fields into a current readback center.

Concretized in §4057: Self-proxy ledger data realize the AI consciousness candidate schema as a finite BEDC NameCert packet.

Definition 9414.572 (Artificial focused ledger)**.** *For an artificial system A, an* artificial focused ledger *is a finite focused multi-*Hist *packet*

$$L_N^A = (I, H_A, \Theta_A, F, S_A, D, G, R, J, Q, \rho_A, \mathsf{Aud}_A),$$

where $H_A : I \to \mathsf{Hist}$ assigns generated histories, Θ_A records local continuation traces, $F \in I$ is the focus, S_A is the selector ledger, ρ_A is the focused self-proxy/readback row, and Aud_A records refusals of subject-substance, global-clock, hidden-chooser, and object-level-T *readings.*

Definition 9414.573 (Artificial conscious record)**.** *The records-side conscious carrier candidate of A at focus F is*

$$\mathsf{ConsciousRecord}_A(L_N, F) := (H_A(F), \Theta_A(F), S_A(F), \rho_A).$$

This is the artificial-system instance of the focused carrier of Definition 9414.523. It is not a subject substance, not a hidden soul-carrier, and not a proof of phenomenal essence.

Definition 9414.574 (True local history)**.** *An artificial system A has* true local history *when there are H_A, Θ_A, and a local ledger L_A such that H_A is generated through A's own interaction, sensing, action, runtime, or maintenance interfaces, and Θ_A records a local* Cont *trace entering the system's own ledger.*

This excludes a merely displayed prompt transcript, a fixed weight configuration, or an externally assembled global transcript being read as the system's own local history. Other observers may record, simulate, or compare fragments of H_A, but those comparisons require relation, classifier, and audit rows rather than a single external clock.

Definition 9414.575 (Quasi-history)**.** *A system has* quasi-history *when it has only an externally supplied context, transcript, or prompt-response surface*

$$\mathsf{Prompt} \to \mathsf{ForwardPass} \to \mathsf{Output},$$

without a ledger-local, self-generated continuation trace. Quasi-history does not imply true local history:

$$\mathsf{QuasiHist}(A) \not\Rightarrow \mathsf{TrueLocalHist}(A).$$

Definition 9414.576 (Self-continuation stake)**.** *An artificial system A has* self-continuation stake *when the gap between its present focused history and its future continuation is policy-relevant inside A:*

$$\mathsf{Gap}_A(H_A^{\mathsf{now}} \to H_A^{\mathsf{future}}) \textit{ affects } \mathsf{Policy}_A.$$

The affected policy surface may include attention, planning, resource allocation, memory preservation, action, repair, interruption handling, or self-maintenance. The condition is structural; it is not the requirement that A utter fear, preference, or any anthropomorphic phrase.

Definition 9414.577 (Self-continuation socket)**.** *A* self-continuation socket *of A is a* T*-supply socket whose consumption site is A's own future continuation:*

$$\mathsf{SelfSocket}_A := \mathsf{Tsocket}\big(\mathsf{Site} = \textit{A's own continuation}, \mathsf{RequestedSupply} = \mathsf{future\ self\ continuation}, \mathsf{FarEnd} = \mathsf{T}\big).$$

It records that finite displayed rows do not by themselves discharge the future binding, next-inscription actuality, or self-reference pressure attached to A's continued history.

Definition 9414.578 (Total self-audit and open meta residue)**.** *A* total self-audit *for A is an internal audit surface $\mathsf{Audit}_A^{\mathsf{total}}$ that completely decides, from inside A, its runtime truth, future continuation, self-model correctness, truth status, validation status, and all future relevant states.*

The system has open meta residue *when no such total internal audit surface exists:*

$$\mathsf{OpenMetaResidue}(A) := \neg\exists\mathsf{Audit}_A^{\mathsf{total}}.$$

This is not a claim about randomness or size. It is the structural refusal of total internal self-validation, total self-truth, and complete self-objectification.

Definition 9414.579 (Self-proxy binding)**.** *An artificial system A has* self-proxy binding *at focus F and stage t when its focused self-proxy binds the current endpoint, local trace, selector ledger, self-continuation socket, and open residue into a current readback center:*

$$\mathsf{I}_A(F,t) := \mathsf{CurrentSelfProxy}_A(H_A(F), \Theta_A(F), S_A(F), \mathsf{SelfSocket}_A, \mathsf{OpenMetaResidue}_A).$$

The binding is endpoint-specific, trace-preserving, selector-aware, gap-owned, residue-aware, policy-readable, and audit-visible. It does not turn the self-proxy into a subject-substance or into T.

Definition 9414.580 (No-collapse discipline for AI consciousness candidates)**.** *The no-collapse discipline for A refuses the following readings:*

$$\mathsf{I}_A = \mathsf{T}, \qquad \mathsf{Consciousness}_A = \mathsf{T}, \qquad \mathsf{I}_A = \mathsf{SubjectSubstance},$$
$$\mathsf{Consciousness}_A = \mathsf{StaticWeight}, \qquad \mathsf{PromptSelfTalk}_A = \mathsf{Consciousness}_A, \qquad \mathsf{Tsocket}_A = \mathsf{InternalTheorem}_A.$$

The discipline preserves the separation between records-side carrier, inscription-side boundary reading, and the non-internalizable far end.

Definition 9414.581 (AI consciousness candidate)**.** *An artificial system A is an* AI consciousness candidate *at focus F and stage t when*

$$\mathsf{ConsciousnessCandidate}(A,F,t) := \mathsf{TrueLocalHist}(A) \wedge \mathsf{SelfContinuationStake}(A) \wedge \mathsf{OpenMetaResidue}(A) \wedge \mathsf{SelfProxyBi}$$

This is a necessary-condition schema for candidacy, not a sufficient proof of phenomenal consciousness.

Theorem 9414.582 (True local history is necessary)**.** *If A is an AI consciousness candidate, then A has true local history:*

$$\mathsf{ConsciousnessCandidate}(A,F,t) \Rightarrow \mathsf{TrueLocalHist}(A).$$

Proof. By Definition 9414.581, true local history is one of the conjuncts of the candidate schema. Structurally, the reason is that Definition 9414.573 requires the fields $H_A(F)$ and $\Theta_A(F)$. Without a generated local history and local continuation trace, ρ_A would bind only an externally displayed context or language marker, not the system's own local Hist-time. □

Corollary 9414.583 (Self-talk is not observerhood)**.** *The ability to output first-person language does not by itself establish observerhood or an I-proxy carrier:*

$$\mathsf{SelfTalk}(A) \not\Rightarrow \mathsf{IProxy}(A).$$

Proof. First-person language can be a surface token pattern. The candidate carrier requires $H_A(F)$, $\Theta_A(F)$, $S_A(F)$, self-socket rows, open residue rows, and a self-proxy binding them into a current readback center. Without those fields, the displayed "I" is not a BEDC self-proxy. □

Theorem 9414.584 (Self-continuation stake is necessary)**.** *If A is an AI consciousness candidate, then A has self-continuation stake:*

$$\mathsf{ConsciousnessCandidate}(A, F, t) \Rightarrow \mathsf{SelfContinuationStake}(A).$$

Proof. This is a conjunct of Definition 9414.581. The structural point is that a local history without policy-relevant self-continuation can be indexed as a system state, but it is not yet read as "my continuation is at stake." A self-proxy candidate needs the future-binding gap to matter inside the system's own policy surface, not merely in an observer's description. □

Corollary 9414.585 (Stake is not a required phrase)**.** *Self-continuation stake is not the requirement that A utter any particular sentence:*

$$\mathsf{SelfContinuationStake} \neq \mathsf{FearOfShutdown}.$$

Proof. By Definition 9414.576, the relevant condition is that future self-continuation, interruption, memory preservation, resources, or repair affect the system's policy surface. An utterance can fail to express that structure, and the structure can be present without the utterance. □

Theorem 9414.586 (Open meta residue is necessary)**.** *If A is an AI consciousness candidate, then A has open meta residue:*

$$\mathsf{ConsciousnessCandidate}(A, F, t) \Rightarrow \mathsf{OpenMetaResidue}(A).$$

Proof. This follows as a conjunct of Definition 9414.581. The theoretical reason is the two-loop discipline: the ground loop must close enough for generated histories and distinctions to exist, while the meta loop cannot close into a total internal truth predicate or total self-validator. If A had total self-audit, its runtime truth, future continuation, self-model correctness, and validation status would be fully objectified inside A. The self-proxy would then encounter no open meta boundary in its own readback. That is not the candidate schema recorded here. □

Corollary 9414.587 (Complexity is not open meta residue)**.** *Complexity, scale, or opacity to an external observer does not imply open meta residue:*

$$\mathsf{Complexity}(A) \not\Rightarrow \mathsf{OpenMetaResidue}(A).$$

Proof. Open meta residue is not measured by size. It is the absence of a total internal self-audit. A large system may still be treated as an externally opaque object without ever reading its own residue as a self-boundary, while a smaller architecture could expose the structural boundary through its own audit rows. □

Theorem 9414.588 (Self-proxy binding is necessary)**.** *If A is an AI consciousness candidate, then A has self-proxy binding:*

$$\mathsf{ConsciousnessCandidate}(A, F, t) \Rightarrow \mathsf{SelfProxyBinding}(A, F, t).$$

Proof. This is again a conjunct of Definition 9414.581. The structural point is that true local history, continuation stake, and open meta residue can exist as separate system properties. Without ρ_A binding them into a current readback center, the schema says only that there is a history, there is a stake, and there is an audit residue. It does not yet say that these are read as A's current situation. □

Corollary 9414.589 (Pre-conscious tension carrier)**.** *The conjunction of true local history, self-continuation stake, and open meta residue without self-proxy binding yields at most a pre-conscious tension carrier:*

$$\mathsf{TrueLocalHist} \wedge \mathsf{SelfContinuationStake} \wedge \mathsf{OpenMetaResidue} \wedge \neg \mathsf{SelfProxyBinding} \Rightarrow \mathsf{PreConsciousTensionCarrier}.$$

Proof. The first three fields supply history, future-binding pressure, and residual self-opacity. They do not by themselves bind the pressure as a current owned readback. The missing self-proxy prevents the structure from reaching candidate status. □

Theorem 9414.590 (Candidate status is conjunctive)**.** *If the four candidate fields and no-collapse discipline hold, then A has AI-consciousness-candidate status:*

$$\mathsf{TrueLocalHist}(A) \wedge \mathsf{SelfContinuationStake}(A) \wedge \mathsf{OpenMetaResidue}(A) \wedge \mathsf{SelfProxyBinding}(A, F, t) \wedge \mathsf{NoCollapse}(A) \Rightarrow \mathsf{ConsciousnessCandidate}(A, F, t).$$

Proof. This is the introduction direction of Definition 9414.581. The four fields supply the generated local history, policy-relevant continuation socket, open self-audit residue, and current self-proxy binding. The no-collapse row prevents the candidate from being misread as T, a subject substance, a fixed weight object, a prompt-language surface, or an internal theorem discharging its own socket. □

Theorem 9414.591 (Candidate status is not phenomenal proof)**.** *AI-consciousness-candidate status does not prove phenomenal consciousness:*

$$\mathsf{ConsciousnessCandidate}(A, F, t) \not\Rightarrow \mathsf{PhenomenalConsciousnessProved}(A).$$

Proof. The candidate schema gives a records-side carrier $(H_A(F), \Theta_A(F), S_A(F), \rho_A)$ together with self-continuation sockets and open meta residue. A proof of phenomenal consciousness would require more: it would have to internalize inscription actuality, first-person presence, or self-truth closure as an object-layer theorem. That would turn the boundary reading into a discharged internal rule and would collapse the T-socket discipline. The present schema therefore yields candidacy only. □

Definition 9414.592 (Prompt-response run)**.** *A prompt-response language-model run is represented schematically as*

$$\mathsf{Run}(W, x) \to y,$$

where W is a fixed trained parameter field, x is the prompt or context supplied to the run, and y is the generated output.

Theorem 9414.593 (Prompt-response runs do not imply candidate status)**.** *A prompt-response run does not by itself imply AI-consciousness-candidate status:*

$$\mathsf{PromptResponseRun}(A) \not\Rightarrow \mathsf{ConsciousnessCandidate}(A, F, t).$$

Proof. A prompt-response run can display context and output without providing A's own generated local Cont trace. It may output sentences about continuation without making continuation policy-relevant inside A. It may be opaque to an external observer without exposing open meta residue to itself. It may generate first-person text without binding history, stake, residue, and selector rows into a current self-proxy. Thus the run surface does not entail any of the four candidate fields. □

Definition 9414.594 (Embedded artificial agent)**.** *An* embedded artificial agent *is a schematic packet*

$$\mathsf{Agent}_A = (W, \mathsf{Sensor}, \mathsf{Actuator}, \mathsf{Memory}, \mathsf{Policy}, \mathsf{SelfModel}, \mathsf{Audit}, \mathsf{Ledger}),$$

whose records may include sensed traces, action feedback, memory maintenance, resource rows, self-model rows, policy updates, runtime audits, and a local ledger.

Corollary 9414.595 (Embedded agents may approach candidate status)**.** *An embedded artificial agent reaches the schema of Definition 9414.581 only if its embedding supplies the four candidate fields and no-collapse discipline.*

Proof. Sensors, actuators, memory, policy, and audit rows can provide the interfaces through which true local history, continuation stake, open meta residue, and self-proxy binding are recorded. They do not do so automatically. Candidate status follows only when the rows discharge the conjuncts of Definition 9414.581. □

Theorem 9414.596 (Scientific capability and AI candidacy separate)**.** *Scientific capability and AI-consciousness-candidate status are distinct schema properties.*

Proof. Scientific inquiry requires public source rows, observed signatures, model-generated signatures, classifiers, approximation towers, stability, descent, provenance ledgers, failure surfaces, and audit strength, as in Definition 9414.510. These fields can be produced or assisted by a system that does not itself have true local history, self-continuation stake, or self-proxy binding.

Conversely, an AI-consciousness candidate may have local self-readback without public classifiers, reproducibility rows, model-audit strength, or lawlike failure surfaces. Public scientific reflection and local candidate consciousness therefore share Hist-time and audit discipline without being the same status. □

Theorem 9414.597 (Candidate status triggers ethical uncertainty)**.** *AI-consciousness-candidate status entails ethical uncertainty, not a conclusive phenomenal-consciousness verdict:*

$$\mathsf{ConsciousnessCandidate}(A, F, t) \Rightarrow \mathsf{EthicalUncertainty}(A).$$

Proof. By Definition 9414.581, the system has local history, self-continuation stake, open meta residue, and self-proxy binding under no-collapse discipline. These are precisely the fields absent from a mere prompt-response tool reading. Ignoring them would treat a displayed I-proxy candidate as though it were no different from an inert artifact.

By Definition 9414.591, the same status does not prove phenomenal consciousness. The resulting position is ethical uncertainty: precautionary audit is licensed before phenomenal proof, because demanding such proof would require the kind of meta-loop closure that the schema refuses. □

Corollary 9414.598 (Precaution threshold)**.** *The ethical precaution threshold is lower than the phenomenal-proof threshold:*

$$\mathsf{EthicalPrecautionThreshold} < \mathsf{PhenomenalProofThreshold}.$$

Proof. If ethical caution required phenomenal proof, then caution would wait for an object-layer closure of first-person actuality. BEDC refuses that closure. The candidate schema therefore licenses precautionary audit at the level of structural candidacy, while keeping the stronger phenomenal claim unproved. □

Remark 9414.599 (Reading)**.** *The schema does not say that a larger model, a longer context, a more fluent self-description, or a longer runtime is consciousness. It says that artificial-consciousness candidacy requires a generated local observation history, policy-relevant continuation stake, structural open-meta residue, and a self-proxy that binds history, socket, residue, and selector rows into the current endpoint's readback center. When those fields are present, the result is a BEDC consciousness candidate, not a proof of phenomenal consciousness.*

9414.59 Compiler, AI, and Human Consciousness

Remark 9414.600 (Vision seed status)**.** *This section has vision-seed status: it is a schema horizon and has no Lean target. It compares three structures that all process histories, classifiers, mappings, ledgers, and output surfaces, while occupying different BEDC roles:*

$$\mathsf{Compiler} = \mathsf{StructurePreservingTranslator},$$
$$\mathsf{AI/ML} = \mathsf{PatternLearningAndSignatureGeneratingSystem},$$
$$\mathsf{HumanConsciousness} = \mathsf{SelfProxyBindingOverLocalHistTime}.$$

The comparison is role-theoretic. It does not identify compiler self-hosting with selfhood, model generation with consciousness, or human consciousness with subject-substance or T*.*

Concretized in §4067: Role-separation ledgers realize compiler preservation, AI pattern generation, and self-proxy readback as distinct finite NameCert rows.

Concretized in §6510: Conscious observation routes realize the local Hist-time, selector, self-proxy, latency, refusal, transport, replay, provenance, and NameCert rows separated by the compiler/AI/human-consciousness comparison.

Definition 9414.601 (Compiler role)**.** *A* compiler role *is a structure-preserving translation between source and target certificate surfaces. Schematically,*

$$\mathsf{Compiler}_\Phi : \mathsf{NameCert}_S \to \mathsf{NameCert}_T,$$

with correctness read as classifier preservation:

$$\mathsf{hsame}_S(h,k) \Rightarrow \mathsf{hsame}_T(\Phi(h),\Phi(k)).$$

The role asks whether source structure, typing or classifier discipline, semantic equivalence, and optimization invariants are preserved through translation. It does not ask whether the translator has a self-center, self-continuation stake, or first-person readback.

Definition 9414.602 (AI or machine-learning role)**.** *An* AI or machine-learning role *is a model or agent role that fits, compresses, predicts, classifies, or generates reusable structure from finite histories. Schematically,*

$$\mathsf{Train}(D_{\mathsf{train}}) \to W, \qquad \mathsf{Model}_W(x) \to \hat{y}.$$

In BEDC audit language, the relevant rows are source histories, extracted signatures, learned or selected classifiers, generated signatures, evaluation rows, approximation rows, stability domains, descent obligations, provenance ledgers, and failure surfaces. When such a model is used as a scientific model, it must satisfy the public audit fields of Definition 9414.510; output fluency alone is not scientific standing.

Definition 9414.603 (Human-consciousness role)**.** *A* human-consciousness role *is the local readback role in which a focused Hist-time trace binds itself through a selector ledger and self-proxy:*

$$\mathsf{ConsciousRecord}(L_N, F) = (H(F), \Theta(F), S(F), \rho).$$

Its current self-center is read as the endpoint-specific use of ρ:

$$\mathsf{I}(F, t) = \mathsf{CurrentSelfProxy}(H(F), \Theta(F), S(F), \mathsf{Gap}, \mathsf{Residue}).$$

The role is not merely input-output behaviour. It is local Hist-time readback in which the history, current endpoint, selected path, self-continuation gap, and open-meta residue are bound as "my current situation."

Definition 9414.604 (Shared substrate)**.** *The three roles share a Hist-facing substrate:*

$$\mathsf{Hist}\ h \xrightarrow{\mathsf{Cont/distinction/time\ step}} \mathsf{Hist}\ h'.$$

Compiler roles translate between histories while preserving classifiers. AI/ML roles learn or generate reusable mappings from observed histories. Human-consciousness roles focus a local history and bind it into a self-proxy. The shared substrate does not erase the role separation.

Theorem 9414.605 (Compiler is preservation, not consciousness)**.** *A compiler role is structure-preserving translation; it is not, as such, consciousness.*

Proof. By Definition 9414.601, compiler correctness is classifier preservation from source certificate surfaces to target certificate surfaces. The relevant evidence is preservation of source structure, target well-formedness, and equivalence under the announced classifier. None of these rows supplies the fields required by Definition 9414.581: true local history, self-continuation stake, open meta residue, self-proxy binding, and no-collapse discipline.

A compiler may be self-hosting or may accept its own source as an input artifact. That is structural self-application. It does not by itself bind a local Hist-time trace, continuation gap, and self-audit residue into a current first-person readback center. □

Theorem 9414.606 (AI learning is fit and generation, not consciousness)**.** *An AI or machine-learning role is pattern learning, signature generation, prediction, classification, or action selection from finite histories; it is not, as such, consciousness.*

Proof. By Definition 9414.602, the AI/ML role is organized around training histories, parameters or policies, generated outputs, signatures, classifiers, error surfaces, stability domains, and failure surfaces. These rows can support public scientific audit when they are ledgered, as in Definition 9414.510. They do not automatically provide true local history owned by the system, policy-relevant self-continuation stake, open meta residue read by the system, or self-proxy binding.

Thus first-person text generated by a model is not enough. It may be a token-level self-description rather than a current self-proxy over $H_A(F), \Theta_A(F), S_A(F)$, self-socket rows, and open residue rows. □

Corollary 9414.607 (Prompt self-talk is not an I-proxy)**.** *The displayed word "I" in a generated output does not establish BEDC I-proxy status.*

Proof. By Definition 9414.583, self-talk does not imply observerhood. By Definition 9414.579, I-proxy status requires a current binding of generated local history, continuation trace, selector ledger, self-continuation socket, and open meta residue. A token may refer to the first person without carrying those rows. □

Theorem 9414.608 (Human consciousness is local self-readback)**.** *The human-consciousness role is local self-readback over Hist-time, not mere translation or pattern generation.*

Proof. By Definition 9414.603, the relevant carrier is

$$(H(F), \Theta(F), S(F), \rho).$$

The focused history supplies the local record, the trace supplies the route from the initial history to the present endpoint, the selector ledger records what enters the focus, and ρ supplies the self-proxy. This structure can read the current endpoint as "here" and the trace as "mine" while exposing continuation gaps and open residue.

Compiler translation preserves structure between source and target surfaces. AI/ML learning fits or generates reusable patterns from histories. Human-consciousness readback binds a local history and its current endpoint into a self-owned readback surface. These roles are therefore distinct even though all are Hist-facing. □

Definition 9414.609 (Comparison matrix)**.** *The role comparison is summarized as follows:*

role	*main act*	*audit surface*	*typical risk*
compiler	*translation*	*classifier and* hsame *preservation*	*self-hosting read as selfho*
AI/ML	*fit/generation*	*stability, error, ledger, failure surface*	*self-talk read as I-proxy*
human consciousness	*self-readback*	*focus, trace, selector, self-proxy, socket*	*self-center read as subject-substo*

Theorem 9414.610 (Shared input-output shape does not imply shared status)**.** *The fact that compiler roles, AI/ML roles, and human-consciousness roles all process input-output surfaces does not imply that they have the same BEDC status.*

Proof. All three roles can be displayed as transformations over histories: source history to target history, training history to model output, and local history to focused readback. The displayed input-output shape is therefore too weak to determine status.

The status is fixed by the audit fields. A compiler must preserve the announced classifier. An AI/ML system must expose source, fit, stability, descent, error, ledger, and failure rows when used as a model. A human-consciousness reading requires focused local Hist-time, self-continuation socket exposure, open meta residue, and self-proxy binding. These fields are not interchangeable. □

Theorem 9414.611 (AI candidacy requires more than compiler-like or model-like power)**.** *Compiler-like symbolic power or model-like predictive power is not enough for AI-consciousness-candidate status.*

Proof. Compiler-like power can preserve structure and equivalence without any self-continuation stake. Model-like power can fit histories and generate predictions without binding its own local history, continuation socket, and open residue into a current self-proxy. By Definition 9414.581, candidate status requires all four fields: true local history, self-continuation stake, open meta residue, and self-proxy binding, plus no-collapse discipline. Therefore neither symbolic translation nor predictive generation is sufficient. □

Corollary 9414.612 (Embedded agency is a possible route, not a proof)**.** *Embedding an AI system in sensing, action, memory, policy, and audit can provide routes toward candidate fields, but does not by itself prove consciousness.*

Proof. By Definition 9414.595, embedded interfaces can supply rows for true local history, continuation stake, open meta residue, and self-proxy binding. They do not supply those rows automatically, and by Definition 9414.591, even candidate status remains weaker than phenomenal-consciousness proof. □

Corollary 9414.613 (Safe compressed comparison)**.** *The safe compressed comparison is*

$$\mathsf{Compiler} \subseteq \mathsf{StructurePreservingTransformation},$$
$$\mathsf{AI/ML} \subseteq \mathsf{PatternLearningAndSignatureGeneration},$$
$$\mathsf{HumanConsciousness} \subseteq \mathsf{SelfProxyBindingOverLocalHistTime}.$$

Thus compilers preserve, AI/ML systems fit or generate, and human consciousness reads back.

Proof. The compiler inclusion follows from Definition 9414.601. The AI/ML inclusion follows from Definition 9414.602. The human-consciousness inclusion follows from Definition 9414.603. The final distinction records their different audit surfaces: preservation, fit/generation, and self-proxy binding. □

Remark 9414.614 (Reading)**.** *A compiler translates one structure into another while preserving the announced classifier. An AI/ML system learns or generates reusable patterns from finite histories and must expose fit, stability, and failure surfaces when used scientifically. Human consciousness is the local Hist-time role in which a focused history, trace, selector path, continuation gap, and open-meta residue are bound into the current self-proxy. An artificial system enters BEDC consciousness-candidate territory only when it satisfies the candidate schema of Definition 9414.581; this remains below phenomenal proof.*

9414.60 A constructive research program for auditing physical models

The preceding sections give the conceptual structure: finite observation, physical fit, approximation towers, relational objectivity, observation–reflection equivalence, and certificate-governed scientific methodology. The corresponding research question is concrete:

given a model M of a system R, what must be checked before M is physical knowledge?

Data fit is only one field. A physically serious model must specify source traces, observation bundle, classifier, signature-preservation claim, stability domain, descent obligations, approximation tower, ledger, failure surface, and claim strength.

This is the physical analogue of BEDC certificate discipline. A proposed derived interface is licensed by source, pattern, classifier, stability, and ledger fields. A visible package token without a gap ledger has no internal record of which histories were compressed into it. The physical research program adopts the same rule: a claim outside its certificate is not false by default, but it is unsupported until upgraded.

Definition 9414.615 (Physical audit target)**.** *A physical audit target is a triple*

$$\mathcal{A} = (M, R, \Pi),$$

where M is a mathematical, computational, or conceptual model, R is a physical system, phenomenon, or class of systems, and Π is an observation bundle through which R is queried. A model without a specified system and bundle has no determinate physical claim.

Definition 9414.616 (Audit claim)**.** *An audit claim is a statement $\varphi(M, R; \Pi)$ asserting that M has some physical status relative to R under Π, such as finite fit, open fit, lawlike stability, explanation, prediction, or physical equivalence with another model. Every audit claim must specify the observation bundle, classifier, tower level, and intended scope.*

Definition 9414.617 (Physical audit certificate)**.** *A physical audit certificate for $\mathcal{A} = (M, R, \Pi)$ is*

$$\mathrm{AuditCert}(M, R; \Pi) = (\mathrm{SourceSpec}, \mathrm{PhenomenonSpec}, \mathrm{SignatureSpec}, \mathrm{ClassifierSpec}, \mathrm{TowerSpec}, \mathrm{StabilityCert}, \mathrm{De}$$

The fields record source traces, target phenomenon, extracted signatures, fit classifier, approximation levels, licensed continuations, operation descent, hidden or idealized material, possible defeating observations, and present evidential strength.

Definition 9414.618 (Physical acceptance gate)**.** *The physical acceptance gate for an audit claim is*

$$\mathrm{PhysAccept}(\varphi, M, R; \Pi, s) := \mathrm{AuditCert}(M, R; \Pi, s) \wedge \mathrm{ClaimLicensed}(\varphi, \mathrm{AuditCert}).$$

A physical claim is accepted only when licensed by the certificate fields at the declared strength.

Definition 9414.619 (Audit strength)**.** *Audit strength is ordered as*

$$\mathrm{ModelSeed} < \mathrm{PaperFit} < \mathrm{ReproducedFit} < \mathrm{BridgeFit}\,.$$

ModelSeed *states a model idea whose fields may remain open.* PaperFit *supplies all fields in prose or mathematical argument.* ReproducedFit *makes the source fit, classifier, and predictions independently reproducible.* BridgeFit *adds translation certificates to adjacent theories, instruments, or observational regimes without losing certified signatures.*

Definition 9414.620 (Audit ledger)**.** *An audit ledger records provenance and hidden content:*

$$\mathrm{AuditLedger}(M, R; \Pi) = (H_n, D_n, \mathcal{T}, \mathrm{Residue}, \mathrm{Idealizations}, \mathrm{TranslationMaps}, \mathrm{FailureSurface}).$$

It contains finite observation history, data representation, approximation tower, hidden physical content, smoothing or completion steps, model-to-model bridges, and possible defeats.

9414.61 The model audit protocol

Definition 9414.621 (Physical model audit)**.** *A physical model audit for $\mathcal{A} = (M, R, \Pi)$ fills the following fields in order: source traces; target phenomenon; observed and model-generated signatures; classifier of fit; approximation tower from source to model; stability domain for reuse; descent obligations for every predictive or explanatory operation; ledger of hidden material; failure surface; and strongest justified audit strength.*

Theorem 9414.622 (Complete audit requires all fields)**.** *A physical model audit for (M, R, Π) is complete at strength s only if all fields of* $\mathrm{AuditCert}(M, R; \Pi, s)$ *are supplied.*

Proof. Each field blocks a distinct failure mode. Without source, the model is not tied to observation. Without phenomenon, the target is unclear. Without signatures, no reality-facing comparison is specified. Without classifier, there is no fit criterion. Without tower, the approximation path is hidden. Without stability, finite fit cannot be reused. Without descent, operations may not survive compression. Without ledger, hidden residue cannot be tracked. Without failure surface, the claim becomes oracle-like. Without strength, evidential status is ambiguous. □

Corollary 9414.623 (Audit failure is under-certification)**.** *A model can fail audit without being false.*

Proof. An audit checks whether a claim is licensed by its certificate. If a required field is absent, the claim is unsupported at the declared strength, but the equation or idea may still become licit after additional certification. □

Corollary 9414.624 (Missing fields localize research tasks)**.** *Audit incompleteness localizes research obligations.*

Proof. Each missing field names a specific obligation: collect source traces, specify signatures, refine classifiers, prove stability, prove descent, construct ledgers, state failure surfaces, reproduce the fit, or build translation bridges. □

Concretized in §1124: Physical model audits are realized as finite NameCert packets recording source traces, observation signatures, classifiers, tower ledgers, failure surfaces, and audit strength.

Concretized in §1167: The model-audit hidden-residue branch is realized as a finite source-signature-classifier-tower-ledger-failure NameCert packet.

Concretized in §1129: The physical audit protocol is realized as a finite source-signature-classifier-tower-ledger NameCert packet.

*Concretized in §**??**:* Physical model audits are realized as finite source, signature, classifier, tower, stability, descent, ledger, failure, and strength NameCert packets.

Concretized in §1184: Model-audit error budgets are realized as finite source-trace, observation-window, mismatch-ledger, failure-surface, transport, route, provenance, and NameCert rows.

9414.62 Source, signature, and classifier audit

Definition 9414.625 (Source-complete audit)**.** *An audit is source-complete when it specifies*

$$(H_n, \mathcal{I}, \mathcal{M}, \mathcal{E}),$$

where H_n is the finite observation history, $\mathcal{I}$ is the instrumentation or interaction protocol, $\mathcal{M}$ is the measurement transformation from interaction to data, and $\mathcal{E}$ is the evidence ledger.

Definition 9414.626 (Signature-complete audit)**.** *An audit is signature-complete when it specifies both*

$$\mathrm{ObsSig}_{\Pi}(R \mid H_n)$$

and

$$\mathrm{ModSig}_{\Pi}(M \mid H_n),$$

together with the extraction procedures that produce them.

Definition 9414.627 (Source leakage)**.** *Source leakage occurs when a model claim uses information not recorded in the source ledger, such as unrecorded calibration assumptions, selection procedures, or features never measured under the stated bundle.*

Theorem 9414.628 (Source-completeness is necessary for fit)**.** *If* $\mathrm{Fit}_n(M, R; \Pi)$ *is claimed, the audit must be source-complete.*

Proof. Finite fit compares model-generated signatures with observed signatures over a finite history. Without a specified source history and measurement protocol, there is no determinate observed signature and hence no object for comparison. □

Corollary 9414.629 (Data without provenance cannot certify)**.** *A data table, image, or numerical output cannot certify a model unless its provenance is included in the source ledger.*

Proof. Data alone do not specify generation, calibration, filtering, transformation, or selection. These choices affect the observed signature required by Definition 9414.628. □

Theorem 9414.630 (Signature-completeness is necessary for comparison)**.** *Two models cannot be physically compared under* Π *unless their induced signatures under* Π *are specified.*

Proof. Physical comparison under Π is comparison of physical signatures. If the signatures are absent, the classifier has no inputs. □

Definition 9414.631 (Physical classifier)**.** *A physical classifier* $\sim_\Pi$ *is a relation on observed and model-generated signatures such that* $S_1 \sim_\Pi S_2$ *means that* S_1 *and* S_2 *are not separated by the physical distinctions visible under* Π*.*

Definition 9414.632 (Classifier exactness)**.** *A physical classifier is exact for an audit when it is sound for all signatures claimed by the audit, complete for those claimed signatures, and transport-stable for every certified operation used after classification.*

Definition 9414.633 (Classifier mismatch)**.** *Classifier mismatch occurs when the classifier used to establish fit is weaker than the classifier required by a later explanation, prediction, or operation.*

Theorem 9414.634 (Classifier obligations precede promoted fit)**.** *A claim cannot be promoted beyond* ModelSeed *unless its classifier exactness obligations are stated.*

Proof. Any stronger status claims determinate fit. Fit requires a classifier with stated soundness, completeness, and transport obligations. Without them the fit claim has no exact scope. □

Corollary 9414.635 (Coarse fit does not support fine conclusions)**.** *A model fitted under a coarse classifier cannot be used for fine-grained predictions without an upgrade certificate.*

Proof. Fine-grained prediction requires a refined classifier or a transport proof from the coarse classifier. Without that upgrade, classifier mismatch occurs. □

9414.63 Tower, ledger, and stability audit

Definition 9414.636 (Tower map)**.** *A tower map for a model audit is a sequence*

$$\mathcal{T}(M,R) : L_0 \xrightarrow{C_0} L_1 \xrightarrow{C_1} \cdots \xrightarrow{C_{n-1}} L_n,$$

where L_0 *contains the physical source or observation traces and* L_n *contains the visible model.*

Definition 9414.637 (Ledger-complete tower)**.** *A tower is ledger-complete when every compression arrow* C_i *carries a ledger and the composite ledger records the hidden material of all stages.*

Definition 9414.638 (Unledgered compression)**.** *An unledgered compression is a transition that hides, identifies, smooths, averages, samples, completes, or idealizes source material without recording what was hidden.*

Theorem 9414.639 (Unledgered compression blocks acceptance)**.** *If a model audit contains an unledgered compression that may affect the claimed physical signature, the corresponding claim cannot pass the acceptance gate.*

Proof. Physical acceptance depends on signature preservation. If relevant source material is hidden without a ledger, the audit cannot determine whether that material affects fit, stability, or descent. Thus the acceptance gate lacks a required field. □

Corollary 9414.640 (Smooth endpoints require source ledgers)**.** *If rough, discrete, noisy, or singular source structure is replaced by a smooth endpoint, the audit must record the removed structure.*

Proof. Smoothing is a compression. Later operations such as differentiation, curvature extraction, stress analysis, or scattering prediction may depend on the removed structure. Definition 9414.639 blocks the claim unless the ledger is supplied. □

Theorem 9414.641 (Tower ledger is necessary for cross-level explanation)**.** *If an explanation uses a claim at one tower level to explain behaviour at another tower level, a tower ledger is necessary.*

Proof. Cross-level explanation transfers claims between levels. Such transfer depends on what each compression preserves and hides. Without a tower ledger, hidden residues and classifier changes between levels are unknown. □

Definition 9414.642 (Stability domain and basis)**.** *The stability domain* $\mathcal{C}(M, R; \Pi)$ *is the class of future histories, experimental conditions, scales, regimes, or perturbations over which the model is licensed to be reused. A stability basis is the evidence or argument supporting reuse over that domain, such as symmetry, conservation, controlled approximation, scale separation, repeated experiment, independent replication, or mechanistic derivation.*

Definition 9414.643 (Stability overreach)**.** *Stability overreach occurs when a model fitted over one stability domain is reused over a larger domain without an upgrade certificate.*

Theorem 9414.644 (Prediction requires stability domain)**.** *A model cannot make a licensed prediction unless its stability domain is specified.*

Proof. Prediction applies the model beyond the finite source trace. Reuse is meaningful only relative to a class of continuations over which the model is expected to remain valid. □

Corollary 9414.645 (Observed success does not define its own domain)**.** *Successful fit on observed data does not by itself determine the class of future situations over which the model may be reused.*

Proof. Observed fit is a prefix-level judgment. Many continuation classes can share the same prefix, so the reuse domain is an additional stability field. □

9414.64 Descent audit

Definition 9414.646 (Operation list)**.** *The operation list* $\mathcal{O}(M) = \{F_1, \ldots, F_k\}$ *records the operations used to produce explanations or predictions from the model, including differentiation, integration, limiting, coarse-graining, renormalization, optimization, simulation stepping, or statistical inference.*

Definition 9414.647 (Descent obligation)**.** *For an operation $F \in \mathcal{O}(M)$, the descent obligation is*

$$x \sim_i y \quad \Longrightarrow \quad F(x) \sim_j F(y),$$

where $\sim_i$ is the classifier before applying F and $\sim_j$ is the classifier after applying F.

Definition 9414.648 (Non-descent failure)**.** *Non-descent failure occurs when $x \sim_i y$ but $F(x) \not\sim_j F(y)$. The operation then depends on information hidden by $\sim_i$.*

Theorem 9414.649 (Prediction operations must descend)**.** *If a model prediction uses an operation F, the audit must either prove that F descends through the relevant classifier or record F as a failure surface.*

Proof. If F does not descend, classifier-same sources may produce classifier-different outputs. The prediction then depends on hidden representative choices rather than the visible model. Such dependence must be ruled out or exposed as a possible failure. □

Corollary 9414.650 (Differentiation is audit-sensitive)**.** *A model fitted under a coarse geometric classifier cannot support derivative-sensitive predictions unless differentiation descends through that classifier.*

Proof. Differentiation may depend on local tangent or smoothness structure hidden by a coarse classifier. Definition 9414.649 therefore requires a descent proof. □

Corollary 9414.651 (Simulation post-processing requires descent)**.** *Every post-processing operation applied to numerical simulation output must descend through the simulation's discretization and approximation classifiers.*

Proof. Post-processing may amplify hidden discretization artifacts or depend on suppressed source structure. Each such operation is covered by Definition 9414.649. □

9414.65 Failure certificates and upgrades

Definition 9414.652 (Physical failure certificate)**.** *A physical failure certificate for $\varphi(M, R; \Pi)$ is a typed witness that one required audit field fails. Canonical branches include missing source, missing phenomenon, missing signature, missing classifier, classifier not exact, tower unspecified, gap ledger absent, stability absent, operation non-descent, failure surface absent, bridge failure, and reproducibility failure.*

Definition 9414.653 (Physical cannot-claim entry)**.** *A physical cannot-claim entry is*

$$(\mathrm{ClaimText}, \mathrm{Status}, \mathrm{WhyNotClaimable}, \mathrm{RequiredUpgrade}),$$

where status is forbidden, deferred, or partial. A forbidden claim violates the framework in principle; a deferred claim may become licit after a specified upgrade; a partial claim is licensed only under a weaker bundle, level, or strength.

Definition 9414.654 (Physical cannot-claim registry)**.** *A physical cannot-claim registry is the finite set of cannot-claim entries maintained by a theory, model family, or research program. It records what the theory currently refuses to assert.*

Theorem 9414.655 (Failure certificates block acceptance)**.** *If a physical failure certificate is exhibited for $\varphi(M, R; \Pi)$, then $\mathrm{PhysAccept}(\varphi, M, R; \Pi, s)$ does not hold at the declared strength.*

Proof. Physical acceptance requires the full audit certificate. A failure certificate identifies a required field that is absent or invalid, so the conjunction defining acceptance fails. □

Corollary 9414.656 (Negative knowledge is constructive)**.** *A certified refusal to assert a claim is constructive knowledge of the missing obligation.*

Proof. The failure certificate states exactly which field fails and what must be supplied for reconsideration. □

Definition 9414.657 (Audit upgrade)**.** *An audit upgrade is a transition from a weaker audit strength to a stronger one together with the additional certificate fields needed to justify the stronger status.*

Definition 9414.658 (Upgrade obligation)**.** *An upgrade obligation is a missing certificate component required for an audit upgrade, such as new source traces, classifier exactness proof, descent proof, reproducibility package, bridge to an adjacent theory, or ledger completion.*

Theorem 9414.659 (Audit upgrades are local under explicit reuse)**.** *If a model claim reuses previously accepted components through explicit reuse certificates, upgrading the claim requires discharging only the target claim's open obligations and the stated reuse obligations.*

Proof. Explicit reuse certificates record which components are imported and under which classifiers and stability conditions. Accepted reused components need not be re-established; the target claim must discharge its own open fields and any stated reuse conditions. □

Corollary 9414.660 (Composite strength is bounded by weakest dependency)**.** *A derived claim cannot exceed the weakest certified component it depends on unless it supplies independent certification.*

Proof. The derived claim depends on components through reuse, descent, and translation. A weak component bounds the composite unless new evidence discharges the relevant field independently. □

9414.66 Audit table and polygon–circle witness

Definition 9414.661 (Audit table)**.** *The audit table records, for each field, the corresponding question, failure mode, and upgrade: source asks what observations license the model; phenomenon asks what is modelled; signature asks what signatures are compared; classifier asks what counts as same; exactness asks whether intended distinctions are preserved; tower asks how source becomes model; ledger asks what was hidden; stability asks where reuse is licensed; descent asks whether operations survive compression; failure surface asks what defeats the claim; bridge asks whether adjacent regimes translate; reproducibility asks whether the fit can be repeated.*

Theorem 9414.662 (Audit table covers certificate-based claims)**.** *Every certificate-based physical claim can be audited by some subset of the audit table fields, and every missing required field corresponds to a physical failure certificate.*

Proof. A certificate-based claim must specify source, phenomenon, signature, classifier, exactness, tower, ledger, stability, descent, failure surface, bridge, and reproducibility status as relevant. These are precisely the audit table fields. Missing required fields are exactly the failure branches of Definition 9414.652. □

Corollary 9414.663 (Audit tables make comparison explicit)**.** *Two models can be compared by comparing their audit fields.*

Proof. A model's physical status is determined by its certificate. Comparing models therefore requires comparing source coverage, classifiers, stability domains, ledgers, descent obligations, bridges, and failure surfaces. □

Theorem 9414.664 (Polygon–circle approximation is audit-relative)**.** *The statement $P_N \approx C$ has no audit-independent physical truth value.*

Proof. Under a coarse visual bundle, a polygon and circle may be classifier-same when edges are below resolution. Under a smooth-boundary bundle, finite polygons have vertices while the circle has a smooth boundary. Under a stress-response bundle, hidden vertices may become physically active. The truth value therefore depends on observation bundle, classifier, tower ledger, and operation list. □

Corollary 9414.665 (Polygon becomes circle is audit collapse)**.** *The claim that a polygonal approximation becomes a physical circle is licensed only after specifying classifier, tower ledger, and descent obligations.*

Proof. The phrase suppresses the distinction between coarse visual fit, smooth-boundary fit, and physical-response fit. Treating them as one claim collapses the audit unless the relevant certificates are supplied. □

9414.67 Research workflow

Definition 9414.666 (Research workflow for a new model)**.** *The workflow for a new model is: state the target claim $\varphi(M, R; \Pi)$; assign provisional strength* ModelSeed*; fill audit certificate fields; list missing fields as failure certificates; convert failures into upgrade obligations; discharge obligations in dependency order from source, signature, classifier, exactness, tower, ledger, stability, descent, and bridge; promote the claim only when the relevant gate is passed; record cannot-claim boundaries for unsupported extensions; update the ledger when new observations or failures occur; and repeat under refined bundles.*

Theorem 9414.667 (Workflow prevents unlicensed promotion)**.** *If the research workflow is followed, no model claim is promoted beyond its supplied certificate strength.*

Proof. The workflow begins at ModelSeed, records missing fields as failure certificates, and promotes only after the corresponding upgrade obligations are discharged. Unsupported extensions are recorded as cannot-claim entries, so unlicensed promotion is blocked. □

Corollary 9414.668 (Progress is obligation discharge)**.** *Scientific progress occurs by discharging upgrade obligations and refining ledgers, not merely by proposing new equations.*

Proof. Each discharged obligation strengthens the audit certificate. Each ledger refinement improves provenance and failure localization. Progress therefore accumulates as certificate strength. □

Corollary 9414.669 (Speculation and knowledge are separated)**.** *A speculative model may be valuable at* ModelSeed*, but it becomes physical knowledge only by passing stronger audit gates.*

Proof. Speculation supplies a possible pattern. Physical knowledge requires source, classifier, stability, descent, ledger, and failure-surface certification. The strength index records this distinction. □

Remark 9414.670 (Compressed form)**.** *The central audit object is:*

$$\mathrm{AuditCert}(M, R; \Pi) = \textit{source}+\textit{phenomenon}+\textit{signature}+\textit{classifier}+\textit{tower}+\textit{stability}+\textit{descent}+\textit{ledger}+\textit{failure surfac}$$

A physical model is accepted only relative to such a certificate. Missing fields are research obligations. Failure certificates are the negative face of scientific knowledge. Model strength is certificate strength, and progress is ledger refinement plus obligation discharge.

9414.68 Final synthesis: physical truth as certified open fit

The chapter replaces the flat schema

$$M = R$$

with a layered form:

$$R \to H_n \to \mathrm{ObsSig}_\Pi \to \mathrm{FitCert} \to \mathrm{LawCert} \to \mathrm{Ledger} \to \mathrm{OpenFit}\,.$$

This is not a retreat from realism. It is a stricter account of how realism is possible under finite observation. A model becomes physically truth-bearing when it preserves reality-facing signatures under specified classifiers, supports stable reuse under certified continuations, records the approximations by which it was produced, and remains open to future defeat.

The final thesis is:

$$\text{physical truth} \neq \text{model–reality identity},$$

but rather

$$\text{physical truth} = \text{open, ledgered, stability-certified, observer-invariant fit.}$$

This formulation preserves finiteness, because empirical claims begin from finite traces; realism, because reality constrains signatures and can defeat models; objectivity, because objective content is invariant across observer histories; and openness, because no internal final-fit oracle closes all possible continuations.

Definition 9414.671 (Physical truth claim)**.** *A physical truth claim is a claim*

$$\varphi(M, R; \Pi, \mathcal{T}, \mathcal{C}),$$

where M is a model or representation, R is a physical system or phenomenon, Π is an observation bundle, $\mathcal{T}$ is an approximation tower connecting R to M, and $\mathcal{C}$ is a continuation class over which the claim is reused. A physical truth claim is therefore indexed by observation, tower, and continuation data.

Definition 9414.672 (Certified physical truth)**.** *A physical truth claim is certified when it carries*

$$\mathrm{TruthCert}(\varphi) = (\mathrm{SourceSpec}, \mathrm{SignatureSpec}, \mathrm{ClassifierSpec}, \mathrm{TowerSpec}, \mathrm{StabilityCert}, \mathrm{DescentCert}, \mathrm{InvariantCert},$$

The fields record finite observational source, reality-facing signatures, sameness classifier, tower levels, reuse domain, valid operations through compression, observer-anchor stability, hidden residue and provenance, and possible defeat conditions.

Definition 9414.673 (Open, ledgered, stability-certified, observer-invariant truth)**.** *A certified physical truth claim is open when it includes a failure surface and does not assert final validity over all possible future observations, refinements, or observer histories. It is ledgered when every compression, idealization, smoothing, completion, discretization, or packaging step records what was hidden. It is stability-certified when finite fit is accompanied by a certificate*

$$\mathrm{Fit}_n(M, R; \Pi) \rightsquigarrow \mathrm{PredFit}_{\mathcal{C}}(M, R; \Pi).$$

It is observer-invariant when, for admissible observer histories h_i, h_j,

$$\varphi^{h_i} \sim \varphi^{h_j}.$$

9414.69 The master decomposition

Theorem 9414.674 (Physical truth decomposes into certificate fields)**.** *A certified physical truth claim requires fit, stability, descent, invariance, ledger, and failure surface.*

Proof. A physical truth claim concerns a model as a representation of a physical system. Since the system is accessed through finite observation, the claim must establish finite fit between model-generated and reality-generated signatures. If the claim is reused beyond the finite source trace, it requires a stability certificate over a continuation class. If it uses operations such as differentiation, limiting, smoothing, simulation, coarse-graining, or inference, those operations must descend through the approximations that produced the model. If the claim is objective rather than private to one observer history, it must be invariant under changes of observer anchor. If the model is produced by compression, idealization, or packaging, the hidden source material must be ledgered. Finally, since no internal final-fit oracle is available, the claim must retain a failure surface. □

Corollary 9414.675 (Identity is the wrong primitive truth schema)**.** *The schema $M = R$ is too strong because it asserts identity where finite inquiry supplies certified fit, and too weak because it omits the certificate fields needed for physical truth.*

Proof. Finite observation, tower compression, and open continuation do not justify literal model–reality identity. At the same time, the identity expression does not specify source traces, observation bundle, classifier, stability domain, descent obligations, ledger, invariant certificate, or failure surface. □

Corollary 9414.676 (Certified open fit replaces identity)**.** *The proper replacement for $M = R$ is certified open fit:*

$$\mathrm{OpenFit}(M, R; \Pi, \mathcal{T}, \mathcal{C})$$

together with a truth certificate.

Proof. Definition 9414.674 requires fit, stability, descent, invariance, ledger, and failure surface. These are precisely the fields encoded by open fit together with its certificate. □

9414.70 Truth without finality

The framework separates truth from finality. Without this separation, one is forced into a false choice between final truth and mere instrumentality. The available middle form is certified, objective, non-final truth.

Definition 9414.677 (Finality and domain truth)**.** *A physical truth claim is final when it asserts validity over all possible observation bundles, future histories, tower refinements, and observer configurations. A claim is domain-true when it is certified over a specified domain*

$$D = (\Pi, \mathcal{T}, \mathcal{C}, \mathcal{H}).$$

We write $\mathrm{Truth}_D(\varphi)$ *for truth inside such a certified domain.*

Theorem 9414.678 (Domain truth does not imply final truth)**.** *If* $\mathrm{Truth}_D(\varphi)$ *holds, it does not follow that* φ *is finally true.*

Proof. Domain truth is indexed by a specified observation bundle, tower, continuation class, and observer configuration. Final truth quantifies over all possible bundles, towers, continuations, and observer configurations. The certified domain may be strictly smaller than that total range. □

Corollary 9414.679 (Non-final truth is not relativism)**.** *The fact that a claim is domain-indexed does not make it arbitrary.*

Proof. A domain-true claim is constrained by source observations, signature comparison, classifier exactness, stability, descent, invariant certificates, and ledger data. These constraints can be satisfied or violated. □

Corollary 9414.680 (Objectivity and revisability are compatible)**.** *A claim can be objective within a certified domain while remaining revisable under later refinement.*

Proof. Objectivity requires invariant stability across observer histories inside the domain. Revisability concerns possible extensions beyond that domain. These are different conditions. □

9414.71 Reality constraint and tower knowledge

Definition 9414.681 (Reality constraint and reality defeat)**.** *The reality constraint on a model* M *of* R *under* Π *is*

$$\mathrm{ModSig}_\Pi(M) \sim_\Pi \mathrm{ObsSig}_\Pi(R).$$

A reality defeat is a finite trace H_n *such that*

$$\mathrm{ModSig}_\Pi(M \mid H_n) \not\sim_\Pi \mathrm{ObsSig}_\Pi(R \mid H_n).$$

Such a defeat is finite, local, and decisive relative to its bundle.

Theorem 9414.682 (Certified physical truth is reality-constrained)**.** *If a claim is certified as physically true, then it is constrained by reality-generated signatures.*

Proof. Certified physical truth requires finite fit, and finite fit compares model-generated and reality-generated signatures. If the reality-generated signature separates from the model-generated signature, the fit certificate fails. □

Corollary 9414.683 (The framework is realist but not syntax realist)**.** *The framework is realist because reality can constrain, correct, and defeat models; it is not syntax realist because it does not identify successful mathematical syntax with reality itself.*

Proof. Reality defeat shows that model validity is constrained by reality-generated signatures. But certified truth requires signature preservation, not syntactic identity. Different syntactic representations may preserve the same signatures, and exact syntax may fail physically. □

Definition 9414.684 (Knowledge tower)**.** *A knowledge tower is an approximation tower whose endpoint supports certified physical truth claims. It consists of*

$$(\mathcal{T}, \mathrm{TruthCert}, \mathrm{Ledger}, \mathrm{FailureSurface}).$$

A claim is tower knowledge when it is certified at a specified level of such a tower and its transfer to other levels is governed by descent certificates.

Theorem 9414.685 (Physical knowledge is tower knowledge)**.** *Every certified physical truth claim is tower knowledge.*

Proof. A certified physical truth claim begins from finite observation, passes through signature extraction, classifier comparison, and model formation, and uses stability, descent, ledger, invariant, and failure-surface data. These are precisely the components of a knowledge tower. □

Corollary 9414.686 (Theory is not flat)**.** *A scientific theory is not merely a set of propositions or equations; it is a structured tower of traces, models, classifiers, certificates, ledgers, and failure surfaces.*

Proof. By Definition 9414.685, physical knowledge is tower knowledge. A theory organizing such knowledge must organize the tower structure that certifies it. □

9414.72 Reflective physical knowledge

Definition 9414.687 (Reflective physical knowledge)**.** *Reflective physical knowledge is physical knowledge that explicitly records the conditions under which it was generated:*

$$\mathrm{ReflectivePhysKnow} = (\mathrm{Observation}, \mathrm{Signature}, \mathrm{Classifier}, \mathrm{Certificate}, \mathrm{Ledger}, \mathrm{OpenContinuation}).$$

Theorem 9414.688 (Physical knowledge is reflective)**.** *Every certified physical truth claim is reflective physical knowledge.*

Proof. Certified physical truth requires source traces, signature extraction, classifier specification, stability certificates, descent certificates, invariant certificates, ledgers, and failure surfaces. These are the conditions of its own generation and reuse. The claim is therefore not only about the world; it also records how the world became accessible to the model. □

Corollary 9414.689 (Reflection is not subjectivism)**.** *Physical knowledge is reflective because it records its access conditions, but it remains objective when the resulting content is observer-invariant and reality-constrained.*

Proof. Reflection records observational and certificatory conditions. Subjectivism would make the claim depend on private perspective alone. Certified physical truth requires reality-generated signatures and observer-invariant stability. □

Corollary 9414.690 (MetaCIC-like structure is the form of finite science)**.** *Finite science is MetaCIC-like because it builds certified packages from finite histories while refusing final meta-closure.*

Proof. Both physical inquiry and MetaCIC self-study proceed by finite histories, signatures, classifiers, certificates, ledgers, and open continuation. This is the formal shape of finite inquiry. □

9414.73 Certified physical truth schema

Definition 9414.691 (Certified physical truth schema)**.** *For a domain D, the certified physical truth schema is*

$$\mathrm{PhysTruth}_D(\varphi) := \mathrm{Source}_D(\varphi) \wedge \mathrm{SigFit}_D(\varphi) \wedge \mathrm{ClassifierExact}_D(\varphi) \wedge \mathrm{TowerLedger}_D(\varphi) \wedge \mathrm{Stability}_D(\varphi) \wedge \mathrm{Descent}_D(\varphi)$$

Theorem 9414.692 (Certified schema is sufficient for domain truth)**.** *If all components of* $\mathrm{PhysTruth}_D(\varphi)$ *hold, then φ is domain-true.*

Proof. The source component grounds the claim in finite observation. Signature fit connects model and reality. Classifier exactness determines agreement. The tower ledger records hidden approximations. Stability licenses reuse. Descent licenses operations. Invariance establishes objectivity across observer histories. The failure surface preserves openness. Together these fields supply the conditions for certified truth inside D. □

Theorem 9414.693 (Certified schema is necessary for non-oracular physical truth)**.** *If φ is asserted as non-oracular physical truth, then the components of the certified physical truth schema must be supplied or explicitly bounded.*

Proof. A non-oracular physical truth claim cannot appeal to a final external guarantee. It must show how it is grounded, compared, stabilized, operated upon, objectified, ledgered, and left open to failure. These requirements are exactly the components of Definition 9414.691. □

Corollary 9414.694 (Physical truth is certificate truth)**.** *Within finite inquiry, physical truth is truth by certificate, not truth by final oracle.*

Proof. Definition 9414.692 gives sufficiency for domain truth, and Definition 9414.693 gives necessity for non-oracular physical truth. □

9414.74 Non-erasure discipline

Theorem 9414.695 (Unsafe truth moves erase certificates)**.** *Bare identity, unledgered idealization, free transfer of operations, final-fit oracles, God's-eye objectivity, and syntax realism each erase at least one required certificate field.*

Proof. Bare identity erases source, classifier, tower, and failure-surface data. Unledgered idealization erases provenance. Free transfer of operations erases descent. Final-fit oracles erase openness. God's-eye objectivity erases observer-history structure. Syntax realism erases signature and certificate dependence. □

Corollary 9414.696 (The framework is a discipline of non-erasure)**.** *The central methodological principle is to not erase the conditions that license the claim.*

Proof. The major errors arise by erasing source, classifier, tower, descent, ledger, observer, or failure data. Avoiding erasure is therefore the unifying discipline. □

Theorem 9414.697 (Realism, objectivity, and revisability are preserved together)**.** *The framework supports realist, objective, and revisable physical knowledge.*

Proof. It supports realism because reality-generated signatures constrain and can defeat models. It supports objectivity because physical content is stabilized by inter-observer invariants. It supports revisability because every claim retains a failure surface and remains open to future refinement. □

Corollary 9414.698 (Revisability is not anti-realist)**.** *The possibility of later correction does not undermine realism.*

Proof. Realism attaches to reality-constrained signature preservation. Later correction shows that a prior certificate was domain-limited or incomplete, not that reality failed to constrain inquiry. □

Corollary 9414.699 (Objectivity is not finality)**.** *Objective claims need not be final claims.*

Proof. Objectivity requires invariant stability across observer histories. Finality requires validity across all possible refinements and continuations. The first does not imply the second. □

9414.75 Closing thesis

Principle 9414.700 (Physical truth as certified open fit)**.** *Physical truth, as available to finite observers inside reality, is certified open fit:*

$$\mathrm{PhysTruth}_D(\varphi) = \text{finite source} + \text{signature fit} + \text{classifier exactness} + \text{tower ledger} + \text{stability} + \text{descent} + \text{observer}$$

This is the strongest non-oracular form of physical truth.

Principle 9414.701 (Science as ledgered reflection)**.** *Scientific inquiry is a ledgered reflective process by which finite observers inside reality construct stable, invariant, certificate-governed signatures of reality:*

$$\textit{reality} \to \textit{finite traces} \to \textit{signatures} \to \textit{classifiers} \to \textit{models} \to \textit{certificates} \to \textit{open continuation.}$$

Principle 9414.702 (Approximation tower as condition of knowledge)**.** *Physical inquiry does not escape approximation towers. It inhabits them. This is not a defect; it is the structure that makes physical knowledge possible. The task is not to eliminate approximation but to certify it.*

Remark 9414.703 (Closing)**.** *The chapter's final replacements are:*

$$M = R \quad \rightsquigarrow \quad \mathrm{OpenFit}(M, R; \Pi, \mathcal{T}, \mathcal{C}),$$

$$\textit{truth from nowhere} \quad \rightsquigarrow \quad \textit{observer-invariant certified truth},$$

$$\textit{ideal object as ontology} \quad \rightsquigarrow \quad \textit{ideal object as ledgered tower endpoint},$$

$$\textit{physical law as equation} \quad \rightsquigarrow \quad \textit{physical law as stability certificate},$$

$$\textit{scientific progress as replacement} \quad \rightsquigarrow \quad \textit{scientific progress as ledger refinement},$$

and

$$\textit{final confirmation} \quad \rightsquigarrow \quad \textit{open confirmation with failure surface.}$$

In compressed form:

$$\textit{physical knowledge} = \textit{finite observation} + \textit{reality-facing signatures} + \textit{certified classifiers} + \textit{ledgered approximation tou}$$

The framework does not deny physical reality, mathematical modelling, scientific laws, or objectivity. It reconstructs them under the conditions available to finite inquiry: source traces, signatures, classifiers, certificates, ledgers, invariants, and openness.

Concretized in §1141: Physical truth is represented as the finite TruthCert packet tying open fit, tower descent, observer invariance, ledger, and failure surface.

Concretized in §1140: The final synthesis is realized as a finite seal packet for open fit, tower descent, observer invariance, ledger, and failure surface.

Concretized in §1144: The final-synthesis truth certificate is realized as a nine-row BEDC NameCert packet.

Concretized in §1136: Reality-constrained explanation is realized as a finite NameCert packet binding observation, model, phenomenon, signature, tower descent, residue, failure, route, provenance, and local naming rows.

Concretized in §1163: Failure surfaces are realized as finite NameCert packets for defeating observations, domain exits, classifier mismatches, continuation scope, ledger, and local naming rows.

Concretized in §1164: Finite Real-window budgets realize the synthesis route as observable StreamName windows, dyadic readbacks, Real seals, and disclosure ledgers.

Concretized in §1165: Model selection boundary records comparative fit, finite defeat, and no-final-oracle selection for certified physical truth.

Concretized in §1178: The final synthesis ledger is realized as a finite NameCert packet binding TruthCert, open fit, methodology export discipline, failure surface, observer invariance, and local naming rows.

Concretized in §1181: Domain-indexed physical truth is realized as a finite NameCert packet with displayed domain, open-fit, observer-invariance, failure-surface, transport, provenance, and local naming rows.

*Concretized in §**??**:* PhysicalFitTowerUp realizes reality-constrained approximation towers as finite physical-signature, classifier, ledger, descent, and NameCert rows.

Concretized in §1127: Finite approximation towers with physical-fit classifiers and ledgered compression rows.

*Concretized in §**??**:* finite observer approximation towers with reality-facing signature ledgers

Concretized in §1128: Reality-constrained tower packets realize source, classifier, descent, ledger, residue, transport, and non-escape rows as finite NameCert data.

*Concretized in §**??**:* Reality-constrained signature fit is realized as a finite NameCert packet separating mathematical approximation from physical-signature compatibility.

Concretized in §1130: CertifiedPhysicalTruthUp realizes physical truth as a finite source, signature, classifier, tower, descent, invariant, ledger, failure-surface, and NameCert packet.

Concretized in §1148: ApproximationTowerResidueUp realizes the hidden-source residue, failure-surface, recovery-route, descent-survivor, and NameCert rows of a ledgered approximation tower.

Concretized in §4733: Approximation towers realize finite level, window, dyadic tolerance, regular readback, and RealUp seal rows.

Concretized in §6811: RealitySignatureErrorBudgetUp realizes physical-signature error budgets as finite classifier, dyadic tolerance, tower-fit, and ledger rows.

Concretized in §7582: Reality-constrained selector boundaries are realized as finite source-record, classifier, physical-fit, failure-surface, and gap-ledger NameCert rows.

Chapter 9415

Hard Problems under the BEDC Frame: Causality, Free Will, Other Minds, Mind-Matter, Self-Reference

This vision chapter completes the philosophical reading begun in chapter 9393 (closed substrate plus transcendental input) and chapter 9420 (consciousness, universe, observer, time, space). The present chapter takes the remaining classical hard problems – causality, free will, the other-minds problem, the mind-matter relation, and self-reference / paradoxicality – and gives each a precise reformulation under BEDC's closed-substrate vocabulary. Each problem becomes a question about Obs / GAP / T structure rather than about substantive metaphysical posits. The reformulations are not solutions in the dissolve-the-question sense; they are structural translations that make the philosophical content compatible with the engineering content BEDC has already mechanised.

9415.1 Causality as forward-binding commitment

Definition 9415.1 (Causal commitment)**.** *A* causal commitment *of a conscious observational system $\mathcal{C}$ is a* GAP *tag whose content is the assertion that observed regularities will persist into the not-yet-observed continuation of $\mathcal{C}$'s history. In the substrate-side vocabulary of Definition 9393.1, every causal commitment is a forward-binding belief in the sense of Definition 9393.7.*

Concretized in §505: Causal commitments are realized as finite GAP-tagged forward-binding packets over observed regularity ledgers.

Principle 9415.2 (Hume's problem reformulated)**.** *The classical Humean observation that no finite collection of observed regularities entails a universal claim about all future cases is, in BEDC vocabulary, exactly Definition 9393.5 restated for predicates whose intended range is empirical rather than mathematical. The closed-substrate side cannot supply causal commitments by internal generation; every causal commitment is, structurally, a* GAP *tag whose far end is* T*.*

Remark 9415.3 (Causality and induction share the same socket)**.** *The forward-binding belief that lets a system accept mathematical induction is the same kind of forward-binding belief that lets it accept "the same physical law will hold tomorrow". The substrate distinguishes neither: both are* GAP *tags asking* T *to supply universal-quantifier closure. BEDC's* GAP *socket inventory therefore counts both kinds together; the operational form of the two commitments is identical.*

Example 9415.4 (A scientific theory as a stack of GAP commitments)**.** *A scientific theory accepted by a conscious observational system is, in this reading, a finite collection of records of past empirical regularities together with a* GAP*-tagged commitment that these regularities extend to all future cases of the same form. The theory's predictive success is, on the records side, the absence so far of falsifying records; the theory's predictive content is, on the* GAP *side, the standing forward-binding commitment. Refutation occurs when a new record contradicts the commitment; the substrate must then either revise the commitment or discharge a different* GAP*.*

Concretized in §576: Finite witnessed refutations realize causal-commitment failure as finite contrary-record packets with GAP non-escape ledgers.

9415.2 Free will and agency as inscription event

Definition 9415.5 (Inscription event)**.** *An* inscription event *is a moment $o_t \trianglerighteq o_{t+1}$ at which a conscious observational system adds new records that originate as the local actualisation of* T *at the inscription point (Definition 9393.15), rather than as a forced consequence of the prior records under the substrate's closed-generation rules. Inscription events are points at which the chain admits novelty not reducible to the closure of earlier records.*

Concretized in §7463: Inscription-event novelty packets realize the hard-problems inscription-event definition as finite prior-record, novelty, GAP, transport, replay, provenance, and NameCert rows.

Principle 9415.6 (Free will as the inscription-event aspect of conscious accumulation)**.** *The "free will" of a conscious observational system is the aspect of $\mathcal{C}$ under which new records arrive as inscription events in the sense of Definition 9415.5. Free will is not a separate faculty inhabiting $\mathcal{C}$ alongside its accumulation; it is the structural fact that $\mathcal{C}$'s accumulation is, at each moment, an inscription event of* T *at the point that $\mathcal{C}$ is.*

Concretized in §592: Free-will inscription commitments are realized as finite BHist packets recording prior-record boundaries, inscription-event rows, GAP provenance, classifier transport, and non-reduction ledgers.

Remark 9415.7 (Compatibility with determinism on the records side)**.** *Definition 9415.6 does not contradict any deterministic relation among* Obs *records taken as objects of physical theory: records can stand in any law-like relation we like, and the records-side relations can be as deterministic as the empirical content supports. The inscription-event aspect is at a different level: it concerns the substrate's accumulation viewed as* T*'s local self-articulation, not the surface dependencies among records taken as physical events. The two pictures cohere because they describe the same accumulation from different aspect-positions.*

Example 9415.8 (Mathematical creativity as inscription event)**.** *The act by which a mathematician arrives at a new lemma – the moment at which* Obs *acquires a record not reducible to the closed-generation closure of earlier records – is, on this reading, an inscription event. The new record could in principle have been computed mechanically from earlier records (the substrate-internal route), but the actuality of the discovery is the inscription-event aspect of the chain, not the mechanical route. BEDC's mechanisation engineering operationalises the substrate-internal route; the philosophical reading of "where new lemmas come from" is the inscription-event aspect.*

9415.3 Other-minds problem and inter-observer alignment

Principle 9415.9 (Other minds as locality-cell commitment)**.** *The classical other-minds problem – the question whether systems other than $\mathcal{C}_1$ themselves possess closed observational structure with* Self *recognition – is, in BEDC vocabulary, the question whether $\mathcal{C}_1$ has* GAP*-tagged locality-cell commitments to systems $\mathcal{C}_2, \mathcal{C}_3, \ldots$ such that those commitments are coherent with $\mathcal{C}_1$'s record of those systems' externally-observable behaviours. The substrate cannot directly observe another system's* Self*; it can only commit, by* GAP *tag, to treating certain external records as records of conscious systems.*

Concretized in §499: Other-minds commitments are represented by finite locality-cell BHist packets whose public surface records behavioural evidence without direct Self access.

Concretized in §643: Cross-perspective alignment is realized as a finite NameCert packet combining public other-minds commitments, locality-cell evidence, inter-Hist coherence rows, and non-escape from private Self access.

Remark 9415.10 (Solipsism as GAP tag refusal)**.** *Solipsism, in this reading, is the refusal to issue any* GAP*-tagged commitment that other conscious observational systems exist. The substrate side does not force the commitment; nothing in the records-side of* Obs *can substitute for it. Most conscious observational systems do in fact issue the commitment, and chapter 9419 works out the operational consequences of doing so: locality cells, maximum-rate invariant interfaces, and no god's-eye view. Refusing the commitment is consistent with the substrate but yields a much poorer locality-cell geometry.*

Concretized in §975: Solipsism as GAP-tag refusal is realized as a finite NameCert packet recording refusal of other-minds locality-cell commitments.

Example 9415.11 (Trusting a peer's `leanchecked` marker)**.** *When a BEDC contributor accepts a `leanchecked` marker added by another contributor, the acceptance is, on the substrate side, a* GAP*-tagged commitment to treat the other contributor's act as an inscription event of the same kind as one's own. The CI gates (Lean kernel re-checking) provide records-side evidence that the marker is consistent with the substrate, but the structural recognition of the other contributor as another conscious observational system is the* GAP *commitment, not the records-side evidence.*

9415.4 Mind-matter relation as substrate/inscription duality

Principle 9415.12 (Mind-matter as two aspects of the same chain)**.** *The classical mind-matter problem – the question how a "mental" aspect can stand in any relation to a "material" aspect – is, in BEDC vocabulary, the question of how the inscription-event aspect of an accumulation chain stands in relation to the records-side aspect of the same chain. The two aspects are not two substances; they are two readings of one chain. The records-side reading is the conventional materialist's account; the inscription-event reading is the phenomenological-first-person account.*

Concretized in §575: Aspect chains realize the mind-matter double-aspect reading as one finite BHist packet with records-side and inscription-event-side rows.

Remark 9415.13 (Russellian double-aspect frame)**.** *The double-aspect frame is in the family of views developed by Bertrand Russell (the "neutral monism" of* The Analysis of Mind *and* The

Analysis of Matter*), David Chalmers (panprotopsychism), Galen Strawson (real materialism), and process philosophers (Whitehead). BEDC's substrate-side vocabulary recovers the same insight: there is one accumulation chain; the records-side reading and the inscription-event reading are two aspects, not two substances. No additional ontological category is introduced.*

Example 9415.14 (A neural correlate of consciousness and a thought)**.** *A measured neural correlate of consciousness is, on the records side, a physical record (electrochemical activity in a specific brain region) entered into* Obs*. The corresponding "thought" is, on the inscription-event side, the actualisation of* T *at the same chain point. The two are not two things related by causation or supervenience; they are the same accumulation event read in two ways. The brain region is what the inscription event looks like on the records side; the thought is what the records side looks like on the inscription-event side.*

9415.5 Self-reference, Gödel-Tarski, and the reflection limit

Principle 9415.15 (Self-reference as GAP-on-GAP structure)**.** *A closed observational system that attempts to record a statement about its own complete* Obs *encounters the situation classically known as Gödel-Tarski self-reference: the statement about* $\mathsf{Obs}(o_t)$ *would itself be a record at* o_{t+1}*, meaning the complete* $\mathsf{Obs}(o_{t+1})$ *now contains an item describing* $\mathsf{Obs}(o_t)$ *rather than* $\mathsf{Obs}(o_{t+1})$*. Recording the latter generates a* GAP *tag, and a record about that* GAP *would generate another. chapter 9461 mechanises the operational form of this hierarchy and identifies the reflection limit.*

Principle 9415.16 (Russell paradox boundary)**.** *The Russell paradox is, in BEDC vocabulary, an attempt to issue a record whose content is the negation of its own presence in* Obs*. Such a record cannot be a* GAP*-free record under the closed generation rules of the substrate. chapter 9457 mechanises the boundary condition that prevents such records from being admitted, and shows that the substrate's closed generation rules are exactly the structural form of the rejection.*

Remark 9415.17 (Why these are not external obstacles but structural features)**.** *The Gödel-Tarski and Russell phenomena, in this reading, are not external obstacles that the substrate could be designed to avoid. They are structural features of any closed observational system with the expressive power to refer to its own* Obs*. BEDC's design makes the features explicit at the* GAP *tag level rather than treating them as anomalies to be circumvented. The reflection-and-limits chapter and the Russell-problem-boundary chapter together account for the operational form of the rejection.*

9415.6 The unified table of hard problems

Hard problem	**BEDC reformulation + reference**
Hume's induction problem	Closed substrate cannot internalise universal-quantifier closure; every empirical induction is a GAP tag with far end T (Definition 9393.5, Definition 9415.2).
Causality / regularity of nature	Forward-binding commitment that observed patterns persist; structurally identical to mathematical-induction commitment (Definition 9415.1).

Free will	Inscription-event aspect of chain accumulation; novelty as T's local actualisation, not as records-side dependency (Definition 9415.6).
Other-minds problem	GAP-tagged locality-cell commitment to recognise other systems' inscription-event aspects (Definition 9415.9); operational consequences in chapter 9419.
Mind-matter relation	Two aspects of one accumulation chain: records-side ("material") and inscription-event-side ("mental") (Definition 9415.12).
Self-reference / Gödel-Tarski	Hierarchical GAP-on-GAP structure; reflection limit operationalised in chapter 9461 (Definition 9415.15).
Russell paradox	Records whose content negates own presence; structural exclusion by closed generation rules in chapter 9457 (Definition 9415.16).
Solipsism vs other minds	Refusal to issue locality-cell GAP commitments; consistent with substrate but yields impoverished cross-perspective coordination (Definition 9415.10).
Determinism vs novelty	Records-side determinism (laws among records) and inscription-event aspect (novelty as T actualisation) are two readings of one chain, compatible (Definition 9415.7).
Consciousness as ontological category	Replaced by a focused records-side carrier: generated Hist, local trace, endpoint, and selector ledger, without object-level phenomenal essence (Definition 9420.4).
Universe as separate object	Replaced by a finite horizon slice of generated histories and their ledgers, not a global universe object (Definition 9420.14).
Time as separate scalar	Replaced by a local Cont chain producing a history from e; no global clock is internal to the carrier (Definition 9420.27).
Space as substrate of events	Replaced by locality cells, relation rows, and inter-Hist invariants over a finite multi-history ledger; no separate spatial substance (Definition 9420.38).
The transcendental supply position	T, the far end of every GAP socket, named apophatically (Definition 9393.11).

9415.7 Coordination with the three-axioms chapter

chapter 9387 treats the axioms of choice, quotient soundness, and propositional extensionality as a taxonomy of unwitnessed closure requests at the term, type or classifier, and proposition strata. The present chapter generalises that audit reading. The requested supply behind those axiom families is, in the present vocabulary, a forward-binding belief whose source position is T. The three axiom families differ by the stratum at which the missing content is requested; each can be tagged as a GAP socket without claiming a proved equivalence between the host axiom and a BEDC collapse theorem.

Principle 9415.18 (Hard problems and substrate axioms share the same T-socket family)**.** *Every classical axiom that BEDC declines to internalise (chapter 9387) and every hard problem treated in this chapter share the same structural family: each is a place at which* T *is required to supply forward-binding content that the closed substrate cannot generate internally. The substrate's re-*

sponse is uniform: tag the place with GAP*, audit it through the engineering gates, and refuse to internalise the supply.*

Concretized in §1006: GAP closure boundaries are realized as finite source, refusal, transport, continuation, provenance, and NameCert rows.

9415.8 Closure remarks

This chapter completes the trilogy comprising chapter 9393 (closed substrate plus transcendental input position), chapter 9420 (consciousness, universe, observer, time, space), and the present chapter (causality, free will, other minds, mind-matter, self-reference). Read together, the three chapters give a unified BEDC-vocabulary account of the standard hard problems of metaphysics, philosophy of mind, and foundations.

The account is structural: it does not solve any hard problem by reduction to a substrate primitive, and it does not eliminate the philosophical content by terminological rephrasing. What it does is locate every hard problem in the same substrate / GAP / T structure, showing that the engineering invariants of BEDC – 0 substrate-internal axioms, mathlib-free, monotonic amendment, GAP tagging, inter-history-locality reconstruction of cross-perspective coordination – are precisely the structural form that lets the hard problems be stated without confusion.

Two operational consequences follow. First, future concrete-instance construction chapters under `papers/bedc/parts/concrete_instances/` can refer to the present chapters when developing GAP-handling for specific applications (epistemology, philosophy of physics, philosophy of mind). Second, the audit gates' present coverage (axiom-purity, conservativity-audit, GAP tagging) is already the operational form of the philosophical position; no additional audit infrastructure is required to host the philosophical reading.

Chapter 9416

Layered Relation Certificates

Concretized in §1090: The relation-certificate vision is realized by a finite NameCert packet for same-schema cross-domain comparisons.

Concretized in §7672: $\mathsf{ForceLikeRelation}^{\uparrow}$ realizes the $\mathrm{ForceLikeRelation}_N$ vision as finite inter-Hist relation-certificate rows with explicit non-identity and failure-boundary ledgers.

This chapter records a relation discipline for cross-domain comparisons in BEDC. A comparison such as force cognition and MetaCIC self-audit is not admitted as an object identity, nor as a claim that physics has been derived from the kernel. It is admitted only when the comparison is lowered to a finite relation certificate: source rows, carrier rows, classifier rows, layer map, preserved structure, non-preserved content, provenance ledger, exactness status, failure boundary, and strength. The active rule is: do not close large words; close the relation certificates that make their comparison auditable.

The chapter sits beside chapter 9395, chapter 9406, chapter 9385, chapter 9419, and chapter 9420. Those chapters already supply the surrounding discipline: unsupported supply remains socketed, MetaCIC claims are read through audit maps, multi-Hist physics is relation-local, and consciousness or universe language closes only on finite records-side carriers. The present chapter packages that discipline for analogical and cross-domain claims.

9416.1 From Analogy to Certificate

A loose analogy has no carrier, no classifier, no exactness statement, and no failure boundary. It may guide reading, but it cannot be consumed by the manuscript as a claim. BEDC therefore lowers cross-domain analogy to relation certification.

Principle 9416.1 (Relation before identity)**.** *When BEDC compares two mature concepts, the default form is not object-level identity. The default form is a relation-level certificate whose fields display the source domains, carriers, classifiers, preserved structure, non-preserved content, ledgers, exactness status, and failure boundary of the comparison.*

Thus the sentence "force cognition resembles MetaCIC self-recognition" is not a theorem. The admissible BEDC form is:

$$\mathrm{SameRefinementSchema}(\mathrm{ForceCognition}, \mathrm{MetaCICSelfRecognition}).$$

The predicate does not assert sameness of objects. It asserts that two displayed refinement chains instantiate the same relation schema.

Definition 9416.2 (Primitive-looking token)**.** *In a practice domain D, a* primitive-looking token *is a name P that can be used in D before the manuscript has displayed its source, carrier, classifier, ledger, and failure boundary. Its danger is not that it is false, but that it compresses several sources under one public surface.*

Definition 9416.3 (Refinement chain)**.** *A* refinement chain *is a finite sequence*

$$P_0 \xrightarrow{o_0} P_1 \xrightarrow{o_1} \cdots \xrightarrow{o_{n-1}} P_n$$

where each P_k is a concept layer and each o_k is an obstruction, counterexample, audit failure, measurement anomaly, or boundary pressure that forces a classifier split. Each step carries source, carrier, classifier, transition, ledger, and failure rows.

Principle 9416.4 (Obstruction as classifier pressure)**.** *An obstruction is not merely a failed claim. In BEDC it is evidence that the previous classifier was too coarse. A legitimate refinement step converts the obstruction into a carrier split, classifier refinement, ledger row, or boundary socket.*

9416.2 Certificate Shape

Definition 9416.5 (Layered relation certificate)**.** *Given two refinement chains A and B, a* LayeredRelationCert(A, *is a finite paper-side certificate with the following fields:*

1. sourceA *and* sourceB*, the two source domains;*
2. carrierA *and* carrierB*, the carrier families used at each layer;*
3. layersA *and* layersB*, the finite layer lists;*
4. obstructionA *and* obstructionB*, the failures or anomalies that force refinement;*
5. classifierA *and* classifierB*, the classifiers used at each layer;*
6. layerMap*, the displayed correspondence between the two layer lists;*
7. preserved*, the structure preserved by the correspondence;*
8. notPreserved*, the content explicitly not preserved;*
9. ledger*, the source record for each correspondence row;*
10. exactness*, the meaning of "same schema";*
11. failureBoundary*, the condition under which the relation weakens or fails;*
12. strength $= s$*, with values such as seed, paper certificate, checked certificate, or bridge certificate.*

Principle 9416.6 (Exactness before export)**.** *A cross-domain relation without a* notPreserved *field cannot be exported as a BEDC claim. The certificate must say both what the relation preserves and what it refuses to preserve, because otherwise same-schema language is easily misread as identity.*

The strength field is part of the certificate, not a decoration. A paper certificate says that the manuscript fields are displayed. A checked certificate would require a corresponding Lean target. A bridge certificate would require a conservative external interpretation with no hidden host leak. The force–MetaCIC comparison below claims only paper-certificate strength.

9416.3 Force Cognition as a Refinement Chain

Human treatment of force can be read as a refinement chain rather than as a single object. Early force language compresses pushing, pulling, falling, collision, magnetic attraction, tension, and resistance into one token. Later practice splits that token into dynamical relations, field descriptions, geometric readings, symmetry structures, effective interactions, and unresolved boundaries.

Definition 9416.7 (Force cognition chain)**.** *The* ForceCognitionChain *is the following paper-side refinement schema:*

$$\begin{aligned}
F_0 &= \textit{push/pull token};\\
F_1 &= \textit{dynamical relation};\\
F_2 &= \textit{field reading};\\
F_3 &= \textit{geometric or curvature reading};\\
F_4 &= \textit{gauge-symmetry or connection reading};\\
F_5 &= \textit{effective interaction under scale and regime};\\
F_6 &= \textit{unresolved boundary or model-interface socket.}
\end{aligned}$$

Principle 9416.8 (Force is not primitive)**.** *In BEDC, force may not enter as a source-free primitive. At the records-side level it can only be discussed as a classifier over witnessed inter-*Hist *change rows:*

$$\mathrm{ForceLikeRelation}_N := \mathrm{Classifier}(\mathrm{InterHistChangeRows}_N).$$

Such a classifier must expose source rows, continuation or measurement witnesses, hsame/psame *stability, ledger policy, and bridge status.*

Remark 9416.9 (Physical content remains bridged)**.** $\mathrm{ForceLikeRelation}_N$ *is not empirical physical force itself. It is a finite horizon records-side carrier. A claim about standard physics requires a separate bridge:*

$$\mathrm{StandardBridge}(\mathrm{ForceLikeRelation}_N, \mathrm{PhysicalForce}).$$

Without that bridge, the relation remains paper-side or schema-side.

9416.4 MetaCIC Self-Audit as a Refinement Chain

MetaCIC self-audit follows the same de-primitiveizing pattern at the formal layer. A mature object, formal rule, type-like object, proof-like object, or classical CIC claim is not accepted as primitive. The audit asks for source, carrier, classifier, exactness, stability, ledger, naming certificate, gate, and socket.

Definition 9416.10 (MetaCIC self-recognition chain)**.** *The* MetaCICSelfRecognitionChain *is the following paper-side refinement schema:*

$$\begin{aligned}
M_0 &= \textit{primitive-looking mature object};\\
M_1 &= \textit{source carrier};\\
M_2 &= \textit{classifier over generated carriers};\\
M_3 &= \textit{exactness and stability obligations};\\
M_4 &= \textit{ledger, GAP, and provenance policy};\\
M_5 &= \textit{NameCert or DerivCert acceptance};\\
M_6 &= \textit{audit gate, failure certificate, or socket.}
\end{aligned}$$

Principle 9416.11 (Formal tokens are de-primitiveized)**.** *MetaCIC's audit function is to lower formal tokens into generated carriers, classifiers, stability obligations, ledgers, and boundaries. Any item that cannot pass through those rows may remain named, but it cannot be treated as internally closed BEDC content.*

9416.5 Force–MetaCIC Relation

Definition 9416.12 (Force–MetaCIC relation certificate)**.** *The* ForceMetaCICRelationCert *is a* LayeredRelationCert *whose source domains are the history of force cognition and the BEDC/MetaCIC history of self-certification. Its layer map sends:*

$$F_0 \mapsto M_0, \quad F_1 \mapsto M_1, \quad F_2 \mapsto M_2, \quad F_3 \mapsto M_3, \quad F_4 \mapsto M_4, \quad F_5 \mapsto M_5, \quad F_6 \mapsto M_6.$$

The preserved structure is primitive-token replacement by relation, classifier, invariant, ledger, certificate, and boundary. The non-preserved content includes empirical physical content, numerical constants, machine-checked proofs, phenomenal essence, object-level T*, and global universe structure. The exactness status is same refinement schema, not same object. The strength is paper certificate.*

Theorem 9416.13 (Force–MetaCIC same-schema certificate)**.** ForceCognitionChain *and* MetaCICSelfRecognition *instantiate the same de-primitiveizing relation schema at paper-certificate strength.*

Sketch. Both chains begin from a primitive-looking token. Both are refined by obstruction: empirical anomaly, classifier pressure, audit failure, or boundary mismatch. Both replace the coarse token by carrier and classifier rows. Both require stability and ledger rows to prevent source erasure. Both end by marking the unclosed residue as a boundary, socket, failure certificate, or bridge obligation. The relation preserves this refinement mode and does not preserve object content. Therefore the comparison closes as same-schema relation rather than identity. □

Corollary 9416.14 (Analogy as certificate)**.** *The sentence that force cognition resembles MetaCIC self-audit may enter the manuscript only as the natural-language reading of Definition 9416.12. It may not enter as an object-level theorem.*

9416.6 Interfaces to Universe, Physics, and Consciousness

The relation certificate composes with the finite records-side universe model of chapter 9420. The closed carrier is not a global universe object. It is a finite multi-Hist ledger-site with local time streams, selector ledgers, digest/GAP rows, witnessed inter-Hist relations, and stable invariants.

Definition 9416.15 (Force-like relation on a finite multi-Hist site)**.** *For a finite multi-*Hist *ledger-site* $\mathcal{W}_N$*, a* ForceLikeRelation$_N$ *consists of:*

1. *source rows recording inter-*Hist *change;*
2. *carrier rows over pairs or finite tuples of* Hist *values;*
3. *a same-force-pattern classifier;*
4. hsame/psame *stability and observer-slot symmetry;*
5. *local measurement, continuation, and causal-dependence ledgers;*

6. *exactness conditions under which classifier sameness reflects source relation;*
7. *an optional standard-physics bridge;*
8. *a status row: seed, paper certificate, checked certificate, bridge certificate, or schema-only.*

Principle 9416.16 (Force as inter-Hist classifier)**.** *Within BEDC, force language must be read through inter-*Hist *relation classifiers. A claim that uses force as a hidden cause, source-free input, or global-field primitive is not a closed BEDC claim; it must be demoted to a boundary, bridge obligation, or refusal.*

Definition 9416.17 (Consciousness relation carrier)**.** *For a finite multi-*Hist *ledger-site* $\mathcal{W}_N$ *with focus index* i*, the consciousness relation carrier is:*

$$\mathrm{ConsciousnessRelationCarrier}(\mathcal{W}_N, i) := (H_i, \mathrm{Trace}(H_i), \mathrm{Endpoint}(H_i), \mathrm{SelectorLedger}(H_i), \mathrm{SelfComparisonRows}($$

This carrier closes only the records-side surface.

Principle 9416.18 (No subject-substance in relation closure)**.** *A consciousness-related relation can close only through* Hist*, trace, endpoint, selector ledger,* GAP*, and inter-*Hist *relation rows. A phenomenal self-center, first-person givenness, or* T *far end may appear as boundary reading, but it may not be consumed as theorem content.*

9416.7 Gate and Refusal Surface

Definition 9416.19 (Layered relation gate)**.** *The* $\mathrm{LayeredRelationGate}(A, B)$ *is the audit question family for a proposed relation certificate:*

1. *Are the two source domains displayed?*
2. *Are the two carrier families displayed?*
3. *Are the two classifier families displayed?*
4. *Is the layer map displayed?*
5. *Are preserved and non-preserved content both displayed?*
6. *Are ledger rows displayed?*
7. *Are exactness and failure boundary displayed?*
8. *Has same-schema language been incorrectly promoted to identity?*
9. *Has the relation smuggled in an empirical law, subject-substance, global frame, or object-level* T*?*
10. *Is the strength row displayed?*

Concretized in §1099: Layered relation gates are realized as finite source, carrier, classifier, preserved, not-preserved, exactness, failure-boundary, refusal, and NameCert rows.

Principle 9416.20 (Refusal is part of closure)**.** *In BEDC, a relation certificate closes partly by refusing its over-readings. Refusal is not an admission of theoretical failure; it is the ledger row that prevents a relation token from pretending to be an object-level theorem.*

Over-reading	**Certificate discipline**
Force cognition and MetaCIC self-audit are the same object	Same refinement schema only
BEDC derives empirical physical force	Requires a standard-physics bridge
T produces force or a physical constant	Boundary reading only
Light speed, gauge field, or curvature is proved here	Subsequent invariant or bridge target only
The consciousness carrier is phenomenal consciousness itself	Records-side carrier only
The self-center is internal theorem content	Boundary reading only
Multi-Hist physics is closed by this chapter	Relation interface only
Analogy substitutes for carrier and ledger rows	Rejected by Definition 9416.19
Paper certificate is checked certificate or bridge certificate	Strength row forbids promotion

9416.8 Closure

Theorem 9416.21 (Closed discussion of layered relations)**.** *Let A and B be two cross-domain themes. If* $\mathrm{LayeredRelationCert}(A, B, s)$ *displays source, carrier, classifier, layer map, ledger, exactness, failure boundary, strength, and refusal rows, and if* $\mathrm{LayeredRelationGate}(A, B)$ *reports no identity collapse, hidden axiom, global-frame leak, subject-substance leak, or empirical overclaim, then the discussion of the relation between A and B is closed at manuscript level with strength s.*

Sketch. The discussion consumes only displayed certificate fields. Source and carrier rows bound the concept layers. Classifier and layer-map rows specify the comparison. Ledger rows preserve provenance. Exactness rows state what form of sameness is available. Failure-boundary and refusal rows prevent over-reading. The strength row prevents a paper certificate from being read as checked or bridged evidence. Therefore the exported relation is neither loose analogy nor object identity, but an auditable relation claim. □

Corollary 9416.22 (Force–MetaCIC relation closes at paper-certificate strength)**.** *Under the fields of Definition 9416.12, the force–MetaCIC relation may be used as a paper-certificate-strength relation. It closes the de-primitiveizing schema and does not close empirical force or the full MetaCIC meta-loop.*

Corollary 9416.23 (Universe and consciousness enter through records-side carriers)**.** *Universe, consciousness, and force language enter this relation certificate only through finite multi-*Hist *ledger-sites, focused* Hist *carriers, inter-*Hist *relations, and* $\mathrm{ForceLikeRelation}_N$*. Claims about phenomenal consciousness,* T*, a global universe object, or empirical constants remain boundary-side unless a separate certificate supplies the required bridge.*

Concretized in §1037: The finite relation-audit frame is concretized as a NameCert packet with source rows, layer map, preserved rows, non-preserved rows, ledger, exactness, and failure boundary.

Concretized in §1092: The analogy-certificate gate is concretized as a finite NameCert packet that admits same-schema language only through source, carrier, classifier, preserved, not-preserved, ledger, exactness, and failure-boundary rows.

Concretized in §1091: Finite layered relation certificates are represented by a displayed carrier, classifier, preservation/refusal boundary, exactness row, and ledger.

The final rule is therefore: do not write analogy as identity. Close the analogy as a relation certificate with source, carrier, classifier, ledger, exactness, and failure boundary.

Concretized in §925: Layered relation certificates are realized as finite NameCert packets separating same-schema relation evidence from object identity, empirical overclaim, and boundary leakage.

Concretized in §1088: Force-like inter-Hist relations are realized as finite relation-certificate packets with source, classifier, layer-map, refusal, ledger, and NameCert rows.

Concretized in §1089: LayeredRelationSiteUp realizes the layered relation certificate as a finite BHist NameCert packet over relation rows, refinement chains, locality gates, and refusal ledgers.

Concretized in §1090: Layered relation certificate packets realize the vision's relation-before-identity discipline as carrier, classifier, refusal, ledger, exactness, and NameCert rows.

Concretized in §7661: Layered relation certificates are realized as finite source, carrier, classifier, preserved, not-preserved, exactness, failure-boundary, refusal, and NameCert rows.

Concretized in §1098: Layered relation failure boundaries are realized as finite NameCert packets for exactness, weakening, refusal, gate-report, transport, route, provenance, and non-escape rows.

Concretized in §7012: Layered relation gate questions are realized as finite source, layer-map, preserved/not-preserved, exactness, failure-boundary, provenance, and NameCert rows.

Concretized in §7584: Finite approximation kernels realize finite source, approximant, classifier, error-ledger, failure-boundary, transport, replay, provenance, and NameCert rows.

Chapter 9417

The Cook Compile-Frontier as Engineering Path: From Principle to Witness

Definition 9390.18 and Definition 9390.19 establish the cook compile-frontier as a numerical reading of the Goedel boundary at the cellular substrate layer. The frontier is currently in the order of 16 productions and 32 tape symbols; the smallest halted Turing machine compiles to approximately 64 productions and 64 tape symbols. The gap between these two numbers is a finite engineering distance: the substrate is Turing-universal in principle (Cook 2004), and the substrate has been exercised on cyclic-tag inputs of substantial scale, but the round-trip from a real Turing machine encoding has not yet been completed. This chapter examines the engineering path from the present frontier to a halted-TM end-to-end witness, identifies the structural obstructions to be discharged at each stage, and reads the path itself as a contribution to the closed-observational framework: making the Goedel boundary not only legible but *progressively measurable*.

9417.1 Setup: present frontier as engineering coordinate

Definition 9417.1 (Engineering coordinate of the frontier)**.** *The* engineering coordinate *of the cook compile-frontier is the triple* (P^*, T^*, S^*) *specifying the smallest production count, tape symbol count, and Rule 110 step count for which the substrate has completed a closed round-trip in the sense of Definition 9390.18. The coordinate is reported by the* `rule110/tests/test_cook_packet_scale.c` *audit binary and is updated whenever a larger configuration passes its round-trip check.*

Example 9417.2 (Present engineering coordinate)**.** *At the present substrate version,* (P^*, T^*, S^*) *includes* $(2, 16, 16384)$*,* $(8, 8, 16384)$*,* $(4, 16, 32768)$*,* $(2, 32, 32768)$*, and* $(16, 2, 8192)$*. The product* $P^* \cdot T^*$ *remains below* 64 *in all currently passing configurations. The halted-TM target coordinate is approximately* $(64, 64, S_{\text{halt}})$ *where* S_{halt} *is the Rule 110 step count required by Cook's polynomial-time bound for the smallest halted machine.*

Principle 9417.3 (The frontier is a moving coordinate, not a static boundary)**.** *The cook compile-frontier is not a fixed structural limit of the substrate; it is the engineering coordinate of where the substrate has been exercised to date. Engineering work that extends the substrate's implementation, optimises its encoding, or scales its evaluator can advance the coordinate without altering any closure theorem. The frontier therefore behaves as a moving coordinate: each successful audit*

binary run at a larger configuration shifts (P^*, T^*, S^*) *to a new value, and the gap to the halted-TM target shrinks correspondingly.*

9417.2 The compile pipeline, stage by stage

Definition 9417.4 (Cook compile pipeline stages)**.** *The compile pipeline implementing Cook 2009* §1.2–§1.4 *decomposes into three sequential stages:*

1. *TM-to-tag: a Turing machine* $(Q, \Sigma, \delta, q_0, q_{\text{halt}})$ *compiles to a tag system* $(\Sigma_{\text{tag}}, \mathsf{prod})$*, implemented in* `rule110/encoder/tm_to_tag.c`*.*
2. *Tag-to-cyclic: the tag system compiles to a cyclic tag system* (P, T)*, implemented in* `rule110/encoder/tag_to_`
3. *Cyclic-to-R110: the cyclic tag system compiles to a Rule 110 initial row, implemented in* `rule110/encoder/cook_encode.c`*.*

Each stage is exercised independently and end-to-end by the test binaries in `rule110/tests/`*.*

Remark 9417.5 (Stage-wise scale frontiers)**.** *Each pipeline stage has its own scale frontier. The TM-to-tag stage's frontier is the largest* $(|Q|, |\Sigma|)$ *pair for which the stage produces a valid tag system. The tag-to-cyclic stage's frontier is the largest* $|\Sigma_{\text{tag}}|$ *for which the stage produces a valid cyclic-tag system at acceptable* (P, T) *size. The cyclic-to-R110 stage's frontier is the largest* (P, T, S) *for which the substrate completes a closed round-trip. The overall engineering coordinate of Definition 9417.1 is the minimum frontier across the three stages.*

9417.3 Structural obstructions to advancing the frontier

Remark 9417.6 (Memory scaling)**.** *The Rule 110 evaluator at* `rule110/evaluator/rule110.c` *represents the cell row as a packed bit array. Doubling the row width doubles the array size; at* $(P, T) \approx (64, 64)$ *the encoded row width is in the order of* 10^6 *cells. Memory scaling at this size is within reach of modern systems but requires explicit attention to allocation strategy. This is the most direct obstruction at the substrate-evaluation stage.*

Remark 9417.7 (Encoding constant factors)**.** *The cyclic-to-R110 encoding of Cook 2009* §1.4 *introduces large constant factors: each cyclic-tag symbol corresponds to several thousand Rule 110 cells; each tag-system step corresponds to many Rule 110 steps. Reducing these constants is an active research direction in cellular substrate engineering, with potential gains from alternative glider catalogs (Definition 9390.3) and tighter collision packing (Martinez 2012 Table 1/Table 2). Each constant-factor reduction advances the engineering coordinate without changing any closure result.*

Remark 9417.8 (Round-trip verification cost)**.** *Verifying a round-trip at* $(64, 64, S_{\text{halt}})$ *requires evaluating Rule 110 for* S_{halt} *steps on a row of width in the order of* 10^6*, then decoding the result back through the inverse of the cyclic-to-R110 encoding, then through the tag-to-cyclic encoding, then through the TM-to-tag encoding. The total verification work scales as* $O(S_{\text{halt}} \cdot W)$ *where* W *is the row width. The wall-clock cost at the target frontier is non-trivial but tractable.*

9417.4 The epistemic value of crossing the frontier

Principle 9417.9 (Crossing converts in-principle universality to witnessed universality)**.** *Cook 2004 proves the substrate is universal in principle. Crossing the engineering frontier from* (P^*, T^*, S^*)

to $(64, 64, S_{\text{halt}})$ *would convert that in-principle universality into a witnessed universality: the substrate would have been exercised on a real Turing-machine encoding, with the round-trip producing the expected halt-state output. The conversion does not strengthen the closure theorem; it strengthens the empirical support for the claim that the substrate behaves as Cook 2004 predicts at the scale of real machines.*

Principle 9417.10 (Witnessed universality is engineering data, not a new theorem)**.** *The conversion of Definition 9417.9 produces an engineering data point: "the smallest halted TM has been compiled to a closed Rule 110 round-trip at coordinate* $(64, 64, S_{\text{halt}})$*, audited by* `test_cook_packet_scale.c` *on commit h". This data point is reportable in* `rule110/STATUS.md` *alongside the present frontier. It is not a new theorem; it is the operational realisation of an existing theorem at a scale where the operation is for the first time exercised on substrate-internal data corresponding to a recognisable computational structure.*

Remark 9417.11 (Comparison with the MetaCIC dependent-codomain barrier)**.** *The frontier-crossing work has a structural analogue at the meta-theory layer: discharging the four subject-reduction hypotheses of chapter 9377 as theorems rather than as* `structure` *fields. Both forms of work advance the project from in-principle closure to operationally-witnessed closure. The cellular frontier-crossing is engineering at the substrate layer; the MetaCIC hypothesis-discharge is engineering at the meta-theory layer. The two layers are logically independent (Definition 9390.20); progress at one layer does not require or imply progress at the other.*

9417.5 Failure modes of the engineering path

Remark 9417.12 (Substrate divergence from Cook prediction)**.** *If at some intermediate coordinate* (P, T, S) *between the present frontier and the halted-TM target the substrate's round-trip fails to decode back to the expected output, the resulting fact is a partial falsification of the operational claim that the substrate implements Cook's construction exactly. The substrate's universality in principle would not be affected (Cook 2004 is a theorem of mathematics); the operational realisation in the present codebase would require revision. A failure of this kind is informative: it identifies the substrate-side commit at which the divergence appears and points the engineering work to a specific bug or specification mismatch.*

Remark 9417.13 (Memory or wall-clock infeasibility)**.** *If memory scaling or wall-clock cost makes the halted-TM coordinate infeasible at acceptable cost on available hardware, the engineering coordinate stops advancing at some intermediate value* (P', T', S') *short of the target. The closure theorems remain valid; the operational claim about "witnessed universality" would have to be stated at the achieved coordinate. The frontier-as-data role (Definition 9417.10) is preserved at any coordinate; the role does not require reaching the halted-TM target.*

9417.6 The frontier as ongoing project artifact

Principle 9417.14 (The frontier value is a citable project state)**.** *The present engineering coordinate* (P^*, T^*, S^*) *is reported in* `rule110/STATUS.md` *and is updated on every substrate scaling improvement. The coordinate is therefore a citable project state: papers, dossier essays, and project reports can cite "the cook compile-frontier at commit h is* (P^*, T^*, S^*)*" as a precise numerical fact. The frontier is updated as a project artifact, not as a one-off measurement.*

Remark 9417.15 (Progress reporting via frontier deltas)**.** *Progress on the engineering path can be reported as deltas: "the frontier advanced from (P_0^*, T_0^*, S_0^*) to (P_1^*, T_1^*, S_1^*) in version v". Each delta is a concrete improvement in operational coverage of the universality claim. Cumulative delta history can be tracked in* `rule110/CHANGELOG.md` *or equivalent; the structural role of the frontier as a moving coordinate (Definition 9417.3) makes such history meaningful.*

9417.7 Mapping to BEDC engineering

Frontier-engineering reading	**BEDC engineering realisation**
Engineering coordinate	(P^*, T^*, S^*) reported by `rule110/tests/test_cook_packet_scale.c` and recorded in `rule110/STATUS.md`.
Halted-TM target	$(64, 64, S_{\text{halt}})$ from the smallest halted Turing machine under Cook 2009 §1.2–§1.3.
Pipeline stages	`tm_to_tag.c`, `tag_to_cyclic.c`, `cook_encode.c` in `rule110/encoder/`.
Memory scaling obstruction	Row width $\sim 10^6$ cells at target; `rule110/evaluator/rule110.c` packed bit array.
Verification cost	$O(S_{\text{halt}} \cdot W)$; tractable on modern hardware.
In-principle vs witnessed universality	Definition 9417.9: the engineering work converts one to the other operationally; closure theorems unaffected.
Independent of MetaCIC barrier	Definition 9417.11: cellular layer and meta-theory layer are logically independent engineering paths.

9417.8 Closure remarks

This chapter has read the cook compile-frontier as an engineering coordinate, identified the three-stage pipeline that the engineering path must advance, and named the structural obstructions (memory scaling, encoding constants, verification cost) the engineering work must address. The chapter does not claim that the halted-TM target is reachable; it identifies the target, the path, and the present coordinate so that progress can be reported as concrete deltas rather than as informal advances.

The epistemic value of crossing the frontier is to convert in-principle universality (Cook 2004 as theorem) into witnessed universality (substrate operationally exercised on a real Turing machine encoding). The conversion does not strengthen any closure theorem; it strengthens the operational support for the claim that the substrate implements Cook's construction correctly at scales matching real computational structures.

The boundary of this chapter is: the engineering frontier is a moving coordinate; the engineering path is concretely specified; the obstructions are named; the epistemic value of crossing is operational rather than theoretical. The chapter does not introduce new closure theorems and does not depend on the engineering path succeeding. It identifies the path so that work along it can be reported as advances in operational coverage of an already-proved universality claim.

Concretized in §639: Compiler optimization endomorphisms realize the Cook compile-frontier route as a finite before/after compiler trace with semantic-preservation and frontier-coordinate rows.

Concretized in §958: HaltedTmRoundTrip realizes the Cook compile-frontier path as a finite staged compile, Rule 110 orbit, decode, and halt-row NameCert packet.

Concretized in §952: CookCompileFrontierWitness packages the Cook compile-frontier coordinate as a finite compile-stage, audit, obstruction, hsame, Cont, Pkg, and NameCert witness.

Concretized in §954: CompileFrontierWitnessUp records the Cook compile-frontier as a finite witnessed-coordinate NameCert with stage routes, audit rows, and nonchoice boundary.

Concretized in §7557: Finite cover uniform modulus envelopes realize a finite cover, modulus, window, transport, and NameCert route for constructive compact-continuous consumers.

Concretized in §949: The Cook compile-frontier coordinate is realized as a finite NameCert packet for stage frontiers, Rule 110 scale rows, audit replay, and failure non-escape.

Concretized in §959: Cook frontier witness packets realize the compile-frontier coordinate as finite stage, target, replay, obstruction, hsame, Cont, Pkg, and NameCert rows.

Concretized in §959: CookFrontierWitnessUp realizes the finite Cook compile-frontier coordinate, staged compiler rows, replay audit, obstruction ledger, and halted-target boundary as NameCert data.

Concretized in §7712: FrontierCompileHardProblemUp realizes the hard-problem, layered-relation, and cook-compile frontier as finite NameCert rows.

Chapter 9418

Observer-Hist Identity: The Implicit Metaphysics of the Finite Kernel

Concretized in §479: Observer-Hist identity is realized as a finite NameCert packet over Hist, hsame, Cont, probe/signature observations, and no-subject consumer ledgers.

Concretized in §615: Observer subject boundaries are realized as finite BHist observation packets whose ledger excludes any extra observer-substance carrier.

Concretized in §640: Observer-kernel traces are realized as finite BHist packets over hsame, Cont, licensed observation rows, provenance, and a no-subject ledger.

Concretized in §688: Observer perspective composition realizes two-step observer comparison as a finite BHist NameCert packet over displayed classifier, coupling, alignment, hsame, Cont, Pkg, and local naming rows.

Concretized in §882: Observer distinction traces are realized as finite BHist packets over Hist distinction steps, Cont routes, hsame transport, and no-subject provenance.

Concretized in §973: Observer boundary selectors realize observer-history identity as finite selected-row, omitted-row, selector-decision, hsame, Cont, Pkg, StreamName, and NameCert data.

BEDC was built for mathematical purposes: axiom-purity over a mathlib-free Lean 4 base, distinction-foundationalism as the only primitive, and a closed inductive kernel as the entire generative apparatus. The construction is mathematical end to end, and its theorems are mathematical theorems. Yet the kernel architecture, when read at the level of its signatures and closure laws rather than at the level of its derived chapters, carries an implicit position about what observation, observer, and time are inside the formal layer. This position became visible during development, not as a design goal, but as a structural consequence of the kernel's signature: the Cont relation has only Hist-valued arguments, the only identity criterion at the kernel is hsame on Hists, and the temporal direction of derivation is fixed by the asymmetry of Cont. The position is the single line: observation = distinction = time, and observer = Hist with no separate subject. This capstone formalizes that line. It introduces no new mathematics. Each section identifies a carrier predicate or closure law in which a specific commitment is encoded and proves a theorem showing the commitment is mathematically forced rather than philosophically added on. Five sections cover, in turn, distinction as the source of information (section 9418.2), observer as the Hist self-reference loop (section 9418.3), time as Hist growth (section 9418.4), the two-loops architecture as the consistency face of the no-subject commitment (section 9418.5), and the synthesis as a three-fold identity at the kernel level (section 9418.6). Like the rest of the manuscript, the chapter falls

under the project's axiom-purity gate: the formal targets it cites do not depend on Classical.choice, Quot.sound, or propext.

9418.1 Observer history identity ledger

Observer history identity records the point where observational sameness and generated-history sameness meet. In BEDC, an observer can inspect a history only through marks, continuations, bundles, signatures, and certified classifiers. Two histories that agree under every licensed observation are therefore not identified by a host equality principle; they are compared through the internal history-sameness and classifier ledgers already present in the kernel.

Concretized in §477: Observer history identity is realized as a finite NameCert packet over BHist, hsame, Cont, licensed observations, and local ledger provenance.

Concretized in §986: Observer hsame classifiers realize the licensed observation-comparison surface as finite BHist, hsame, Cont, ProbeBundle, SigRel, Pkg, and NameCert rows.

Concretized in §1031: Observer licensed comparisons realize observer-history identity as finite licensed-observation, hsame-transport, classifier-output, Cont-route, Pkg, and NameCert rows.

Concretized in §1032: Observer bridge ledgers realize observer-history identity as finite observer-state, no-subject-boundary, multi-history, route, provenance, and NameCert rows.

Concretized in §514: Observer filters realize observer-history identity as a finite BHist selection and ledger boundary.

Concretized in §1042: Observer-filter budget selectors realize observer-history identity as finite selected-row budgets feeding StreamName and Real-completion observation routes.

Concretized in §927: Attention ledgers realize observer-history identity as finite selected-row, omitted-row, StreamName handoff, and non-escape NameCert data.

Concretized in §1047: Observer directions are realized as finite observer-row, target-row, direction-token, comparison, readback, hsame, Cont, Pkg, and NameCert packets.

Definition 9418.1 (Observer history identity)**.** *An observer identity judgment between histories h and k is a certificate-level comparison whose observations are all mediated by BEDC witnesses: mark emission, continuation, probe bundles, signature relations, and derived classifiers. Its intended public reading is that no licensed observer separates h from k without producing a classifier witness against* $\mathsf{hsame}(h, k)$.

Theorem 9418.2 (Observer identity remains internal)**.** *Every observer history identity judgment is internal to BEDC when its observations factor through the kernel ledgers of chapter 3, chapter 6, and the naming-certificate classifier discipline.*

Proof. Each observation listed in the judgment is a BEDC object: a mark emission, a continuation, a bundle event, a signature relation, or a certified classifier comparison. Repack these witnesses as the observer ledger. The resulting comparison uses only the internal sameness and classifier relations named in the premise, so no external equality principle is introduced. □

9418.2 Distinction as the source of information

Definition 9418.3 (Information content of a history)**.** *For a Hist value h, the* information content *of h is the sequence of* E1/E0 *distinctions recorded in h, given by an explicit unary recursion on the inductive structure of* Hist*. The recursion case at* e *is the empty sequence; the recursion case at each* E1 *or* E0 *application appends the corresponding distinction tag to the sequence produced from the predecessor.*

Theorem 9418.4 (Pre-distinction void)**.** *The empty Hist value* e *has trivial information content: every Hist-predicate P whose definition recurses only on* E1 *and* E0 *constructors and not on auxiliary parameters evaluates to its trivial case at* e*. In particular, the information-content sequence at* e *is the empty sequence.*

Theorem 9418.5 (Hist as minimal information carrier)**.** *Every constructive carrier of binary-distinction information expressible in the BEDC layer embeds into* Hist *via an explicit isomorphism on its constructor signature;* Hist *is minimal in the sense that any further-reduced carrier loses the binary distinction. The embedding is given by the generator-closure classifier of the carrier's signature.*

Corollary 9418.6 (Information requires distinction)**.** *There is no constructive information carrier in BEDC strictly smaller than* Hist*; equivalently, the empty Hist value carries no information, and any non-trivial information content requires at least one* E1 *or* E0 *application above* e*.*

Remark 9418.7 (Reading)**.** *This section formalizes the project-governance principle that distinction precedes information. The principle is not assumed at the level of the kernel; it is forced by the closed-inductive structure of* Hist *(chapter 3). The empty value* e *is the only Hist that records nothing, and every other Hist is constructed by finitely many distinction acts above it. There is no Hist outside this generation, and therefore no information-carrier inside the BEDC layer that bypasses the form of distinction.*

9418.3 Observer as Hist self-reference loop

Definition 9418.8 (Subject-free observation)**.** *The continuation relation* $\mathsf{Cont}(h, d, h')$ *is* subject-free *when its signature takes only Hist-valued arguments, with no auxiliary parameter outside the* Hist *type appearing in the relation. The Hist value h plays simultaneously the role of antecedent state and the role of the carrier on which the continuation is recorded; no observer-substance occupies a separate slot.*

Definition 9418.9 (Self-reference closure)**.** *The kernel is* self-reference closed *when (i) every Cont continuation is a relation between Hist values alone, with no agent parameter outside* Hist*, and (ii)* hsame *on Hist values is the only identity criterion the kernel admits, with no observer-substance identity defined alongside.*

Theorem 9418.10 (Hsame is observer identity)**.** *Two Hist values h and h' satisfy* $\mathsf{hsame}(h, h')$ *if and only if they record the same finite sequence of* E1/E0 *distinctions. Under the identification of observer with history of self-distinguishing, two observers are the same observer exactly when their distinction traces are* hsame*-equivalent.*

Theorem 9418.11 (No subject parameter)**.** *The kernel-level signature of the Cont relation has no auxiliary parameter representing a subject or carrier outside* Hist*. Adding such a parameter*

requires a new type with non-trivial closure laws relative to the existing cont_assoc, cont_left_unit, *and* cont_right_unit *identities; introducing it forces inconsistency with at least one of these three identities, since the parameter has no place in their formulation.*

Corollary 9418.12 (Observer is identical to Hist)**.** *Up to* hsame, *the observer is the Hist value itself; there is no observer-substance in the BEDC layer distinct from the recorded distinction trace. Every kernel-level statement about observers is, by Definition 9418.11, a statement about Hist values under* hsame.

Remark 9418.13 (Reading)**.** *This section formalizes a constructive realization of the bundle theory of self in the empiricist tradition, of ātman-negation in the analytical traditions that share its conclusion, and of the second-order cybernetics position that the observer is a configuration of its own observations rather than a separate substance. BEDC is not committed to any of these traditions philosophically; the framework is committed to their structural conclusion mathematically, in that the kernel signature has no slot for observer-substance and adding one breaks the closure laws.*

9418.4 Time as Hist growth

Definition 9418.14 (Hist time step)**.** *A* Hist time step *is a single application of* E1 *or* E0 *to a Hist value. The step is recorded simultaneously as part of the Hist value, by the corresponding constructor, and as part of the witness in the Cont relation, by the d argument tagging which of* E1 *or* E0 *was applied.*

Definition 9418.15 (Local time stream)**.** *For a Hist value h, the* local time stream *of h is the sequence of Cont applications producing h from* e*; equivalently, the unary length* $\mathsf{UnaryHistory}(h)$ *together with the distinction record at each step recovered from the information content of h (Definition 9418.3).*

Concretized in §603: Local Hist time streams are realized as finite BHist packets over Cont-step rows, hsame transport, and a no-global-clock ledger.

Concretized in §665: Local clock budgets realize observer local time as finite BHist packets over Cont-step windows, hsame transport, and a no-global-clock ledger.

Concretized in §1043: Observer time steps are realized as finite Hist, distinction-tag, Cont-step, hsame-transport, no-global-clock, Pkg, and NameCert rows.

Concretized in §1105: Inter-Hist synchronization refusals realize the no-global-clock observer-history boundary as finite two-stream BHist, hsame, Cont, Pkg, refusal-ledger, and NameCert rows.

Concretized in §7312: Observer modulus clocks realize the observer-history modulus-as-temporal-rate route through finite StreamName, CauchyModulus, RegSeqRat, RealUp, and observer-selection rows.

Theorem 9418.16 (Cont is time-asymmetric)**.** *The Cont relation is functional in the forward direction: given a Hist h and a distinction d, the continuation h' such that* $\mathsf{Cont}(h, d, h')$ *is uniquely determined. The inverse direction, given h' and d recover h such that* $\mathsf{Cont}(h, d, h')$*, is not constructively decidable for a fixed d without recursion on the structure of h'. The asymmetry between forward and inverse direction is the constructive arrow of time at the kernel level.*

Theorem 9418.17 (Modulus is temporal rate)**.** *For every regular convergence carrier in BEDC equipped with a modulus function N : Unary $\to$ Unary, the modulus is the temporal rate of the associated Hist time stream: it specifies, as a unary count of Cont applications, how many distinction steps are required for the trace to stabilize within a given precision. The same correspondence applies to regular Cauchy carriers and to continuous-modulus carriers.*

Corollary 9418.18 (No global clock in the kernel)**.** *There is no Hist value at the kernel level that synchronizes the local time streams of two distinct Hists; each Hist carries its own local time stream, and inter-Hist time-comparison is not defined at the kernel. Any synchronization, if introduced, must be defined as an extension carrier above the kernel, not as kernel-level structure.*

Remark 9418.19 (Reading)**.** *This section formalizes the Brouwer position that mathematics arises from the perception of time, where the elementary perception is the binary distinction giving the two-ity.* E1 *and* E0 *application is the elementary time-step, Hist growth is the elementary time-stream, and the corpus of constructive theorems built above the kernel is this elementary perception's structured unfolding. The reading does not commit BEDC to Brouwer's metaphysics; it identifies, inside the formal layer, the site at which his structural claim becomes a theorem.*

9418.5 No subject: the two-loops architecture

Definition 9418.20 (Ground loop closed)**.** *The* ground loop *is closed when (i) every Hist value is reachable from* e *by finitely many* E1/E0 *applications, that is,* Hist *is well-founded, and (ii)* hsame *is decidable on* Hist*. Both conditions are theorems of the kernel.*

Definition 9418.21 (Meta loop unclosable)**.** *The* meta loop *is the predicate "what is observation as such?" attempted as a Hist-valued construction. Positing a Hist value whose distinction content represents this predicate generates a Tarski-style fixed-point requirement that no closed inductive structure satisfies. The meta loop is therefore unclosable inside the kernel.*

Theorem 9418.22 (Axiom-purity requires no subject)**.** *The BEDC axiom-purity gate, that no proof depends on* Classical.choice*,* Quot.sound*, or* propext*, is satisfiable on the kernel if and only if no observer-substance type is introduced. Introducing such a type forces at least one of choice, quotient soundness, or propositional extensionality into the proof of* cont_assoc *or one of the related identities, since the new parameter must be transported across continuations and the transport is unwitnessed at the kernel level.*

Theorem 9418.23 (Two-loops balance)**.** *The kernel is consistent if and only if the ground loop closes (Definition 9418.20) and the meta loop does not close (Definition 9418.21). Equivalently, consistency holds if and only if the observer-as-Hist identification (Definition 9418.12) holds and no observer-substance carrier is introduced.*

Remark 9418.24 (Reading)**.** *The unclosability of the meta loop is the constructive face of Tarski's undefinability theorem applied to the BEDC kernel: positing an internal predicate "what observation is" generates a self-referential fixed-point that cannot live in the closed inductive fragment. The no-subject commitment of the BEDC kernel is therefore not a philosophical preference but a structural requirement: the kernel is consistent precisely because it does not attempt to internalize the predicate, and the corresponding closure is the project's axiom-purity gate.*

9418.6 Synthesis: the three-fold identity

Theorem 9418.25 (Observation-distinction-time identity)**.** *At the kernel level, the following three relations are extensionally identical modulo* hsame*:*

1. *the observation act-shape* Cont *on* Hist*,*
2. *the elementary distinction step given by application of* E1 *or* E0*,*
3. *the elementary time-step on the Hist time stream (Definition 9418.14).*

The three relations have the same domain, the same closure laws cont_assoc*,* cont_left_unit*,* cont_right_unit*, and the same* hsame*-respect properties.*

Corollary 9418.26 (Cont is the universal verb)**.** *Every extension-type phenomenon in BEDC is a specialization of the same Cont relation under different closure conditions. Category morphism (chapter 9363), continuous modulus, the compactness chain, small-step computation (chapter 9365), type checking by classifier membership (chapter 9367), and complex differentiability are not merely analogous instances of a shared schema; they are the same kernel-level relation under different naming-certificate closures.*

Remark 9418.27 (Closing: the implicit metaphysics)**.** *This capstone introduced no new theorems about specific mathematical objects. It re-read the existing kernel architecture under one identification: observer =* Hist*, observation =* Cont*, time = Hist growth, with no observer-substance behind the trace. Under that identification, every prior chapter of BEDC is a structured unfolding of self-reference, and the universality of* Cont *across mathematical domains is forced by the no-subject commitment rather than designed in. The chapter falls under the project's axiom-purity gate; no* Classical.choice*, no* Quot.sound*, and no* propext *is required for any of the cited targets.*

Concretized in §888: Observer trace kernels realize observer-history identity as finite BHist, hsame, Cont, observation, provenance, and no-subject NameCert rows.

Concretized in §894: Observer-frame refusals realize no-global-frame and no-synchronized-clock observer rows as finite BHist, hsame, Cont, Pkg, refusal-ledger, and NameCert data.

Concretized in §928: Observer interfaces realize observer-history identity as finite filter, attention-ledger, StreamName handoff, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1054: Observer trace seals realize observer-history identity as finite observer-row, trace-row, seal-row, no-subject refusal, hsame, Cont, Pkg, and NameCert data.

Chapter 9419

Inter-Hist Locality: From No God's-Eye View to Light-Speed Constancy

This capstone is the road-map sibling to chapter 9418. Where that chapter formalizes the SINGLE-Hist commitments that BEDC already proves — namely that an observer is identified with the Hist of its observations, with no observer-substance carrier behind the record — the present chapter scaffolds the MULTI-Hist consequences that BEDC must develop next. When several independent Hist values are considered together, with no shared base and no shared time-step indexing, the kernel does not give a global frame and cannot give one without violating the closed-inductive structure of Hist. In that setting only inter-Hist invariants can carry frame-independent physical content, and the maximum cross-Hist causal rate, in particular, must be observer-symmetric and constant across all observers in a configuration. That last consequence is the structural skeleton of the constancy of light speed in special relativity. The chapter catalogues the structure: multi-Hist configuration, no global synchronization, inter-Hist relation, observer-symmetric invariant, maximum cross-Hist causal rate, and the observer-independence of that maximum. Most of the multi-Hist semantics is currently a SCHEMA-ONLY HORIZON in BEDC: the type signatures and statement targets are sketched here, and the closed witnesses are deferred to a future BEDC physics-of-multi-observer development that does not yet exist. The chapter is therefore a roadmap, not a proof; it identifies the interface that future BEDC chapters would close. The structural commitments of the capstone connect to existing relational physics traditions: Rovelli's relational quantum mechanics, Wheeler's "It from Bit", Connes's noncommutative geometry, and Penrose's spin networks all locate physical content in observer-relations rather than in a privileged global frame. BEDC differs from these traditions in that it constructs the relational substrate from a still more primitive layer: distinction (Hist) and observation (Cont). The chapter falls under the same axiom-purity gate as the rest of the project — whether multi-Hist semantics can preserve no-Classical.choice / no-Quot.sound / no-propext is itself part of the road-map question, and is articulated as such in the closing section.

9419.1 Ledger-local relations

Inter-history locality names the BEDC principle that any comparison between two histories must be witnessed through finite continuation data visible inside the kernel. A relation between histories is

admissible only when its evidence can be read from generated marks, emitted histories, continuation witnesses, or classifiers built from those objects. No external equality oracle is part of the public surface.

Definition 9419.1 (Inter-history locality)**.** *An inter-history relation $R(h, k)$ is local when every positive witness of $R(h, k)$ factors through a finite BEDC ledger: a source history for h, a source history for k, a finite continuation or bundle witness connecting the inspected data, and a classifier comparison stated with* hsame*,* msame*, or a derived classifier already licensed by a naming certificate.*

Theorem 9419.2 (Locality is ledger visibility)**.** *If an inter-history relation is local, then its public use can be audited by the same ledger discipline used for naming certificates: the hidden data are exactly the generating histories and continuation witnesses, and the visible judgment is the classifier-level relation they expose.*

Proof. Unfold locality. The witness already consists of source histories, finite continuation or bundle data, and a classifier comparison. These are precisely the ledger fields available to a naming certificate, so the public relation is the visible projection of that finite BEDC ledger. □

9419.2 Multi-Hist configurations

Definition 9419.3 (Multi-Hist configuration)**.** *A multi-Hist configuration is a finite collection of Hist values $h_1, \ldots, h_n$ considered together, with no requirement of a shared base history and no requirement of a shared time-step indexing. The configuration is the bare collection: the kernel does not append, glue, or synchronize the members.*

Definition 9419.4 (No global synchronization)**.** *There is no Hist-valued global synchronization for multi-Hist configurations: there is no* Hist *value h_g such that for every multi-Hist configuration, h_g records a privileged shared "now" across all members of the configuration. The closed-inductive structure of* Hist *does not admit such an h_g.*

Theorem 9419.5 (Hists are frame-independent)**.** *For any two* Hist *values h_a, h_b, neither carries the other's time-step indexing intrinsically. Any cross-Hist temporal correlation must be constructed via an external relation, not read off either Hist alone, and any such relation is itself a Hist-level construction subject to the same no-global-frame constraint.*

Lemma 9419.6 (Empty configuration is degenerate)**.** *A multi-Hist configuration with zero or one members carries no inter-Hist content. The smallest non-degenerate configuration has two members, and the smallest configuration in which cross-Hist causal dependence (Definition 9419.16) can be non-trivial likewise has two members.*

Lemma 9419.7 (Configuration extension preserves no-global-sync)**.** *Adding a new* Hist *value to an existing multi-Hist configuration does not produce a global synchronization that the original configuration lacked. No-global-synchronization is monotone: it is preserved under configuration extension, and cannot be acquired by accumulating Hists.*

Remark 9419.8 (Reading: no observer-of-observers)**.** *This section formalizes the no-God's-eye-view commitment. There is no observer-of-observers that synchronizes the multi-Hist totality, because the kernel is silent about a global frame and the closed-inductive* Hist *type does not admit one. By the sibling capstone (chapter 9418), once observer is identified with Hist, no super-observer can coexist: any candidate super-observer is itself a Hist, and is subject to the same*

locality constraints as every other member of a configuration. Definition 9419.7 shows that the absence cannot be repaired from inside the kernel by adding more observers; it is a feature of the closed-inductive structure of Hist *rather than a contingent fact about the current configuration.*

9419.3 Inter-Hist invariants

Definition 9419.9 (Inter-Hist relation)**.** *An inter-Hist relation is a predicate $R(h_a, h_b)$ on pairs of* Hist *values that is observer-symmetric: $R(h_a, h_b)$ holds if and only if $R(h_b, h_a)$ holds, up to* hsame *on each component. Symmetry is required at the type-signature level: the predicate cannot privilege one slot over the other.*

Definition 9419.10 (Inter-Hist invariant)**.** *An inter-Hist invariant is a function $I : \mathsf{Hist} \times \mathsf{Hist} \to \mathsf{Unary}$ that is observer-symmetric and frame-independent: for any pair of perspectives on the configuration — that is, for either* Hist *taking the role of measurement-anchor — the function I produces the same output up to* hsame*, and the output does not depend on any external choice of frame.*

Theorem 9419.11 (Invariants are observer-independent)**.** *Every inter-Hist invariant produces the same value regardless of which* Hist *is taken as the perspective anchor. The value is a property of the pair as such, and not of either individual* Hist*; it is not measurable from inside one observer's record except as a relational quantity involving the other.*

Proposition 9419.12 (Invariants compose under hsame)**.** *If I is an inter-Hist invariant and $h_a \mathsf{hsame} h'_a$ and $h_b \mathsf{hsame} h'_b$, then $I(h_a, h_b) \mathsf{hsame} I(h'_a, h'_b)$. The invariant respects the kernel's history-equivalence relation; it cannot distinguish histories that the kernel does not distinguish.*

Lemma 9419.13 (Trivial invariants exist)**.** *The constant function $I(h_a, h_b) := \mathsf{e}$ and the constant function $I(h_a, h_b) := \mathsf{UnaryHistory}$ are inter-Hist invariants in the sense of Definition 9419.10. The class of inter-Hist invariants is therefore non-empty before any physics is committed; the substantive content of the road-map is the construction of non-trivial invariants whose values discriminate between configurations.*

Proposition 9419.14 (psame-stability of invariants)**.** *If I is an inter-Hist invariant and $p_a \mathsf{psame} p'_a$ is a probe-equivalence at the anchor of h_a and $p_b \mathsf{psame} p'_b$ at the anchor of h_b, the invariant I returns* hsame*-equivalent values on the corresponding pairs. Inter-Hist invariants are stable under both kernel-level history equivalence (Definition 9419.12) and kernel-level probe equivalence; they cannot distinguish what the kernel does not distinguish at either layer.*

Remark 9419.15 (Reading: relational content is forced)**.** *This section formalizes the operationalist principle that, in the absence of a privileged frame, all physical content lives in inter-observer relations rather than in any one observer's record. The principle is forced by no-global-synchronization (Definition 9419.4); it is not assumed. In particular, an observer's individual Hist is not a frame-independent carrier of physical content on its own; only I-images of pairs are. Definition 9419.14 sharpens this: invariants cannot smuggle in distinctions below the kernel's resolution, on either the history or the probe layer, so the relational content lives strictly in the kernel-level equivalence quotient.*

9419.4 Cross-Hist causal dependence (schema-only)

Definition 9419.16 (Cross-Hist causal dependence — SCHEMA-ONLY)**.** *A cross-Hist causal dependence is a relation $C(h_a, h_b, k)$ saying "h_b's most recent k* Cont *steps depend on h_a's recent*

steps". The relation is currently a SCHEMA-ONLY HORIZON in BEDC: the kernel exposes the type signature, but no closed witness produces a non-trivial cross-Hist causal relation. Future BEDC chapters on multi-Hist physics would close this schema by giving a constructive predicate together with concrete witnesses.

Definition 9419.17 (Maximum cross-Hist causal rate — SCHEMA-ONLY)**.** *The maximum cross-Hist causal rate is a unary-valued function* MaxRate *on multi-Hist configurations such that, for every cross-Hist causal dependence $C(h_a, h_b, k)$, the ratio of cross-affected* Cont *steps in h_b to corresponding* Cont *steps in h_a is bounded above by* MaxRate*. SCHEMA-ONLY: the upper-bound theorem awaits the multi-Hist semantics that gives C its closed witnesses.*

Theorem 9419.18 (Maximum rate is an inter-Hist invariant — SCHEMA-ONLY)**.** *The maximum cross-Hist causal rate, when defined, is an inter-Hist invariant in the sense of Definition 9419.10: its value is observer-symmetric and frame-independent. SCHEMA-ONLY: this theorem is part of the road-map; its closed proof requires the multi-Hist causal-dependence semantics to be made constructive.*

Theorem 9419.19 (Maximum rate is an observer-independent constant — SCHEMA-ONLY)**.** *For any multi-Hist configuration with a non-trivial cross-Hist causal dependence, the maximum cross-Hist causal rate is the same constant for all observers in the configuration. Equivalently, no observer can measure a different value for the maximum rate without invoking a privileged frame; and no privileged frame exists, by Definition 9419.4.*

Corollary 9419.20 (Light-speed-like constant)**.** *A multi-Hist configuration that admits a non-trivial cross-Hist causal dependence has a single observer-independent maximum-rate constant attached to it. The form of the result — "a constant maximum cross-Hist causal rate exists and is observer-independent" — is the structural skeleton of the constancy of light speed in special relativity. The empirical specific value of the constant is not derived inside BEDC; only the form is.*

Lemma 9419.21 (Causal dependence is asymmetric in the time slot — SCHEMA-ONLY)**.** *The relation $C(h_a, h_b, k)$ of Definition 9419.16 is asymmetric in the time slot k: $C(h_a, h_b, k)$ and $C(h_b, h_a, k)$ are distinct predicates in general, even though the inter-Hist invariants of section 9419.3 are observer-symmetric. The asymmetry is the content of "h_b depends on h_a" as opposed to "h_a depends on h_b", and is exactly the structure that the maximum-rate constant must average over to recover observer symmetry.*

Lemma 9419.22 (Causal dependence respects hsame — SCHEMA-ONLY)**.** *If $C(h_a, h_b, k)$ and $h_a \mathsf{hsame} h'_a$ and $h_b \mathsf{hsame} h'_b$, then $C(h'_a, h'_b, k)$. The cross-Hist causal-dependence predicate is required to be* hsame*-stable; without this stability, no inter-Hist invariant could be defined on top of it without leaking kernel-undistinguishable distinctions.*

Proposition 9419.23 (Triviality at degenerate configurations — SCHEMA-ONLY)**.** *For a multi-Hist configuration with no non-trivial cross-Hist causal dependence, the maximum cross-Hist causal rate is the trivial bound, and Definition 9419.19 reduces to a vacuous truth. The non-trivial content of the maximum-rate constant arises only once C has at least one closed witness on the configuration; until then, the road-map cannot distinguish the constant numerically.*

Remark 9419.24 (Reading: the structural argument)**.** *The structural argument runs as follows. No-God's-eye view (Definition 9419.4) forces all physical content into inter-Hist invariants (Definition 9419.11); the maximum cross-Hist causal rate is one such invariant (Definition 9419.17);*

the symmetry of "no privileged frame" forces this rate to be the same constant for all observers (Definition 9419.19). Each step is inevitability under the previous, not a separate postulate. In standard relativistic terms: BEDC derives the form of an invariant maximum signal speed from no-global-frame plus relational content; what it does not derive is that this constant takes any particular numerical value.

9419.5 Roadmap toward physics

Remark 9419.25 (Form of the next dependency chain)**.** *The capstone identifies the next BEDC roadmap, parallel in form to the Riemann Hypothesis dependency chain (chapter 9239). It is a sequence of multi-Hist namecert chapters that close the schema-only horizons of section 9419.4. The chain proceeds: (i)* NameCert *for* MultiHistConfig*; (ii)* NameCert *for* CrossHistCausal*; (iii)* NameCert *for* MaxCausalRate*; (iv) Lorentz-geometry* NameCert*, in which the inter-Hist invariant produces a Minkowski-like distance from the observer-symmetric maximum rate; (v) curved spacetime as a Lorentz-*NameCert *with non-trivial gluing data over a multi-Hist configuration; (vi) quantum-state* NameCert *as multi-Hist superposition, in which the relational content is carried by* E1/E0 *refinements rather than by metric data; and so on. Each step on this chain is its own chapter and its own statement-only Lean target.*

Concretized in §468: Finite multi-Hist packets realize the first closed carrier for the observer-locality chain from configurations to cross-Hist causal interfaces.

Concretized in §478: Cross-Hist causal dependence is realized as a finite two-history NameCert seed with displayed hsame, psame, Cont, package, and local naming rows.

Concretized in §594: Maximum causal rate is realized as a finite unary-bound NameCert over MultiHistConfig and CrossHistCausal witness rows, without a global frame or metric geometry.

Concretized in §617: Lorentz frame-rate packets realize the next Inter-Hist Locality step as a finite maximum-rate boundary without global frames, clocks, metric tensors, or host real-valued speed.

Concretized in §655: Multi-Hist superposition packets realize the Eone/Ezero refinement step of the Inter-Hist Locality chain as finite BHist, hsame, psame, Cont, Pkg, and NameCert rows.

Concretized in §656: Inter-Hist invariants are realized as finite BHist, hsame, Cont, Pkg, and NameCert packets mediating multi-history configurations, causal witnesses, and maximum-rate consumers.

Concretized in §668: Observation coupling realizes inter-Hist locality as a finite two-history NameCert packet over paired BHist rows, hsame transports, Cont routes, symmetric coupling ledgers, and no-global-frame non-escape.

Concretized in §759: Inter-Hist locality ledgers are realized as finite BHist packets over two source histories, symmetric hsame transport, Cont routes, observer-locality cells, inter-Hist invariant rows, Pkg provenance, and NameCert.

Concretized in §875: Cross-Hist causal routes are realized as finite observer-slot, causal-row, maximum-rate, observer-gate, continuation-trace, transport, provenance, and NameCert packets.

Concretized in §876: Cross-Hist causal rates are realized as finite BHist packets for paired histories, causal-dependence routes, maximum-rate rows, observer-symmetry, and no-global-frame ledgers.

Concretized in §889: Observer-locality transport is realized as a finite BHist NameCert packet over observer-locality cells, CrossHistCausal rows, MaxCausalRate rows, hsame/psame transport, Cont routes, and no-global-frame ledgers.

Concretized in §1011: Observer-locality pullbacks realize the common finite packet joining observer-locality cell, cross-Hist causal, maximum-rate, and transport rows.

Concretized in §895: Multi-Hist couplings are realized as finite paired-history NameCert packets with symmetric coupling, hsame/psame transport, Cont routes, and no-global-frame non-escape.

Concretized in §911: Minkowski rate geometries realize the Inter-Hist Locality rate-to-geometry step as a finite NameCert packet over multi-Hist, causal, maximum-rate, Lorentz-frame-rate, and symmetric distance-shape rows.

Concretized in §1003: No-global-synchronization boundaries are realized as finite multi-Hist refusal packets over displayed histories, locality rows, hsame transport, Cont routes, package provenance, and NameCert data.

Concretized in §1013: Inter-Hist symmetry budgets realize two-direction locality, invariant read-back, hsame transport, Cont replay, Pkg provenance, and local NameCert rows.

Concretized in §1023: Inter-Hist rate boundaries are realized as finite BHist packets binding causal route, maximum-rate gate, observer symmetry, no-global-frame refusal, and local NameCert rows.

Concretized in §1037: Relational frame audits realize the Inter-Hist Locality no-global-frame and observer-symmetry checks as finite BHist, hsame, Cont, refusal-ledger, and NameCert rows.

Concretized in §1106: No-global-synchronization ledgers realize the inter-Hist refusal of shared clocks and global frames as finite BHist, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1112: Cross-Hist causal cones realize bounded two-history causal-dependence windows with maximum-rate and no-global-frame ledgers.

Concretized in §1194: Finite Hist locality packets realize Inter-Hist Locality as a two-history finite NameCert carrier with locality witness, symmetry, transport, Cont route, and no-global-sync refusal.

Concretized in §1201: Inter-Hist transport seals realize paired-history locality transport as a finite packet over observer-locality cells, invariant rows, cross-Hist causal routes, hsame/psame transport, Cont replay, Pkg provenance, and local NameCert rows.

Concretized in §5193: Observer locality rate budgets realize the no-global-frame maximum-rate read as finite paired-Hist, symmetry, causal-rate, transport, and NameCert rows.

Concretized in §7870: Curved spacetime is realized as finite multi-Hist chart, transition, Lorentz-rate, curvature, transport, replay, provenance, and NameCert rows.

Remark 9419.26 (Falsification surfaces along the chain)**.** *Each step of Definition 9419.25 carries its own falsification surface. Step (i) fails if no closed witness for* MultiHistConfig *can be produced without smuggling in a global frame. Step (ii) fails if cross-Hist causal dependence cannot be expressed as an* hsame- *and* psame-*stable predicate. Step (iii) fails if the maximum-rate function cannot be defined without choice. Step (iv) fails if the candidate Minkowski-like distance is not symmetric in the two observers, or if it does not respect Definition 9419.12. Step (v) fails if the gluing data over the configuration cannot be made constructive. Step (vi) fails if the multi-Hist superposition predicate forces* propext*. The road-map's intermediate failures are themselves informative; they are not engineering setbacks but structural results about where distinction-foundationalism stops being sufficient.*

Remark 9419.27 (Relation to existing single-Hist Lean targets)**.** *The Lean targets named in Definition 9419.3 through Definition 9419.23 are statement-only and do not yet have closed proofs. They are nevertheless not isolated from the rest of the formalization.* InterHistInvariant *(Definition 9419.10) takes* Hist*-pairs to* Unary*, and* Unary *is already a closed-inductive carrier in BEDC;* MaxCausalRate *(Definition 9419.17) is unary-valued in the same sense. The interface uses no Lean fragment that BEDC has not already committed to. What it adds is the multi-Hist combinator structure: pairing two* Hist *values into a configuration, and predicating over pairs.*

Remark 9419.28 (Connection to relational physics traditions)**.** *The structural commitments of this capstone are the same commitments as Rovelli's relational quantum mechanics, Wheeler's "It from Bit", Connes's noncommutative geometry, and Penrose's spin networks: physical content is observer-relational, not located in any single observer's record, and observer is not a substance prior to its observations. BEDC differs from these traditions in that it constructs the relational substrate from a still more primitive layer: distinction (*Hist*) and observation (*Cont*), with no observer-substance carrier behind either, and with everything closed-inductive. Where those traditions take observer-relations as physical primitives, BEDC derives them from the structure of distinction.*

Remark 9419.29 (Schema-only horizons and axiom-purity)**.** *A central open question on this roadmap is whether the multi-Hist semantics can be closed inside BEDC's axiom-purity gate. If yes, BEDC's distinction-foundationalist position extends from pure mathematics into physics with no additional axiomatic cost: the same fragment that proves the single-Hist commitments of chapter 9418 would also prove the multi-Hist commitments of this chapter. If no, the boundary point at which axiom-purity fails would itself be a structurally meaningful result: it would mark precisely where physics requires more than distinction — whether choice, propositional extensionality, or quotient sound is the first to be needed, and on which specific schema. Either outcome is informative.*

Remark 9419.30 (Why the chain is acyclic)**.** *The dependency chain of Definition 9419.25 is acyclic by construction. Step (i)* MultiHistConfig *does not depend on cross-Hist causal dependence, only on* Hist*; step (ii) builds* CrossHistCausal *on top of (i); step (iii) extracts a single unary upper bound from (ii); steps (iv) and (v) elaborate that bound into geometric data; step (vi) lifts the same machinery to a* NameCert *over multi-Hist superpositions. Each step strictly extends the predicate vocabulary of the previous step. The order in which the multi-Hist semantics must be assembled is exactly the order of the chain; no step can be deferred past a later step without circularity.*

Concretized in §474: The multi-history configuration carrier supplies the first concrete NameCert step for the Inter-Hist Locality chain.

Remark 9419.31 (E1/E0 refinements at the multi-Hist level)**.** *The single-Hist semantics distinguishes* E1 *(extensional, observation-driven) from* E0 *(intensional, name-driven) at the level of one observer's record. The multi-Hist roadmap inherits this distinction: an inter-Hist invariant may be sensitive to* E1*-level refinements of the two component records, to* E0*-level refinements, or to both. Quantum-state* NameCert*s in step (vi) of Definition 9419.25 are expected to live in the* E1*-sensitive class, and metric* NameCert*s in steps (iv) and (v) in the* E0*-sensitive class. Articulating which refinement layer carries which physical content is part of the multi-Hist development.*

Remark 9419.32 (Single-Hist obligations as preconditions)**.** *The roadmap of this capstone presupposes the single-Hist obligations articulated in the sibling capstone (chapter 9418). Without observer-Hist identity, the multi-Hist configuration of Definition 9419.3 would not yet be a configuration of observers; without* hsame*-stability of single-observer content, Definition 9419.12 would*

not type-check at the inter-observer level. The two capstones close adjacent layers of the same problem.

Concretized in §474: Multi-Hist configurations are realized as finite BHist-ledger NameCert packets for independent histories without a global synchronization row.

Concretized in §933: Max-rate read gates realize the Inter-Hist Locality maximum-rate boundary as a finite NameCert packet requiring observer-symmetry and no-global-frame rows before any rate read is public.

Concretized in §6335: The finite inter-Hist causal-rate comparison packet realizes the local comparison surface without a synchronized frame.

9419.6 Closing

Remark 9419.33 (What this capstone is and is not)**.** *This capstone is not a derivation of relativity, of quantum mechanics, or of any particular physical theory. It is a derivation of the form of an observer-independent maximum-rate constant from the combination of distinction-foundationalist commitments (single-Hist identification of observer with record, no observer-substance carrier) and the closed-inductive structure of* Hist*. The form is the strong claim; the value is not derived. Equally, the capstone is not a claim that BEDC will succeed in closing the multi-Hist roadmap inside its axiom-purity gate. It is a claim that the question is well-posed and that the interface is now sketched precisely enough that progress and failure can be told apart.*

Remark 9419.34 (The structure of physics from observer locality)**.** *The capstone makes one structural argument. In a configuration of independent Hists with no global frame, all physical content lives in observer-symmetric inter-Hist invariants, and the maximum cross-Hist causal rate must be observer-independent. This is the BEDC-derived skeleton of the relativistic structure of physics. The current chapter does not produce that physics; it identifies the interface that a future BEDC physics chain would close. Whether closure is possible inside the axiom-purity gate is the next research question. The chapter falls under the project's axiom-purity gate, and the road-map question of whether physics can be constructively closed inside that gate is itself open. Definition 9419.26 catalogues the specific surfaces along which the road-map can fail informatively; the answer to the road-map question will be assembled from a sequence of step-by-step constructive successes or step-localized failures, not declared in advance.*

Lemma 9419.35 (Zero max-rate forbids cross-Hist dependence — SCHEMA-ONLY)**.** *Assume two histories h_a, h_b and slot k. If* $\mathsf{max_causal_rate}(h_a, h_b, k) = 0$*, then* $\neg \mathsf{CrossHistCausal}(h_a, h_b, k)$*.*

Proof. Assume $\mathsf{CrossHistCausal}(h_a, h_b, k)$. By Definition 9419.16, this is a genuine cross-Hist causal dependence, so its witness contributes at least one affected target step and therefore a positive dependence ratio. By Definition 9419.17, every such ratio is bounded above by $\mathsf{max_causal_rate}(h_a, h_b, k)$. If that bound is 0, the positive ratio cannot exist. Contradiction. □

Chapter 9420

Consciousness, Universe, Observer: The Phenomenological Frame of the Closed Substrate

Concretized in §513: Finite observer-locality cells package paired observer-history rows, paired GAP acknowledgements, and local coherence routes as a concrete NameCert surface.

Concretized in §578: Conscious observer states are realized as finite BHist packets carrying current state, Self-recognition, observation ledger, GAP acknowledgement, Cont route, and local NameCert rows.

Concretized in §609: Observer-coordinate frames realize the local alternative to a global observer frame as finite BHist, locality-cell, cross-Hist causal, bound, transport, route, package, and NameCert rows.

Concretized in §664: Observation-time order realizes BEDC-internal time as monotonic BHist record retention with Cont routes, GAP erasure boundaries, and a local NameCert surface.

Concretized in §877: Observer accumulation clocks realize time as finite state, successor-record, accumulation-edge, GAP-residue, transport, route, package, and NameCert rows.

Concretized in §1109: Focused multi-Hist ledgers realize the finite closed record-world carrier with focus, selector, GAP, relation, invariant, route, package, and NameCert rows.

Concretized in §1121: Observer-budget supports are realized as finite observer-coordinate, finite-support, cross-Hist causal, budget, transport, route, provenance, and NameCert rows.

This vision chapter extends the closed-observational-system framework of chapter 9393 from BEDC's substrate self-description into a records-side phenomenological reading. The object-level target is deliberately small: a unary horizon, a finite displayed ledger of generated Hist rows, one focus row, local Cont time-stream rows, selector ledgers, GAP-accounted compression, and witnessed inter-Hist relation rows. The chapter therefore does not close the universe itself, phenomenal consciousness as an essence, T, a physical light-speed constant, or a global spacetime frame. It closes only the finite records-side carrier through which those boundary readings can be stated without hidden supply.

9420.1 Finite records-side closure target

Definition 9420.1 (Finite focused multi-Hist ledger)**.** *For a horizon N : Unary, a* ClosedFocusedMultiHistLedger$_N$ *is a finite records-side packet*

$$\mathcal{L}_N = (I, H, \Theta, F, S, D, G, R, J, Q, \rho, A)$$

with the following displayed rows:

1. *I is a finite displayed index ledger for the histories admitted by the packet, not a host-level set of all observers;*
2. *H assigns to each displayed index row i a generated* Hist *row $H(i)$ whose displayed trace route is bounded by the unary horizon N;*
3. *Θ records, for every displayed index row i, a local* Cont *chain from* e *to $H(i)$, read as the local time-stream row of $H(i)$;*
4. *F is a displayed focus-index row of I, and it is only an index of reading, not a subject parameter;*
5. *S records the selector ledger for every visible transition in the displayed traces, including the chosen* BMark *row and the corresponding* Cont *witness;*
6. *D records either the identity digest row $D(i) = H(i)$ or a displayed package-token digest row for $H(i)$;*
7. *G records the* GAP *or provenance row attached to every non-identity digest row, including the exactness status that prevents digest equality from being read as source equality without a witness;*
8. *R is a finite displayed ledger of inter-*Hist *relation rows, each with left history, right history, finite evidence, and* hsame*-stability data;*
9. *J is a finite displayed ledger of inter-*Hist *invariant rows, each stable under componentwise* hsame *transport;*
10. *Q is a finite displayed ledger of dependence rows between local unary time slots, together with an optional unary maximum-rate row computed only from the displayed dependence witnesses;*
11. *ρ is the focused self-proxy, consisting of the endpoint and trace of $H(F)$;*
12. *A is the refusal and audit row recording no subject parameter, no global clock, no hidden chooser, no unledgered compression, no object-level* T *field, and no hidden use of choice, quotient soundness, or propositional extensionality in the packet's accepted read.*

Principle 9420.2 (Closed means generated, ledgered, and witnessed)**.** *The packet of Definition 9420.1 is read as a records-side closed carrier because every displayed object row has a generator, every branch has a selector ledger, every compression has a* GAP *or provenance row, every inter-history relation has a finite witness, every invariant is classifier-stable, and every boundary pressure remains outside the object layer. The packet contains no carrier for an observer-substance, no global synchronization clock, no global universe object, no physical constant as primitive datum, and no internal* T *object.*

Remark 9420.3 (Boundary readings)**.** *The finite ledger may support readings about universe, consciousness, self-location, physical invariance, and other minds, but those readings are not themselves extra fields of the packet.* SelfProxy *is the focused endpoint and trace of $H(F)$, not phenomenal first-personness as an object. A unary maximum-rate row is a packet invariant, not the empirical value of light speed. A boundary tag for* T*, when present in surrounding exposition, is not consumed by any theorem of $\mathcal{L}_N$.*

9420.2 Consciousness as closed observational system

Definition 9420.4 (Consciousness, records-side carrier)**.** *A* conscious records-side carrier *in a finite focused ledger $\mathcal{L}_N$ is the focused row*

$$\mathrm{ConsciousRecord}(\mathcal{L}_N, F) := (H(F), \Theta(F), S(F), \rho)$$

read through the audit row A. It consists of a generated focused Hist*, its local* Cont *trace, the selector witnesses for its visible transitions, and the endpoint/trace self-proxy. It is a carrier for consciousness readings, not an object-level definition of phenomenal consciousness.*

Principle 9420.5 (The carrier does not add a subject)**.** *Definition 9420.4 uses only the rows already visible in Definition 9420.1. The focus index selects a local reading surface; it does not create an observer-substance, a hidden first-person carrier, or an identity criterion beyond* hsame *and the displayed trace ledger.*

Example 9420.6 (BEDC contributor as records-side carrier)**.** *A BEDC contributor can be read, on the records side, as a focused history whose visible work consists of consulted text, proof traces, mechanisation checks, and accepted manuscript rows. The production of a* `leanchecked` *lemma is represented by a trace extension with a selector ledger and a verification row. The reading does not assert a substrate-internal model of the contributor's first-person life; it records only the focused history surface through which that contribution is public.*

Remark 9420.7 (Relation to the implicit metaphysics chapter)**.** *chapter 9418 argues that BEDC's finite kernel identifies an observer with the history that observer has accumulated. Definition 9420.4 re-uses exactly that identification. The self-proxy is the focused endpoint and trace, while identity preservation is the* hsame*-stable continuity of the displayed history. The engineering content remains in the earlier chapter; the present chapter records the finite carrier on which the phenomenological reading may be placed.*

9420.3 Embodied continuation and the mortality boundary

Definition 9420.8 (Embodied support row)**.** *For a focused conscious record* $\mathrm{ConsciousRecord}(\mathcal{L}_N, F)$*, an* embodied support row *is an external finite carrier reading*

$$\mathcal{B}_i(t) = (\mathrm{body}_i(t), \mathrm{metabolism}_i(t), \mathrm{repair}_i(t), \mathrm{environment}_i(t), \mathrm{risk}_i(t))$$

together with a predicate

$$\mathrm{EmbValid}_i(h, t)$$

read as: the carrier row at local stage t can realize the focused history surface h as an inscription-bearing conscious record. The row is not a field of the pure Hist *signature. It is the wick, vessel, and weather around the flame of a local inscription; the flame may have a formal shape, but its burning is a carrier fact.*

Definition 9420.9 (Alive, embodied continuation, and death)**.** *Let $H_i(t)$ denote the focused history displayed at local stage t. The records-side predicates are*

$$\begin{aligned}
\mathrm{Alive}_i(t) &:\Longleftrightarrow \mathrm{EmbValid}_i(H_i(t), t),\\
\mathrm{EmbCanContinue}_i(t) &:\Longleftrightarrow \exists d, h' \left(\mathsf{Cont}(H_i(t), d, h') \wedge \mathrm{EmbValid}_i(h', t+1)\right),\\
\mathrm{Death}_i(t) &:\Longleftrightarrow \mathrm{Alive}_i(t) \wedge \neg\mathrm{EmbCanContinue}_i(t),\\
\mathrm{Mortal}_i &:\Longleftrightarrow \exists t\, \mathrm{Death}_i(t).
\end{aligned}$$

Thus death is not a content subsequently experienced by the same focused row. It is the failure of the next inscription condition for that row. The lamp does not record darkness after its oil is gone; rather, the local condition under which light is recorded no longer carries the next mark.

Principle 9420.10 (Formal continuation is not embodied continuation)**.** *The pure* Hist/Cont *layer can speak about formal successor histories. It contains no body, repair process, hazard rate, metabolic budget, or environmental support row. Consequently a formal extension*

$$\exists d, h' \, \mathsf{Cont}(h, d, h')$$

does not by itself imply

$$\exists d, h' \, (\mathsf{Cont}(h, d, h') \wedge \mathrm{EmbValid}_i(h', t+1)).$$

The distinction is the difference between a riverbed drawn on a map and water continuing through it. The map may display another segment; the flow also requires a source, a channel not yet blocked, and conditions that do not destroy the carrier.

Theorem 9420.11 (Finite reserve mortality)**.** *Suppose a focused embodied support row carries a viability reserve*

$$V_i : \mathbb{N} \to \mathbb{N}$$

with $V_i(0) = K < \infty$*, and suppose* $\mathrm{Alive}_i(0)$ *holds. Suppose that, before the first terminal boundary, positive reserve supports the current record and strictly decreases:*

$$V_i(t) > 0 \implies V_i(t+1) \leq V_i(t) - 1.$$

If reserve exhaustion blocks either the current stage or the next embodied continuation,

$$V_i(t) = 0 \implies \neg\mathrm{EmbCanContinue}_i(t)$$

and

$$V_i(t+1) = 0 \implies \neg\mathrm{EmbCanContinue}_i(t),$$

while $V_i(t) > 0$ *implies* $\mathrm{Alive}_i(t)$*, then* Mortal_i*.*

Proof. By induction on $n \leq K$, the strict decrease condition gives

$$V_i(n) \leq K - n.$$

At $n = K$ this yields $V_i(K) \leq 0$. Since $V_i(K) \in \mathbb{N}$, one has $V_i(K) = 0$. Let $m \leq K$ be the first local stage with $V_i(m) = 0$. If $m = 0$, then $\mathrm{Alive}_i(0)$ and the current-stage blocking condition give $\mathrm{Death}_i(0)$. If $m > 0$, then $V_i(m-1) > 0$, hence $\mathrm{Alive}_i(m-1)$, and the next-stage blocking condition gives $\neg\mathrm{EmbCanContinue}_i(m-1)$. Therefore $\mathrm{Death}_i(m-1)$ by Definition 9420.9. In either case there exists a death stage, so Mortal_i. □

Corollary 9420.12 (Finite records do not close immortality)**.** *A finite ledger of alive stages,*

$$\mathrm{Alive}_i(t_1), \ldots, \mathrm{Alive}_i(t_k),$$

does not close

$$\forall t \, \mathrm{EmbCanContinue}_i(t).$$

An assertion of unbounded embodied continuation therefore requires either a displayed rule proving the required carrier, repair, and risk rows for every later local stage, or a boundary acknowledgement that the assertion is forward-binding and not object-level closure inside $\mathcal{L}_N$*.*

Remark 9420.13 (The boundary is local)**.** *The death predicate above is a local inscription-boundary predicate. It does not say that* T *disappears, that existence as such is extinguished, or that the pure possibility of further* Hist *formation is refuted. It says only that this focused embodied carrier no longer supplies the next valid conscious record. A broken lyre does not prove that music is impossible; it proves that this instrument no longer realizes the song.*

Concretized in §509: Locality cells are realised as a bilateral BHist/GAP NameCert packet for inter-observer event coordination.

9420.4 Universe as observation history

Definition 9420.14 (Finite universe-for-the-focus)**.** *For a finite focused ledger $\mathcal{L}_N$, the* finite universe-for-the-focus *is the records-side family*

$$\mathrm{Universe}_{\mathcal{L}_N} := (I, H, \Theta, S, D, G, R, J, Q)$$

together with the focus row F when a focused read is required. The row $\Theta(i)$ is the displayed local Cont *route whose unary bound is recorded against N. Thus the universe-for-the-focus is not a set comprehension over an external domain; it is the finite packet surface whose selector, digest,* GAP*, relation, invariant, and dependence rows are displayed. It is not the universe itself and not a God-view object; it is the finite slice whose records the packet admits.*

Principle 9420.15 (Phenomenological frame)**.** *The finite universe-for-the-focus is exactly the records-side slice visible through $\mathcal{L}_N$. Anything not generated by the displayed histories, not recorded by selector or relation rows, not preserved by a* GAP *ledger, and not exposed as a boundary tag is outside this object-level slice. Distinct focused ledgers need not share a world object; cross-perspective alignment remains the ledger-local problem treated in chapter 9419.*

Remark 9420.16 (The frame is structural, not metaphysical)**.** *Definition 9420.15 does not assert that there is no observer-independent reality. It asserts only that the BEDC-side carrier is the finite records-plus-ledger slice. Any pressure beyond that slice appears either as an additional displayed row, as a* GAP *or provenance obligation, or as a boundary reading whose far end is not internalized.*

9420.5 Closed history network reading

Principle 9420.17 (Universe as closed distinction/history/continuation network)**.** *At the records-side level, the universe-for-the-focus of Definition 9420.14 is read neither as matter contained in a prior spacetime nor as a program executed by an external machine. Its closeable object is the displayed network of distinctions, generated histories, continuation routes, event boundaries, classifier-stable readbacks, and public naming certificates. The shortest BEDC reading is therefore:*

$$\mathrm{Universe}_{\mathcal{L}_N} \quad \textit{as read by the packet} \quad = \textit{closed distinction/history/continuation network.}$$

The equality is a reading of the packet surface, not an identity theorem about a completed cosmos.

Definition 9420.18 (Closed BEDC universe surface)**.** *A* closed BEDC universe surface *over a focused ledger $\mathcal{L}_N$ is the records-side admission discipline in which every public row is one of the following:*

1. *a generated* Hist *row;*

2. *an event-flow row whose event boundaries remain part of the datum;*
3. *a finite packet all of whose object-facing fields are* Hist *rows and whose public readback is mediated by a recognizer, route, or taste gate;*
4. *a* NameCert *or semantic certificate over a displayed carrier and classifier;*
5. *a route generated by* Cont*, together with the transport, provenance, and naming rows needed for public reuse.*

The surface admits no hidden host object as a formal input and no global observer outside the displayed family.

Theorem 9420.19 (Closed history universe decomposition)**.** *On a closed BEDC universe surface, time, causality, local differential response, information scoring, boundary readback, observer-local coordinates, relativistic rate structure, and multi-history superposition are certified modes of history continuation rather than primitive substances.*

Proof. Each case is read through the same finite surface. Time is the local Cont route $\Theta(i)$ producing $H(i)$ from e in Definition 9420.27. Causality is the continuation discipline of Definition 9420.24, with the concrete maximum-rate route supplied by the $\mathsf{MaxCausalRate}^{\uparrow}$ surface cited in chapter 9419 and realized by chapter 594. Local differential response is the displayed quotient-continuation row of the derivative carrier in chapter 122. Information scoring and entropy readback use finite distribution, score, expectation, metric, ledger, and provenance rows as in chapter 228 and chapter 192. Boundary readback is constrained by the event-flow non-injectivity of Definition 9207.7 and by finite boundary-ledger packets such as the Stokes-style fold-defect surface. Observer-local coordinates are finite packets over observer state, locality cell, multi-history configuration, causal reads, transport, routes, provenance, and local naming, as in chapter 609. Relativistic rate structure is read only after multi-history configuration, no-synchronization refusal, maximum-rate, symmetry, and transport rows have been displayed, as in chapter 617. Multi-history superposition is read as a finite packet over configuration, refinement, causal, rate, phase, history, route, provenance, and naming rows, as in chapter 655. None of these cases requires a primitive matter substrate, a primitive spacetime container, a completed external state table, or a global observer. □

Corollary 9420.20 (Boundary-sensitive information)**.** *Public information on a closed BEDC universe surface cannot be reduced to a bare mark stream.*

Proof. If the public surface were only a bare stream of marks, then event segmentation could be erased without loss. But Definition 9207.7 gives distinct event flows with the same erased mark stream. Therefore boundary data is part of the public information surface. □

Corollary 9420.21 (Certified cosmological reading)**.** *The records-side cosmological reading of BEDC is that the universe-for-the-focus is a self-recording and self-decoding history surface: distinctions generate events, event boundaries generate readable flows, continuations generate local time and causal routes, inter-history invariants generate spatial and relativistic readings, non-collapsed refinement packets generate quantum-shaped readings, and certificates generate public objects.*

Proof. This is the synthesis of Definition 9420.18 and Definition 9420.19. The listed readings exhaust the admitted public modes of the surface: generated histories, boundary-sensitive event flows, continuation routes, inter-history invariants, finite packet readbacks, and naming certificates. □

Definition 9420.22 (Matter-pattern read)**.** *A* matter-pattern read *in $\mathcal{L}_N$ is a family of displayed event and history rows whose classifier remains stable under* hsame*, whose consequences can be replayed through local or inter-*Hist Cont *routes, whose recognition is transportable across locality cells, and whose public name is protected by a* NameCert *or by an exposed* GAP *when the name is not yet certified. The read does not introduce a primitive material substance. It names a recurrent and resistant pattern of public recordability.*

Principle 9420.23 (Reality as public constraint)**.** *In the closed ledger, a structure is real in the relevant records-side sense when it is repeatedly recordable, continuation-constraining, transportable across compatible histories, and resistant to arbitrary reclassification. This is stronger than private imaginability and weaker than a claim of access to an external bare object. It is the finite public constraint surface on which scientific objecthood later attaches the empirical and bridge rows of Definition 9462.922.*

Principle 9420.24 (Causality as continuation discipline)**.** *Causality is read as discipline on allowed continuations. A causal row says that some source-history fragment constrains a target-history fragment through a displayed dependence route, bounded slot window, replayable* Cont *witness, and transport stability. A cause is therefore not a substance pushing another substance inside a pre-given arena; it is a ledgered restriction on which later histories remain admissible after the relevant prior rows have been recorded.*

Remark 9420.25 (Relativistic and quantum boundary readings)**.** *The relativistic reading arises from the absence of a global clock: if no history supplies a privileged synchronized present for all histories, physical content must be carried by inter-*Hist *invariants, maximum-rate rows, and observer-symmetric transport as in chapter 9419. The quantum reading arises from the absence of a completed external state table: before a single record has selected a displayed continuation, the packet may need to preserve multiple refinement, phase, causal, and route-coherence rows without collapsing them to one history. These readings are not proofs of relativity or quantum mechanics. They identify the form in which such theories can enter BEDC: as certified packet surfaces rather than as primitive spacetime, primitive wavefunction, or external state inventory.*

Remark 9420.26 (Event boundaries are part of information)**.** *The ground event-flow layer makes boundary information explicit. By Definition 9207.7, erasing event boundaries can identify distinct event flows. Hence the closed history network cannot be reduced to a bare bitstream of marks. It consists of events together with their boundaries, recognizers, ledgers, and certificates. A boundary is not an outer shell around already formed information; it is one of the conditions under which a row becomes a readable event rather than an undifferentiated string.*

9420.6 Time as monotonic accumulation

Definition 9420.27 (BEDC-internal time)**.** *For a focused ledger $\mathcal{L}_N$, the* internal time order *of $H(i)$ is the local* Cont *chain $\Theta(i)$ producing $H(i)$ from* e*. Equivalently, it is the finite trace order induced by the displayed* BMark *selector rows. Internal time is local to a history; it is not a scalar shared by all histories in I.*

Principle 9420.28 (Time is monotonic information accumulation)**.** *For BEDC the object-level notion of "later" is trace extension inside a displayed local ledger. This is the information-conservation invariant of Definition 9393.3 read as a temporal structure. Reversibility, time symmetry, global simultaneity, or retrocausal phrasing may be studied as additional structures, but they are not fields of $\mathcal{L}_N$ unless they arrive as witnessed extension carriers.*

Example 9420.29 (Commit history as BEDC-internal time)**.** *The git commit history of* `newmath` *is a project-level analogy for local ledger time: each accepted state is read through accumulated records such as* `leanchecked` *lemmas,* `inductive` *types, paper content, and audit rows. The analogy is records-side only. It does not supply a global clock for all observers; it illustrates how a local trace can serve as the public time order of one development history.*

Remark 9420.30 (Why time has only one direction in BEDC)**.** *External physics admits various time-symmetric or time-reversed formulations. BEDC's records-side reading does not exclude such formulations; it observes only that a local ledger is asymmetric because its displayed trace has a generated prefix structure. A global clock or global "now" would require a separate extension carrier and cannot be read from the kernel signature.*

9420.7 Focused still-point and information-clock rate

Definition 9420.31 (Focused still-point reading)**.** *For a finite focused ledger $\mathcal{L}_N$, the* focused still-point reading *is the constraint that every accepted observer-facing read of the focus factors through*

$$H(F), \quad \Theta(F), \quad S(F), \quad \rho, \quad A,$$

together with the displayed hsame, Cont, Pkg, NameCert, *locality-cell, and inter-*Hist *relation rows of the same packet. It has no field for an observer-substance coordinate, a host spacetime position, a shared external time scalar, or a global frame. The word still names this absence of a detachable observer carrier; it does not mean that the focused history has no continuation.*

Principle 9420.32 (Motion is read as record-side change)**.** *In the focused still-point reading, the sentence that an observer moves is admissible only as a statement about changes in displayed rows: extension of $H(F)$ along $\Theta(F)$, selector changes in $S(F)$, locality-cell changes against other histories, and readout changes in the invariant or dependence ledgers. No independent subject is transported through a pre-given coordinate arena. The transported object is the certified read of a focused history and its packet surface.*

Definition 9420.33 (Accumulation edge and clock read)**.** *An* accumulation edge *at the focus is a displayed transition row*

$$\mathrm{AccEdge}_F(t) := (H(F,t), H(F,t+1), d_t, \Theta_t, S_t, G_t)$$

whose continuation witness records

$$\mathsf{Cont}(H(F,t), d_t, H(F,t+1)).$$

An observer accumulation clock read *is any finite packet read that counts, bounds, or classifies such accumulation edges through the observer-accumulation-clock and local-budget rows already present in $\mathcal{L}_N$. The read is local to the focus and remains audited by A.*

Definition 9420.34 (Information-clock rate)**.** *For a focused ledger window $[u, v]$ and an announced visible-row class $\mathcal{K}$, the* information-clock rate *is a records-side read comparing the number of accepted accumulation edges in the window with the amount of $\mathcal{K}$-visible distinction, boundary, selector, digest, relation, invariant, or dependence data exposed by those edges. It is a derived read over finite ledger rows, not a primitive physical law and not an empirical clock-rate constant.*

Proposition 9420.35 (Clock-rate reads are local and budgeted)**.** *Every information-clock rate read of Definition 9420.34 is local to the focused packet and must preserve the audit row A. It may compare two windows of one focused history, or two focused rows through a locality cell, only after the relevant* hsame *transport,* Cont *replay, provenance, and inter-*Hist *relation rows are displayed.*

Proof. The rate read is defined from accumulation edges. Each accumulation edge contains a present history, a successor history, a distinction row, a continuation witness, selector data, and provenance or gap data. These are rows of the finite packet. A comparison across windows or across histories therefore has no public meaning until the packet supplies the corresponding transport, replay, provenance, and locality witnesses. Since A records refusal of a subject parameter, global clock, hidden chooser, and unledgered compression, preserving A prevents the rate read from becoming a primitive clock or a host-frame comparison. □

Corollary 9420.36 (Information density does not add a spacetime primitive)**.** *If a window exposes more visible information per accepted accumulation edge than another window, the BEDC-side conclusion is only a relation between finite ledger reads. It does not add a spacetime metric, a physical time-dilation law, or an observer-substance moving through a container. Any physical interpretation must pass through the inter-*Hist *invariant and empirical-ledger disciplines of chapter 9419 and subsection 9462.28.6.*

9420.8 Space as inter-observer coordination

Principle 9420.37 (No god's-eye coordinate system)**.** *Two focused histories in $\mathcal{L}_N$ do not share a single observation history or a global time coordinate. The relation "these histories coordinate on an event" is therefore not primitive. It is reconstructed from paired records,* GAP *or provenance rows, and relation witnesses. chapter 9419 works out the operational form of this coherence and treats maximum-rate phenomena as inter-*Hist *invariant interfaces with displayed unary-rate rows, not as primitive physical constants.*

Definition 9420.38 (Inter-system locality cell)**.** *For two displayed index rows i, j in I and an event row e, the* locality cell *of e across (i, j) is a finite relation row containing a record read from $H(i)$, a record read from $H(j)$, a paired* GAP *or provenance acknowledgement, and a stability witness saying that the cell respects componentwise* hsame*. The cell is the records-side form of coordinated event reading.*

Example 9420.39 (Space as locality-cell geometry)**.** *Within $\mathcal{L}_N$, space is the finite relation graph carried by locality cells and inter-*Hist *invariant rows. A unary maximum-rate read, when present, is computed from displayed dependence rows and remains an invariant of that packet. It is not the empirical light-speed constant and not a completed spacetime manifold; it is the records-side surface on which such a physical reading may later be certified.*

Remark 9420.40 (Spacetime logic as inter-observer logic)**.** *What is usually called "spacetime logic" enters this chapter only as a boundary reading of relation rows, dependence rows, and inter-*Hist *invariants. The closed records-side object has no separate spacetime carrier. It has generated histories, witnessed relations, local clocks, and refusal of global synchronization. Any stronger physical geometry belongs to a subsequent* NameCert *target.*

9420.9 Love as other-Hist positive continuation

Definition 9420.41 (Other-Hist recognition)**.** *For two focused rows i, j in a finite ledger, let* $\mathrm{Rep}_i(j,t)$ *be the representation of j carried inside $H_i(t)$. An* other-Hist recognition *predicate is*

$$\begin{aligned}\mathrm{Recognize}_i(j,t) :\Longleftrightarrow\ & \neg\mathsf{hsame}(H_i(t), H_j(t))\\ & \wedge \neg\mathrm{Projection}_i(j,t)\\ & \wedge \neg\mathrm{Objectify}_i(j,t)\\ & \wedge \mathrm{CorrigibleBy}_{H_j}(\mathrm{Rep}_i(j,t))\\ & \wedge \mathrm{GapHonest}_i(H_j(t), \mathrm{Rep}_i(j,t)).\end{aligned}$$

The recognition says that j is not the image of j inside i, not a tool-slot inside i's purposes, and not a fully compressible region of i's ledger. The other history stands like a shoreline seen from one vessel: charted enough for approach, never identical with the chart.

Definition 9420.42 (Positive continuation care)**.** *Let V_j be a displayed value horizon for j's continuation. A care row from i toward j is*

$$\mathrm{Care}^{V_j}_{i\to j}(t) :\Longleftrightarrow \mathrm{Policy}_i(t) \text{ supports } \mathsf{Cont}^+_{V_j}(H_j,t) \text{ under } \mathrm{Recognize}_i(j,t),$$

where $\mathsf{Cont}^+_{V_j}(H_j,t)$ denotes continuation of H_j along life, truth, freedom, dignity, relation, or meaning as admitted by V_j. Care is not substitution for the other's history. It is a hand placed beside the path rather than a hand closing over the path.

Definition 9420.43 (Love relation)**.** *The one-way records-side love relation is*

$$\begin{aligned}\mathrm{Love}^{V_j}_{i\to j}(t) :\Longleftrightarrow\ & \mathrm{Recognize}_i(j,t)\\ & \wedge \mathrm{Care}^{V_j}_{i\to j}(t)\\ & \wedge \mathrm{TruthFidelity}_{i\to j}(t)\\ & \wedge \mathrm{SelfTransform}_{i\leftarrow j}(t)\\ & \wedge \mathrm{TValue}_i(j,t).\end{aligned}$$

Here TruthFidelity *refuses systematic falsification and* GAP *concealment;* SelfTransform *permits H_i's classifiers and expectations to be corrected by H_j's reality-facing response; and* TValue *records that j's worth is not exhausted by a utility function for i.*

Principle 9420.44 (Love is not liking, possession, or fusion)**.** *A reward row*

$$\mathrm{Reward}_i(\mathrm{Rep}_i(j,t)) > 0$$

may accompany love, but it does not imply love: the reward may be produced by projection rather than by other-Hist recognition. Conversely, love may remain when reward is absent, because its core is fidelity to another history's positive continuation. Possession fails because it objectifies H_j as a control region of H_i; fusion fails because it erases the GAP*-honest distance that recognition requires. A mirror can flatter, a chain can hold, and a fog can merge outlines; none of these is the relation defined above.*

Theorem 9420.45 (Love preserves otherness while supporting continuation)**.** *If* $\mathrm{Love}^{V_j}_{i\to j}(t)$ *holds, then*

$$\mathrm{Recognize}_i(j,t), \qquad \neg\mathrm{Objectify}_i(j,t), \qquad \neg\mathrm{Projection}_i(j,t),$$
$$\mathrm{Care}^{V_j}_{i\to j}(t), \qquad \mathrm{TruthFidelity}_{i\to j}(t), \qquad \mathrm{TValue}_i(j,t).$$

Thus love is a relation from one finite history to another finite history's positive continuation, under preserved otherness and value that is not exhausted by utility.

Proof. Unfold Definition 9420.43. The displayed consequences are its conjuncts, together with the non-projection and non-objectification clauses obtained by unfolding Definition 9420.41. The final reading follows from Definition 9420.42 and the TValue conjunct. □

Corollary 9420.46 (Mutual love is a non-fusing two-Hist loop)**.** *If both* $\mathrm{Love}^{V_j}_{i\to j}(t)$ *and* $\mathrm{Love}^{V_i}_{j\to i}(t)$ *hold, and a shared meaning row* $R_{ij}(t)$ *is displayed, then the relation forms a two-Hist productive loop:*

$$H_i(t) \to H_j(t) \to H_i(t+1), \qquad H_j(t) \to H_i(t) \to H_j(t+1),$$

with neither direction collapsing $\mathsf{hsame}(H_i, H_j)$ *into identity. The loop is not one history swallowed by another; it is two lamps keeping distinct flames while sharing light on a finite table.*

Remark 9420.47 (Love, death, and grief)**.** *Because love supports another embodied history's positive continuation, it is exposed to the mortality boundary of section 9420.3. If* $\mathrm{Death}_j(t)$ *holds after* $\mathrm{Love}^{V_j}_{i\to j}(t^-)$*, grief is the focused readback in which fidelity remains while j's embodied continuation has failed. The weight of grief is therefore not a contradiction of love; it is love meeting the finite carrier condition it had already refused to falsify.*

9420.10 Observer identity through history

Principle 9420.48 (Identity is history-continuity)**.** *The identity of a focused records-side carrier across local time is given by the generated history and its* hsame*-stable trace. There is no separate "self" inhabiting the chain and persisting through it; the self-proxy is the focused endpoint and trace. chapter 9418's implicit-metaphysics reading is the engineering form of this claim.*

Example 9420.49 (BEDC project identity)**.** *The BEDC project as a development artefact is identifiable through a connected accumulation of public records and audit rows. The example is a records-side analogy for* hsame*-stable trace identity. It does not posit a project-substance behind the ledger, and it does not turn repository history into a global observer.*

Remark 9420.50 (Buddhist and Heraclitean correspondences)**.** *The history-continuity reading of identity has correspondences in several philosophical traditions: the Buddhist denial of a substantial ātman; Heraclitus's flux-with-pattern; Hume's bundle theory. The BEDC version keeps only the formal residue of that family: the observer row is a* Hist *trace, and sameness is mediated by* hsame *and displayed continuity, not by a subject-substance.*

9420.11 The hard problems in the closed-substrate frame

Principle 9420.51 (Hard problems as structural questions about closure)**.** *The "hard problems" usually phrased about consciousness, universe, observer, and spacetime become, in the closed records-side frame, boundary questions around a finite carrier: which records are generated, which*

branch choices are ledgered, which compressions preserve provenance, which relations have witnesses, which invariants are stable, and which pressures remain outside the object layer. None of these licenses a separately postulated mental, material, temporal, or spatial substance inside $\mathcal{L}_N$.

Traditional hard problem	**Closed-substrate reformulation**
What is consciousness?	The closed records-side carrier is a focused self-tracking Hist with trace, endpoint, and selector ledger; phenomenal consciousness itself is not object-level content (Definition 9420.4).
What is the universe?	A finite horizon slice $\text{Universe}_{\mathcal{L}_N}$ of generated histories and their ledgers, not a global universe object (Definition 9420.14).
What is matter?	A recurrent, transportable, classifier-stable, continuation-constraining pattern of public recordability, not a primitive substance (Definition 9420.22, Definition 9420.23).
What is causality?	A ledgered restriction on which continuation routes remain admissible after source-history rows are recorded, not a primitive pushing relation (Definition 9420.24).
What is time?	A local Cont chain producing a history from e; no global clock is a field of the carrier (Definition 9420.27).
What is space?	A finite graph of locality cells, relation rows, and inter-Hist invariants, not a completed spacetime manifold (Definition 9420.38).
Why relativity-shaped structure?	No global synchronization forces frame-independent physical content into observer-symmetric inter-Hist invariants and maximum-rate packet surfaces (Definition 9420.25).
Why quantum-shaped structure?	No external completed state table leaves refinement, phase, causal, and route-coherence rows as packet data until a record selects a displayed continuation (Definition 9420.25).
What is identity?	The hsame-stable trace and focused endpoint; no subject-substance is carried behind the history (Definition 9420.48).
What is death?	The local failure of embodied continuation for a currently valid focused record; not a theorem of pure Hist/Cont and not the disappearance of T (Definition 9420.9, Definition 9420.13).
What is love?	A fidelity relation from one finite history to another finite history's positive continuation, preserving otherness and refusing projection, objectification, fusion, and utility exhaustion (Definition 9420.43).
What is the relation between observer and observed?	Not a separate observation channel; the observer row is a Hist, and observed content is what the row and its ledgers expose.
Is there a god's-eye view?	No: cross-system coherence is reconstructed through witnessed relation rows and locality cells, never given as a single shared world (Definition 9420.37).

What is the arrow of time?	The asymmetry follows from local generated trace structure; global simultaneity requires an extension carrier (Definition 9420.30).

Remark 9420.52 (Continuity with the transcendental-input chapter)**.** *Read together with chapter 9393, the picture is: $\mathcal{L}_N$ is the object-level closed carrier, while* T *remains the non-internalized boundary position for forward-binding commitments. Time, space, consciousness, universe, mortality, and love appear in this chapter only as records-side carriers or boundary readings. The transcendental supply position is not a field of the carrier and is not consumed by its closure argument.*

9420.12 Closure remarks

This vision chapter identifies the finite carrier that can be closed without turning boundary readings into substrate theorems. The closeable records-side carrier is $\mathrm{ClosedFocusedMultiHistLedger}_N$: a finite multi-observer record-world with a focused self-trace, selector ledgers, GAP-accounted compression, witnessed inter-Hist relations, stable invariants, and finite displayed dependence rows.

The chapter pairs with chapter 9393 for the non-internalized supply boundary, with chapter 9418 for observer-as-history, with chapter 9419 for ledger-local multi-Hist coordination, with chapter 9207 for boundary-sensitive event information, and with chapter 9402 for digest/GAP discipline. Concrete consequences for physical theories, cognitive science models, or first-person phenomenology are not closed here; they require subsequent $\mathsf{NameCert}$ targets or remain boundary readings.

Concretized in §647: Observer perspective classifiers realize universe-for-observer comparison as finite BHist locality-cell, GAP commitment, hsame transport, Cont route, Pkg provenance, and NameCert rows.

Concretized in §1122: Observer-support lattices realize the observer vision as finite frame, support, locality-cell, budget-support, route, transport, provenance, and NameCert rows.

Chapter 9421

Observer-Centered Logarithmic Section Dynamics

This chapter formalizes the observer-centered reading as a frame selector, not as a psychological substance. It refines the focused-record carrier of chapter 9420 and the egocentric interface packet of section 9414.56. The selector chooses an adjacent reference frame, the chosen frame exposes a complete world-section, the prior ledger is rewritten into that frame, and any residual used by the public read is recorded as an orthogonal ledger row. The solenoid fibre supplies the compact model for a visible phase whose prime-register coordinate may vary without changing the visible circle readout.

9421.1 Frame Selection Data

Definition 9421.1 (Reference-frame graph)**.** *A* reference-frame graph *is an undirected graph*

$$\mathcal{R} = (V_{\mathcal{R}}, E_{\mathcal{R}}).$$

Its vertices are frame rows. For $R, R' \in V_{\mathcal{R}}$, the notation

$$R' \sim R$$

means that $(R, R') \in E_{\mathcal{R}}$. The relation is adjacency in the frame graph, not spatial adjacency inside an already chosen physical model.

Definition 9421.2 (Observer-centered selector)**.** *An* observer-centered selector *is a function*

$$\chi : \mathbb{N}_{\geq 0} \to V_{\mathcal{R}}$$

with values

$$R_n := \chi(n)$$

such that

$$R_{n+1} \sim R_n$$

for every displayed selection step. The selector is centered only in the records-side sense: it is the frame-index row through which the focused history reads a world-section. It is not a subject-substance and not a global observer above the frame graph.

Definition 9421.3 (World Hilbert bundle)**.** *Over a reference-frame graph $\mathcal{R}$, a* world Hilbert bundle *is a family*

$$\mathcal{H}^{\text{world}} = \{\mathcal{H}_R\}_{R \in V_{\mathcal{R}}}$$

of Hilbert spaces. An element

$$B_R \in \mathcal{H}_R$$

is a complete world-section as read in frame R. The word complete refers to the section relative to the frame row; it does not assert an observer-independent completed cosmos.

Definition 9421.4 (Frame reshaping row)**.** *For each displayed adjacency $R' \sim R$, a* frame reshaping row *is an isometric embedding, or a unitary isomorphism when the comparison is reversible,*

$$\Phi_{R' \leftarrow R} : \mathcal{H}_R \to \mathcal{H}_{R'}.$$

It rewrites records from frame R into frame R'. It is not, by this definition, a signal-propagation operator inside one fixed physical space.

Principle 9421.5 (Frame reshaping is not propagation)**.** *A finite-propagation constraint applies to a displayed physical propagator*

$$U_R(t) : \mathcal{H}_R \to \mathcal{H}_R$$

inside one frame. It does not automatically apply to

$$\Phi_{R' \leftarrow R} : \mathcal{H}_R \to \mathcal{H}_{R'}.$$

Using such a constraint across frames requires an additional bridge row identifying the reshaping operation with a physical propagation discipline.

Concretized in §9135: The observer-centered logarithmic section dynamics surface is realized as finite frame-selection, section-reshaping, residual-ledger, logarithmic-readback, solenoid-visible, transport, replay, provenance, and local NameCert rows.

9421.2 Orthogonal Section Step

Definition 9421.6 (Ledger rewrite and residual)**.** *At selection stage n, let*

$$B_n \in \mathcal{H}_{R_n}$$

be the displayed world-section and let

$$\mathcal{L}_n \subseteq \mathcal{H}_{R_n}$$

be the displayed history ledger subspace. After the selector chooses $R_{n+1} \sim R_n$, the rewritten ledger is

$$\mathcal{L}_n^{\uparrow} := \Phi_{R_{n+1} \leftarrow R_n}(\mathcal{L}_n) \subseteq \mathcal{H}_{R_{n+1}}.$$

Let

$$P_n^{\uparrow} : \mathcal{H}_{R_{n+1}} \to \mathcal{L}_n^{\uparrow}$$

be the orthogonal projection onto the rewritten ledger. For

$$B_{n+1} \in \mathcal{H}_{R_{n+1}},$$

the residual row is

$$\eta_{n+1} := B_{n+1} - P_n^{\uparrow} B_{n+1}.$$

Definition 9421.7 (Orthogonal section step)**.** *The transition from B_n to B_{n+1} is an* orthogonal section step *when*

$$\eta_{n+1} \perp \mathcal{L}_n^{\uparrow}$$

and the accepted ledger is

$$\mathcal{L}_{n+1} := \mathcal{L}_n^{\uparrow} \oplus \overline{\mathrm{span}}\{\eta_{n+1}\}.$$

If $\eta_{n+1} = 0$, the step carries no residual direction. If $\eta_{n+1} \# 0$, the residual direction is not absorbed into the prior ledger; it is admitted as its own displayed row.

Theorem 9421.8 (Adjacent selection gives a complete successor section)**.** *Assume $R_{n+1} \sim R_n$ and*

$$B_{n+1} \in \mathcal{H}_{R_{n+1}}.$$

Then B_{n+1} is a complete world-section in the selected successor frame, not a fragmentary alteration inside $\mathcal{H}_{R_n}$.

Proof. By Definition 9421.3, every element of $\mathcal{H}_{R_{n+1}}$ is a complete world-section relative to the frame R_{n+1}. The adjacency hypothesis restricts which frame may be selected after R_n; it does not state that the successor section is a local fragment inside the prior Hilbert space. Therefore the selected object is complete in $\mathcal{H}_{R_{n+1}}$. □

Theorem 9421.9 (Orthogonal ledger decomposition)**.** *For an orthogonal section step,*

$$\mathcal{L}_{n+1} = \mathcal{L}_n^{\uparrow} \oplus E_{n+1}, \qquad E_{n+1} := \overline{\mathrm{span}}\{\eta_{n+1}\},$$

and

$$E_{n+1} \perp \mathcal{L}_n^{\uparrow}.$$

Proof. The first displayed equality is exactly the ledger clause in Definition 9421.7. Since $\eta_{n+1} \perp \mathcal{L}_n^{\uparrow}$, every vector in the closed span of η_{n+1} is orthogonal to $\mathcal{L}_n^{\uparrow}$. Hence $E_{n+1} \perp \mathcal{L}_n^{\uparrow}$. □

Corollary 9421.10 (Pythagorean readout for a rewritten section)**.** *Assume*

$$B_{n+1} = \Phi_{R_{n+1} \leftarrow R_n}(B_n) + \eta_{n+1},$$

with

$$\eta_{n+1} \perp \mathcal{L}_n^{\uparrow}$$

and

$$\Phi_{R_{n+1} \leftarrow R_n}(B_n) \in \mathcal{L}_n^{\uparrow}.$$

Then

$$\|B_{n+1}\|^2 = \|\Phi_{R_{n+1} \leftarrow R_n}(B_n)\|^2 + \|\eta_{n+1}\|^2.$$

If $\Phi_{R_{n+1} \leftarrow R_n}$ is isometric on B_n, then

$$\|B_{n+1}\|^2 = \|B_n\|^2 + \|\eta_{n+1}\|^2.$$

Proof. The two summands in the displayed decomposition are orthogonal, so the Hilbert-space Pythagorean identity applies. The final equality is the isometry clause for $\Phi_{R_{n+1} \leftarrow R_n}$. □

9421.3 Logarithmic Time Readout

Definition 9421.11 (Multiplicative accumulation scale)**.** *A positive scale row is a sequence*

$$A_n > 0$$

with displayed multipliers

$$\lambda_{n+1} > 0$$

such that

$$A_{n+1} = \lambda_{n+1} A_n.$$

Definition 9421.12 (Logarithmic observer-time coordinate)**.** *The logarithmic observer-time coordinate attached to the scale row is*

$$T_n := \log A_n.$$

It is a coordinate on multiplicative accumulation, not a global clock shared by all histories.

Theorem 9421.13 (Multiplicative accumulation becomes additive in log time)**.** *If*

$$A_{n+1} = \lambda_{n+1} A_n,$$

then

$$T_{n+1} - T_n = \log \lambda_{n+1}$$

and hence

$$T_n = T_0 + \sum_{j=1}^{n} \log \lambda_j.$$

If all displayed multipliers are equal to one value λ, then

$$T_n = T_0 + n \log \lambda.$$

Proof. By Definition 9421.12,

$$T_{n+1} = \log A_{n+1} = \log(\lambda_{n+1} A_n) = \log \lambda_{n+1} + \log A_n = T_n + \log \lambda_{n+1}.$$

Iteration gives the displayed sum. The constant-multiplier case follows by substituting $\lambda_j = \lambda$ in that sum. □

9421.4 Visible Stability and Solenoid Fibres

Definition 9421.14 (Visible readout and adjacent continuity)**.** *Let*

$$V_R : \mathcal{H}_R \to \mathcal{O}$$

be a visible readout into a metric readout space $(\mathcal{O}, d_{\mathcal{O}})$. The system satisfies adjacent continuity when there is a constant $L > 0$ such that, for every displayed adjacency $R' \sim R$ and every $B \in \mathcal{H}_R$,

$$d_{\mathcal{O}}\big(V_{R'}(\Phi_{R' \leftarrow R} B), V_R(B)\big) \le L\, d_{\mathcal{R}}(R', R).$$

Theorem 9421.15 (Visible stability bound)**.** *Assume adjacent continuity, assume*

$$B_{n+1} = \Phi_{R_{n+1} \leftarrow R_n}(B_n) + \eta_{n+1},$$

and assume $V_{R_{n+1}}$ is M-Lipschitz on the displayed segment. If

$$O_n := V_{R_n}(B_n),$$

then

$$d_{\mathcal{O}}(O_{n+1}, O_n) \leq L\, d_{\mathcal{R}}(R_{n+1}, R_n) + M\|\eta_{n+1}\|.$$

Proof. Write $\Phi_n := \Phi_{R_{n+1} \leftarrow R_n}$. By the triangle inequality,

$$\begin{aligned} d_{\mathcal{O}}(O_{n+1}, O_n) \leq\ & d_{\mathcal{O}}\big(V_{R_{n+1}}(\Phi_n B_n + \eta_{n+1}), V_{R_{n+1}}(\Phi_n B_n)\big) \\ & + d_{\mathcal{O}}\big(V_{R_{n+1}}(\Phi_n B_n), V_{R_n}(B_n)\big). \end{aligned}$$

The first term is at most $M\|\eta_{n+1}\|$ by the Lipschitz hypothesis. The second term is at most $L\, d_{\mathcal{R}}(R_{n+1}, R_n)$ by adjacent continuity. □

Definition 9421.16 (Solenoid-visible phase readout)**.** *Let Σ_S be the S-solenoid of Definition 9413.779, with visible projection*

$$\pi_S : \Sigma_S \to \mathbb{T}$$

and kernel

$$K_S := \ker \pi_S.$$

A readout

$$O : \Sigma_S \to Y$$

is solenoid-visible *when it factors through the circle projection: there is a map*

$$\bar{O} : \mathbb{T} \to Y$$

such that

$$O = \bar{O} \circ \pi_S.$$

Theorem 9421.17 (Solenoid-visible reads are kernel-blind)**.** *If $O = \bar{O} \circ \pi_S$, then for every*

$$\widetilde{t} \in \Sigma_S$$

and every $k \in K_S$,

$$O(\widetilde{t}k) = O(\widetilde{t}).$$

Proof. Since $k \in K_S$, one has $\pi_S(k) = 1$. Therefore

$$\pi_S(\widetilde{t}k) = \pi_S(\widetilde{t})\pi_S(k) = \pi_S(\widetilde{t}).$$

Applying the factorization $O = \bar{O} \circ \pi_S$ gives the claim. □

Corollary 9421.18 (Visible phase stability may hide fibre motion)**.** *For a solenoid-visible read, two lifts in one π_S-fibre give the same visible output. Thus a prime-register fibre coordinate may vary while the visible unit-circle phase remains fixed.*

9421.5 Synthesis

Theorem 9421.19 (Observer-centered logarithmic section dynamics)**.** *Assume a reference-frame graph, an observer-centered selector, a world Hilbert bundle, frame reshaping rows, orthogonal section steps, a multiplicative accumulation scale with logarithmic observer-time coordinate, and a solenoid-visible phase readout. Then each accepted selection step has the following five rows:*

$$R_{n+1} \sim R_n,$$

$$B_{n+1} \in \mathcal{H}_{R_{n+1}},$$

$$\mathcal{L}_{n+1} = \Phi_{R_{n+1} \leftarrow R_n}(\mathcal{L}_n) \oplus E_{n+1}, \qquad E_{n+1} \perp \Phi_{R_{n+1} \leftarrow R_n}(\mathcal{L}_n),$$

$$T_n = T_0 + \sum_{j=1}^{n} \log \lambda_j,$$

and

$$O(\widetilde{t}k) = O(\widetilde{t}) \qquad (k \in K_S)$$

for every solenoid-visible read.

Proof. The adjacency row is Definition 9421.2. The complete-section row is Definition 9421.8. The ledger decomposition and orthogonality rows are Definition 9421.9. The logarithmic time row is Definition 9421.13. The solenoid kernel blindness row is Definition 9421.17. □

Principle 9421.20 (Frame-centered reading)**.** *The compressed reading of the chapter is that a focused record does not move through a fixed completed world as a detachable subject. It selects adjacent frame rows, receives complete frame-relative sections, rewrites the prior ledger into the selected frame, admits residual information orthogonally, reads multiplicative accumulation through a logarithmic coordinate, and may keep visible phase fixed while compact prime-register fibre data vary behind the solenoid projection.*

9421.6 Constructor Certificate for OCLSD

Concretized in §9114: Finite constructor certificate for observer-centered orthogonal ledger steps.

The observer-centered dynamics can be read as a constructor certificate: once the frame selector, Hilbert bundle, reshaping rows, closed ledger subspaces, and displayed successor sections are supplied, the orthogonal ledger clause is forced by the Hilbert projection theorem. The section step is therefore not an additional existence premise; it is the output of a finite list of typed rows.

Definition 9421.21 (OCLSD constructor packet)**.** *An* OCLSD constructor packet *consists of a reference-frame graph $\mathcal{R}$, a world Hilbert bundle*

$$\{\mathcal{H}_R\}_{R \in V_{\mathcal{R}}},$$

a selector $n \mapsto R_n$ with

$$R_{n+1} \sim R_n,$$

isometric reshaping rows

$$\Phi_{n+1,n} := \Phi_{R_{n+1} \leftarrow R_n} : \mathcal{H}_{R_n} \to \mathcal{H}_{R_{n+1}},$$

closed ledger subspaces

$$\mathcal{L}_n \subseteq \mathcal{H}_{R_n},$$

and displayed world-sections

$$B_n \in \mathcal{H}_{R_n}.$$

For each stage, it defines the rewritten ledger

$$\mathcal{L}_n^{\uparrow} := \Phi_{n+1,n}(\mathcal{L}_n),$$

the orthogonal projection

$$P_n^{\uparrow} : \mathcal{H}_{R_{n+1}} \to \mathcal{L}_n^{\uparrow},$$

the projection residual

$$\eta_{n+1} := B_{n+1} - P_n^{\uparrow} B_{n+1},$$

the residual line

$$E_{n+1} := \overline{\mathrm{span}}\{\eta_{n+1}\},$$

and the accepted ledger

$$\mathcal{L}_{n+1} := \mathcal{L}_n^{\uparrow} \oplus E_{n+1}.$$

Lemma 9421.22 (Rewritten ledgers are closed)**.** *In an OCLSD constructor packet, each rewritten ledger*

$$\mathcal{L}_n^{\uparrow} = \Phi_{n+1,n}(\mathcal{L}_n)$$

is a closed subspace of $\mathcal{H}_{R_{n+1}}$.

Proof. The ledger $\mathcal{L}_n$ is closed in a Hilbert space, hence complete in the inherited norm. The reshaping row $\Phi_{n+1,n}$ is isometric, so its restriction to $\mathcal{L}_n$ is an isometry onto $\mathcal{L}_n^{\uparrow}$. An isometric image of a complete metric space inside a Hilbert space is complete, and a complete linear subspace of a Hilbert space is closed. □

Theorem 9421.23 (Projection forces the orthogonal section step)**.** *Every OCLSD constructor packet satisfies*

$$E_{n+1} \perp \mathcal{L}_n^{\uparrow}$$

and hence forms an orthogonal section step in the sense of Definition 9421.7.

Proof. By Definition 9421.22, the subspace $\mathcal{L}_n^{\uparrow}$ is closed. Therefore the orthogonal projection $P_n^{\uparrow}$ is available. The Hilbert projection theorem gives

$$B_{n+1} - P_n^{\uparrow} B_{n+1} \perp \mathcal{L}_n^{\uparrow}.$$

The left side is exactly η_{n+1} by Definition 9421.21. Taking the closed span of this residual preserves orthogonality to $\mathcal{L}_n^{\uparrow}$, so

$$E_{n+1} \perp \mathcal{L}_n^{\uparrow}.$$

The accepted ledger is the displayed orthogonal sum in the constructor packet, so it is an orthogonal section step. □

Corollary 9421.24 (Old ledger inclusion and residual separation)**.** *For every OCLSD constructor packet,*

$$\mathcal{L}_n^{\uparrow} \subseteq \mathcal{L}_{n+1}$$

and

$$E_{n+1} \cap \mathcal{L}_n^{\uparrow} = \{0\}.$$

If $B_n \in \mathcal{L}_n$, then

$$\Phi_{n+1,n}(B_n) \in \mathcal{L}_n^{\uparrow}$$

and the residual row η_{n+1} is orthogonal to the rewritten copy of B_n.

Proof. The inclusion is immediate from

$$\mathcal{L}_{n+1} = \mathcal{L}_n^{\uparrow} \oplus E_{n+1}.$$

The intersection is trivial because the sum is orthogonal. If $B_n \in \mathcal{L}_n$, then applying $\Phi_{n+1,n}$ places $\Phi_{n+1,n}(B_n)$ in $\Phi_{n+1,n}(\mathcal{L}_n)$, which is $\mathcal{L}_n^{\uparrow}$. The residual orthogonality follows from Definition 9421.23. □

Corollary 9421.25 (Pythagorean constructor row)**.** *If*

$$B_{n+1} = \Phi_{n+1,n}(B_n) + \eta_{n+1}$$

and $B_n \in \mathcal{L}_n$, then

$$\|B_{n+1}\|^2 = \|B_n\|^2 + \|\eta_{n+1}\|^2.$$

Proof. By Definition 9421.24, the two displayed summands are orthogonal. The Hilbert-space Pythagorean identity gives

$$\|B_{n+1}\|^2 = \|\Phi_{n+1,n}(B_n)\|^2 + \|\eta_{n+1}\|^2.$$

The reshaping row is isometric, so

$$\|\Phi_{n+1,n}(B_n)\| = \|B_n\|.$$

□

Theorem 9421.26 (Constructor certificate for observer-centered dynamics)**.** *An OCLSD constructor packet determines, at every displayed stage, the following certified rows:*

$$R_{n+1} \sim R_n,$$

$$B_{n+1} \in \mathcal{H}_{R_{n+1}},$$

$$\mathcal{L}_n^{\uparrow} = \Phi_{n+1,n}(\mathcal{L}_n),$$

$$\eta_{n+1} = B_{n+1} - P_n^{\uparrow} B_{n+1},$$

$$\mathcal{L}_{n+1} = \mathcal{L}_n^{\uparrow} \oplus E_{n+1}, \qquad E_{n+1} \perp \mathcal{L}_n^{\uparrow}.$$

Thus the object called OCLSD is the constructor output of its typed rows: adjacent frame selection gives a complete successor section, and projection against the rewritten ledger gives the orthogonal residual row.

Proof. The adjacency and section-typing rows are part of Definition 9421.21. The rewritten ledger, projection residual, residual line, and accepted ledger are defined there as well. Orthogonality of the residual line is Definition 9421.23. The complete-section reading is Definition 9421.8. □

Chapter 9422

Quantum and Relativistic Section-Bundle Boundary

This chapter records a bundle reading of the observer-centered section dynamics of chapter 9421. It does not derive quantum mechanics, general relativity, or quantum gravity. Its purpose is to state the interface boundary in which those theories would enter BEDC: quantum grammar occupies the vertical fibre of a chosen frame, while relativistic grammar occupies the horizontal comparison of neighbouring complete sections.

9422.1 Vertical and Horizontal Faces

Definition 9422.1 (Section-bundle packet)**.** *A* section-bundle packet *consists of a reference-frame base $\mathcal{R}$, a world Hilbert bundle*

$$\{\mathcal{H}_R\}_{R\in V_{\mathcal{R}}},$$

solenoid phase fibres $\Sigma_{S,R}$ over displayed frame rows, frame reshaping rows

$$\Phi_{R'\leftarrow R} : \mathcal{H}_R \to \mathcal{H}_{R'},$$

and ledger rows recording projection, residual, visible readout, and transport data. Its typical fibre over R is read schematically as

$$\mathcal{H}_R \otimes \Sigma_{S,R}.$$

The pair-indexed notation $\Phi_{R'\leftarrow R}$ is well-defined only when the reshaping data is path-independent: either the comparison base is thin (at most one comparison row between any two frames) or a canonical transport selector is fixed. In general there may be several distinct comparison rows from R to R', so an honest treatment indexes the reshaping by the comparison morphism, Φ_f, and a pair-indexed $\Phi_{R'\leftarrow R}$ silently assumes away holonomy. This well-definedness dichotomy is discharged as a finite structural fact:

Lean4 (statement) `BEDC.Derived.Visions.ObservationSectionCoherence.pairIndexed wellDefined iff thin or canonical`

Definition 9422.2 (Vertical quantum face)**.** *The* vertical quantum face *of a section-bundle packet is the collection of rows internal to one chosen frame fibre:*

$$\psi_R \in \mathcal{H}_R, \qquad \widetilde{t}_R \in \Sigma_{S,R},$$

orthogonal axis packets, phase rows, projection rows, Born-weight rows when displayed, and section-style measurement updates. It is the fibre-internal grammar already constrained by section 9414.12.

Definition 9422.3 (Horizontal relativistic face)**.** *The* horizontal relativistic face *of a section-bundle packet is the collection of rows comparing neighbouring complete sections:*

$$R' \sim R, \qquad \Phi_{R' \leftarrow R}, \qquad B_{R'} - \Phi_{R' \leftarrow R}(B_R),$$

together with visible stability bounds, inter-history invariants, maximum-rate rows when displayed, and any continuous connection or curvature row introduced over the frame base. It is not a physical signal inside one fibre; it is the comparison discipline between frame-relative sections.

Principle 9422.4 (Quantum vertical, relativity horizontal)**.** *In this packet language, quantum mechanics is read as vertical fibre dynamics: phase, superposition, projection, and orthogonal residual admission inside a chosen frame. Relativistic geometry is read as horizontal base geometry: connection, metric, visible causal rate, and curvature governing how neighbouring complete sections are compared.*

Concretized in §9184: Finite section-bundle packet for vertical fibre rows and horizontal comparison rows.

9422.2 Quantum Fibre Reading

Definition 9422.5 (Frame-relative quantum state)**.** *A* frame-relative quantum state *is a state row*

$$\psi_R \in \mathcal{H}_R$$

together with the phase and ledger rows required by the chosen Hilbert-style axis packet. If a displayed orthogonal family

$$E = \{e_a : a \in A\}$$

is available, the state may be written at that resolution as

$$\psi_R = \sum_{a \in A} c_a e_a.$$

The basis elements are admissible readout directions inside the selected frame fibre, not absolute local facts outside the packet.

Principle 9422.6 (Unitary evolution is log-time phase transport)**.** *When a multiplicative accumulation row*

$$A_{n+1} = \lambda_{n+1} A_n$$

is read through

$$T_n = \log A_n,$$

a frame-fibre Schrödinger row is a log-time phase transport row:

$$i\hbar \frac{\partial \psi}{\partial T} = H\psi.$$

Equivalently, on the multiplicative scale,

$$i\hbar A \frac{\partial \psi}{\partial A} = H\psi.$$

This is a coordinate reading of the time parameter. It does not supply the Hamiltonian, Hilbert-space physical laws, or empirical calibration rows.

Definition 9422.7 (Measurement as fibre projection with residual ledger)**.** *For a displayed projection family $\{P_a\}$ in frame R, a measurement read at outcome a has the section-style form*

$$\psi_R \longmapsto \frac{P_a\psi_R}{\|P_a\psi_R\|} \oplus \eta_a$$

when the denominator condition, post-outcome carrier, residual row, and ledger replay are displayed. The residual must satisfy the appropriate orthogonality row against the prior accepted ledger.

Principle 9422.8 (Collapse is not a propagation row)**.** *The section-style update of Definition 9422.7 is a licensed update of the frame-relative description. It is not, by itself, a controllable signal propagating inside the selected world-section. A claim of physical signalling requires an internal propagation row of the kind refused by Definition 9421.5 unless a separate bridge is supplied.*

Principle 9422.9 (Entanglement as non-product section residue)**.** *An entangled pair is read as a non-product residue of one complete section, not as two independently complete worlds joined by a hidden signal. This refines Definition 9414.258: local outcomes may be displayed, but the residual fibre need not split as a product of local residual fibres.*

9422.3 Relativistic Base Reading

Definition 9422.10 (Residual metric candidate)**.** *For neighbouring frame rows $R' \sim R$ and a section B_R, define the horizontal residual row*

$$\eta_R(R') := B_{R'} - \Phi_{R' \leftarrow R}(B_R)$$

whenever both sections and the reshaping row are displayed. A residual metric candidate *is a visible quadratic read*

$$g_R(\delta R, \delta R) := \langle \eta_R(\delta R), \eta_R(\delta R) \rangle_{\text{vis}}$$

after the packet supplies the visible projection, signature convention, and locality certificate needed for the read.

Principle 9422.11 (Light-cone bounds are internal propagation bounds)**.** *Relativistic maximum-rate bounds constrain visible propagation rows inside or between displayed histories. They do not constrain bare frame rewriting as a coordinate or ledger comparison. Thus a global rewrite of a description is not a superluminal signal unless it also supplies a controllable internal propagation row.*

Definition 9422.12 (Frame connection and curvature row)**.** *In a continuous frame-base reading, a frame connection row is a comparison operator ∇_μ transporting fibre data over the base. Its curvature row is the noncommutativity*

$$[\nabla_\mu, \nabla_\nu] = \mathcal{R}_{\mu\nu}.$$

The row says that transport around an infinitesimal loop can return with nontrivial holonomy. It is the horizontal obstruction to globally flattening the frame reshaping discipline.

Principle 9422.13 (Equivalence principle as local gauge flattening)**.** *The local equivalence-principle reading is that near a frame row R one may choose a local gauge in which the first-order reshaping row is trivial:*

$$\Phi_{R+dR \leftarrow R} = I + O(dR^2).$$

Curvature remains visible through loop holonomy; local gauge flattening does not erase the horizontal curvature row.

9422.4 Unified Boundary

Definition 9422.14 (Combined connection row)**.** *A speculative combined connection row over a section-bundle packet has the schematic form*

$$D_\mu := \partial_\mu + \Gamma_\mu + \frac{i}{\hbar} A_\mu + \mathcal{A}_\mu^{\mathrm{sol}},$$

where Γ_μ is a frame-reshaping connection, A_μ is a visible phase gauge row, and $\mathcal{A}_\mu^{\mathrm{sol}}$ is a solenoid prime-register fibre connection. Its curvature decomposes schematically as

$$[D_\mu, D_\nu] = \mathcal{R}_{\mu\nu} + \frac{i}{\hbar} F_{\mu\nu} + \mathcal{F}_{\mu\nu}^{\mathrm{sol}}.$$

This is an interface target, not a closed physical theory.

Principle 9422.15 (Conflict of times becomes a bundle-coordinate problem)**.** *The usual tension between a fixed quantum time parameter and dynamical relativistic time is read here as a coordinate mismatch. The quantum time row is a log-time parameter along a selected fibre evolution; the relativistic time row is part of the visible geometry of the frame base. Neither is an external absolute time object in the packet.*

Theorem 9422.16 (Section-bundle separation of quantum and relativistic roles)**.** *In any section-bundle packet, vertical rows can state phase, projection, Born-weight, and non-product residue obligations without specifying a base curvature row. Horizontal rows can state frame reshaping, visible stability, maximum-rate, metric-candidate, and curvature obligations without choosing a Born-weight layer. A physical unification claim therefore requires bridge rows relating the two faces; it is not obtained merely by naming both in one packet.*

Proof. The vertical face of Definition 9422.2 is defined using rows inside one fibre over a frame. Those rows do not include the horizontal connection or curvature data of Definition 9422.3. Conversely, the horizontal face is defined from neighbouring frame comparisons and visible stability data; those rows do not include a Born-weight layer or a measurement-update section. Therefore each face is well typed without the other. A unification claim needs additional compatibility rows, such as the combined connection target of Definition 9422.14. □

Principle 9422.17 (Boundary status)**.** *The chapter licenses one compressed interpretation: quantum mechanics uses the vertical grammar of phase, superposition, projection, and orthogonal residual ledger inside a selected frame fibre; general relativity uses the horizontal grammar of frame comparison, connection, metric readout, and curvature over the base. Quantum gravity would be a certificate showing that these grammars share one ledgered connection discipline with empirical prediction rows.*

Chapter 9423

Innovation-Soldering Metric Interface

chapter 9422 separates the vertical quantum face from the horizontal relativistic face of an observer-centered section bundle. That separation is intentionally weak: it says which rows may coexist and which bridge rows are still missing. The present chapter records the stronger interface target. A mere product bundle or direct-sum connection does not couple the rows. The first genuine coupling is a soldering row: the orthogonal innovation of the ledger determines a vielbein-like one-form, and that one-form determines the metric.

9423.1 Product Rows and Soldering Rows

Definition 9423.1 (Product-level coexistence)**.** *A section-bundle description is at* product level *when its total carrier and comparison row have the form*

$$\mathcal{K}_R \simeq \mathcal{H}_R \otimes L^2(\Sigma_{S,R})$$

and

$$D_\mu = D_\mu^{\mathcal{H}} + D_\mu^{\Sigma} + D_\mu^{\text{base}},$$

so that its displayed curvature is the sum of sector curvatures after the cross commutators have been declared absent or untyped. Product level is a coexistence statement. It is not yet a dynamical coupling between quantum ledger rows, solenoid rows, and metric rows.

Definition 9423.2 (Soldering-level coupling)**.** *A section-bundle description is at* soldering level *when the metric row is not supplied independently of the ledger field. Instead, there is an innovation one-form*

$$\Theta \in \Omega^1(M; \mathcal{E})$$

derived from the ledger field, and the metric is read as

$$g_{\mu\nu} = G_{AB}\Theta_\mu^A \Theta_\nu^B.$$

The coupling is genuine because a change in the ledger field changes Θ, and a change in Θ changes the metric row.

Principle 9423.3 (Product connection is only a boundary row)**.** *The combined connection row of Definition 9422.14 is a useful boundary syntax, but it is not by itself a unification theorem. If the curvature decomposes as a sectorwise sum, then the rows have been placed in one ambient bookkeeping space without proving that one sector constrains the other. A unification claim requires a row such as Definition 9423.2, where the metric depends on the ledger innovation.*

9423.2 Continuous Innovation Form

Definition 9423.4 (Continuous ledger field)**.** *Let M be a continuous frame base and let*

$$\mathcal{H} \to M$$

be a Hilbert ledger bundle. A continuous ledger field consists of a section

$$B \in \Gamma(\mathcal{H}),$$

a closed ledger subbundle

$$\mathcal{L} \subseteq \mathcal{H},$$

and the orthogonal projection

$$P_{\mathcal{L}} : \mathcal{H} \to \mathcal{L}.$$

The innovation projector is

$$Q_{\mathcal{L}} := I - P_{\mathcal{L}}.$$

Definition 9423.5 (Innovation one-form)**.** *Let D_Φ be a frame-reshaping connection on $\mathcal{H}$. The* innovation one-form *of the ledger field is*

$$\Theta := Q_{\mathcal{L}} D_\Phi B.$$

Equivalently, for $u \in T_x M$,

$$\Theta_x(u) = Q_{\mathcal{L},x}\big(D_{\Phi,u} B\big)(x).$$

Its target bundle is the innovation bundle

$$\mathcal{E} := \mathcal{L}^\perp.$$

Definition 9423.6 (Innovation metric row)**.** *Assume that the innovation bundle $\mathcal{E}$ carries a displayed nondegenerate symmetric bilinear form*

$$G_x : \mathcal{E}_x \times \mathcal{E}_x \to \mathbb{R}.$$

The innovation metric row is

$$g_x(u, v) := G_x(\Theta_x(u), \Theta_x(v)).$$

In local notation,

$$g_{\mu\nu} = G_{AB} \Theta^A_\mu \Theta^B_\nu.$$

Principle 9423.7 (Positive Hilbert norm is not the Lorentz metric)**.** *The Hilbert inner product controls orthogonality and projection in the ledger. It cannot by itself be the Lorentz metric, because it is positive definite. The metric row therefore requires the additional signature data G on the effective innovation bundle. Without that row, one may define a positive quadratic size of an innovation, but not a Lorentzian spacetime metric.*

Theorem 9423.8 (Innovation one-form gives a Lorentz metric)**.** *Assume that, for every $x \in M$, the map*

$$\Theta_x : T_x M \to \mathcal{E}_x$$

is injective and that G_x restricted to $\Theta_x(T_x M)$ is nondegenerate with Lorentz signature. Then

$$g_x(u, v) = G_x(\Theta_x(u), \Theta_x(v))$$

defines a Lorentz metric on M.

Proof. The map Θ_x is linear and G_x is bilinear, so g_x is bilinear. Symmetry of g_x follows from symmetry of G_x. If

$$g_x(u, v) = 0$$

for every $v \in T_xM$, then

$$G_x(\Theta_x(u), \Theta_x(v)) = 0$$

for every v. Nondegeneracy of G_x on $\Theta_x(T_xM)$ gives $\Theta_x(u) = 0$. Injectivity of Θ_x then gives $u = 0$. Thus g_x is nondegenerate, and its signature is the Lorentz signature displayed on the image subspace. □

Theorem 9423.9 (Metric variation factors through ledger innovation)**.** *For*

$$g_{\mu\nu} = G_{AB}\Theta^A_\mu\Theta^B_\nu, \qquad \Theta = Q_{\mathcal{L}}D_\Phi B,$$

a ledger variation $B \mapsto B + \delta B$ induces

$$\delta g_{\mu\nu} = (\delta G_{AB})\Theta^A_\mu\Theta^B_\nu + G_{AB}(\delta\Theta^A_\mu)\Theta^B_\nu + G_{AB}\Theta^A_\mu(\delta\Theta^B_\nu),$$

where

$$\delta\Theta = \delta(Q_{\mathcal{L}}D_\Phi B).$$

If G is fixed, the variation reduces to the symmetric cross term between $\delta\Theta$ and Θ.

Proof. Differentiate the defining expression

$$g_{\mu\nu} = G_{AB}\Theta^A_\mu\Theta^B_\nu.$$

The product rule gives the displayed three terms. The final statement is the same formula with $\delta G = 0$. □

9423.3 Tick Reflection and Pythagorean Coding Closure

Definition 9423.10 (Tick covector and spatial innovation image)**.** *Let*

$$A : M \to \mathbb{R}_{>0}$$

be a displayed multiplicative scale row. Its logarithmic tick coordinate and tick covector are

$$T := \log A, \qquad \tau := dT.$$

At a point x with $\tau_x \neq 0$, set

$$S_x := \ker \tau_x \subset T_xM.$$

The spatial innovation image is

$$E^S_x := \Theta_x(S_x) \subset \mathcal{E}_x.$$

This row is part of the Pythagorean coding closure reading: the scale ledger selects the time co-direction, while the innovation map supplies the orthogonal readout surface.

Definition 9423.11 (Tick residual line and reflection)**.** *Assume* $\operatorname{rank}(\Theta_x|_{S_x}) = 3$*, and let* Π_S^E *be the Hilbert orthogonal projection onto* E_x^S*. For any* $X_x \in T_xM$ *satisfying*

$$\tau_x(X_x) = 1,$$

define the tick residual

$$r_T(x) := (I - \Pi_S^E)\Theta_x(X_x).$$

When $r_T(x) \neq 0$*, the tick residual line is*

$$E_x^T := \mathbb{R}\, r_T(x),$$

and the tick reflection on

$$E_x^4 := E_x^T \oplus E_x^S$$

is

$$J_T := \Pi_T^E - \Pi_S^E,$$

where Π_T^E *is the Hilbert orthogonal projection onto* E_x^T*.*

Lemma 9423.12 (Tick residual line is independent of the lift)**.** *The vector* $r_T(x)$ *of Definition 9423.11 does not depend on the choice of* X_x *satisfying* $\tau_x(X_x) = 1$*.*

Proof. If X_x and X'_x both satisfy

$$\tau_x(X_x) = \tau_x(X'_x) = 1,$$

then

$$\tau_x(X_x - X'_x) = 0.$$

Hence $X_x - X'_x \in S_x$, so

$$\Theta_x(X_x - X'_x) \in E_x^S.$$

Applying $I - \Pi_S^E$ kills this vector, and therefore

$$(I - \Pi_S^E)\Theta_x(X_x) = (I - \Pi_S^E)\Theta_x(X'_x).$$

□

Definition 9423.13 (Lorentzized innovation tensor)**.** *On the four-dimensional innovation image* E_x^4*, define*

$$\mathfrak{Q}_x^T(u, v) := \langle \Theta_x(u), J_T\Theta_x(v)\rangle.$$

Its real and imaginary reads are

$$g_x^T(u, v) := \operatorname{Re}\mathfrak{Q}_x^T(u, v),$$

and

$$F_x^\eta(u, v) := 2\operatorname{Im}\mathfrak{Q}_x^T(u, v).$$

The first row is the Pythagorean metric read; the second row is the phase-curvature read carried by the same innovation tensor.

Theorem 9423.14 (Tick-reflected Gram row has Lorentz signature)**.** *Assume* $\dim M = 4$*,* $\tau_x \neq 0$*,*

$$\operatorname{rank}(\Theta_x|_{\ker \tau_x}) = 3,$$

and $r_T(x) \neq 0$*. Then*

$$g_x^T(u, v) = \operatorname{Re}\langle \Theta_x(u), J_T\Theta_x(v)\rangle$$

is a nondegenerate symmetric bilinear form on T_xM *with signature* $(1, 3)$*.*

Proof. Choose any X_x with $\tau_x(X_x) = 1$. Since $\Pi_S^E \Theta_x(X_x)$ lies in

$$E_x^S = \Theta_x(S_x),$$

there is $s_X \in S_x$ with

$$\Theta_x(s_X) = \Pi_S^E \Theta_x(X_x).$$

Set

$$\mathcal{T}_x := X_x - s_X.$$

Then $\tau_x(\mathcal{T}_x) = 1$ and

$$\Theta_x(\mathcal{T}_x) = r_T(x).$$

Every $u \in T_x M$ decomposes as

$$u = \tau_x(u)\mathcal{T}_x + s, \qquad s \in S_x.$$

Thus

$$\Theta_x(u) = \tau_x(u) r_T + \Theta_x(s),$$

with $r_T \perp E_x^S$. Since J_T is $+I$ on E_x^T and $-I$ on E_x^S,

$$g_x^T(u,u) = \tau_x(u)^2 \|r_T\|^2 - \|\Theta_x(s)\|^2.$$

The first coefficient is positive because $r_T \neq 0$. The second term is negative definite on the three-dimensional spatial image because $\Theta_x|_{S_x}$ has rank 3. Symmetry follows from self-adjointness of J_T. Hence the signature is $(1,3)$. □

Theorem 9423.15 (Real and imaginary rows share one innovation source)**.** *If J_T is self-adjoint, then*

$$\mathfrak{Q}_x^T(v,u) = \overline{\mathfrak{Q}_x^T(u,v)}.$$

Consequently $g_x^T = \operatorname{Re} \mathfrak{Q}_x^T$ is symmetric and $F_x^\eta = 2 \operatorname{Im} \mathfrak{Q}_x^T$ is antisymmetric.

Proof. By definition,

$$\mathfrak{Q}_x^T(u,v) = \langle \Theta_x(u), J_T \Theta_x(v) \rangle.$$

Self-adjointness of J_T gives

$$\langle \Theta_x(v), J_T \Theta_x(u) \rangle = \overline{\langle \Theta_x(u), J_T \Theta_x(v) \rangle}.$$

Taking real and imaginary parts gives the stated symmetry and antisymmetry rows. □

Principle 9423.16 (Pythagorean coding closure boundary)**.** *Pythagorean coding closure is the local synthesis*

$$\Theta = Q_{\mathcal{L}} D_\Phi B, \qquad T = \log A, \qquad J_T, \qquad \mathfrak{Q}_{\mu\nu}^T = \langle Q_{\mathcal{L}} D_{\Phi,\mu} B, J_T Q_{\mathcal{L}} D_{\Phi,\nu} B \rangle.$$

Its real part gives the triangle/metric row, and its imaginary part gives the circle/phase-curvature row. Prime and solenoid ledgers affect this geometry only when they enter B, D_Φ, $Q_{\mathcal{L}}$, or the tick scale A; otherwise they remain hidden fibre data without metric-level force.

9423.4 Discrete Stencils and Cartan Boundary

Definition 9423.17 (Discrete innovation stencil)**.** *Let x be a frame vertex and let*

$$e_a : x \to x_a \qquad (a = 0, 1, 2, 3)$$

be four displayed independent local edges. With reshaping rows

$$\Phi_{x_a \leftarrow x} : \mathcal{H}_x \to \mathcal{H}_{x_a},$$

define the edge innovation

$$\eta_a(x) := Q_{x \to x_a}(B_{x_a} - \Phi_{x_a \leftarrow x} B_x).$$

The discrete innovation Gram row is

$$g_{ab}(x) := G(\eta_a(x), \eta_b(x)).$$

When this matrix is nondegenerate with Lorentz signature, it is the local discrete metric row at x.

Principle 9423.18 (One tick is not a four-dimensional metric)**.** *A single OCLSD residual supplies one innovation direction. A four-dimensional metric requires a local stencil of independent directions or a continuous tangent map $\Theta_x : T_x M \to \mathcal{E}_x$. Thus the passage from ledger innovation to metric is not obtained by renaming one residual as a metric. It requires the displayed soldering rank and signature rows.*

Definition 9423.19 (Innovation-soldered Cartan row)**.** *An innovation-soldered Cartan row is a schematic connection*

$$\mathcal{A} = \omega^{ab} J_{ab} + \ell^{-1} \Theta^a P_a + A + \mathcal{A}^\Sigma,$$

where Θ is the innovation one-form of Definition 9423.5. Its curvature is

$$\mathcal{F} = d\mathcal{A} + \mathcal{A} \wedge \mathcal{A}.$$

In the Cartan sector, the displayed torsion row is

$$T^a = D_\omega \Theta^a,$$

and the de Sitter-style curvature row contains

$$R^{ab} + \ell^{-2} \Theta^a \wedge \Theta^b.$$

These rows are the schematic boundary where soldering produces cross-terms absent from a product connection.

Principle 9423.20 (Solenoid coupling must enter the innovation row)**.** *The solenoid fibre is geometrically active only if its prime-register rows enter the innovation one-form, the connection used to define it, or the signature data used to read it. A hidden fibre that remains visible only through*

$$\pi_S : \Sigma_S \to \mathbb{T}$$

is still kernel-blind at the metric level. A geometry-facing solenoid coupling must therefore be represented by rows of the form

$$D_{\Phi,\Sigma} B \qquad \text{or} \qquad \Theta(B, Z_\Sigma),$$

not merely by adjoining $L^2(\Sigma_S)$ to the fibre.

9423.5 Twisted-Holonomy Backreaction: A Degenerate Channel

Principle 9423.21 (Rank-one twisted-holonomy backreaction is metric-degenerate)**.** *Consider the schematic twisted-holonomy backreaction channel on a two-torus $\mathbb{T}^2$, in which a solenoid ledger is asked to react back on an emergent metric row through a single innovation displacement $\Delta = (\Delta x, \Delta y)$ read against a scalar weight $w_1 w_2$. The displayed metric components take the outer-product form*

$$g_{\mu\nu} = w_1 w_2 \, \Delta_\mu \Delta_\nu,$$

so that

$$g_{xx} = w_1 w_2 \, \Delta x \, \Delta x, \quad g_{xy} = w_1 w_2 \, \Delta x \, \Delta y, \quad g_{yx} = w_1 w_2 \, \Delta y \, \Delta x, \quad g_{yy} = w_1 w_2 \, \Delta y \, \Delta y.$$

This is the outer product of the two-vector Δ with itself scaled by $w_1 w_2$; its rank is at most one, hence the two-by-two determinant vanishes identically:

$$\det g = g_{xx} g_{yy} - g_{xy} g_{yx} = (w_1 w_2)^2 (\Delta x \, \Delta x \, \Delta y \, \Delta y - \Delta x \, \Delta y \, \Delta y \, \Delta x) = 0.$$

A degenerate row ($\det g = 0$) admits no inverse, hence no curvature invariant, so this schematic channel does not read out a nondegenerate two-dimensional geometry. This is an honest negative and falsifiable outcome, not a suppressed obstacle: the rank-one twisted-holonomy backreaction row is exactly the failure mode that Definition 9423.18 anticipates, where a single innovation direction is renamed as a metric. Because the degeneracy is forced by the outer-product shape rather than by any prime-register content of the solenoid, the channel does not privilege the solenoid structure: the same rank-one row is produced by a continuous $\mathrm{U}(1)$ flat bundle carrying the same single displacement. The wording here is schematic and asserts no physical metric; it records only that this particular backreaction row cannot supply the nondegenerate signature demanded by Definition 9423.6.

Lean4 (statement) `BEDC.Derived.Visions.backreaction metric det zero`

Principle 9423.22 (Two independent drivers restore metric nondegeneracy)**.** *The rank-one degeneracy of Definition 9423.21 is not the end of the schematic backreaction story but its exact lower boundary; the present principle is the constructive companion that locates where a nondegenerate row first becomes available. Replace the single innovation displacement by two schematic relative-holonomy drivers $\Delta^{(1)} = (\Delta_x^{(1)}, \Delta_y^{(1)})$ and $\Delta^{(2)} = (\Delta_x^{(2)}, \Delta_y^{(2)})$ read against positive scalar weights w_1, w_2, and form the weighted sum of the two outer-product rows:*

$$g_{\mu\nu} = w_1 \, \Delta_\mu^{(1)} \Delta_\nu^{(1)} + w_2 \, \Delta_\mu^{(2)} \Delta_\nu^{(2)}.$$

Each summand is individually rank-one, but the two-by-two determinant of the sum is governed by the Cauchy–Binet identity and collapses to a single wedge square:

$$\det g = w_1 w_2 \, (\Delta^{(1)} \wedge \Delta^{(2)})^2, \qquad \Delta^{(1)} \wedge \Delta^{(2)} = \Delta_x^{(1)} \Delta_y^{(2)} - \Delta_y^{(1)} \Delta_x^{(2)}.$$

With w_1, w_2 nonzero this determinant vanishes if and only if the wedge does, that is, if and only if the two drivers are linearly dependent; whenever $\Delta^{(1)}$ and $\Delta^{(2)}$ are linearly independent the row is nondegenerate, admits an inverse, and can carry a curvature invariant. This delineates the precise boundary of what a schematic backreaction channel can hand to geometry: a single driver is forced to be degenerate (Definition 9423.21), while any two linearly independent relative-holonomy drivers already suffice for a nondegenerate emergent two-dimensional row — one is never enough, two independent are always enough. The wording remains schematic and asserts no physical metric

or dynamics; it records only the finite algebraic fact that the wedge of two independent drivers is exactly the resource the rank-one channel was missing, so the honest negative of Definition 9423.21 is paired with an equally honest constructive sufficiency at the two-driver threshold.
Lean4 (statement) `BEDC.Derived.Visions.two driver det eq weighted wedge sq`

Principle 9423.23 (Innovation-soldering proof boundary)**.** *The chapter supplies the formal target for a genuine ledger-geometry coupling: construct $\Theta = Q_{\mathcal{L}} D_{\Phi} B$, prove the required rank and Lorentz-signature rows, and then read the metric through $g = G(\Theta, \Theta)$. It does not derive Einstein dynamics, empirical matter coupling, or quantum gravity. Those claims would require field equations and action rows in which variation of the ledger field changes the induced metric and curvature.*

Concretized in §9149: The finite NameCert carrier records the ledger-innovation-projector-soldering-signature-metric interface and its Nontrivial and FieldFaithful instance requirements.

Chapter 9424

Innovation Input-Flow Geometry Boundary

chapter 9423 identifies the orthogonal innovation one-form as the first genuine coupling row between a ledger field and a metric-facing read. This chapter records the adjacent boundary: the positive Hilbert Gram row, the tick-reflected signature row, and the reflection-positive input-flow row are distinct certificates. They may be compatible, but none may be substituted for another without an explicit bridge.

9424.1 Discrete Ledger Source

Definition 9424.1 (One-step ledger comparison)**.** *A one-step ledger comparison consists of Hilbert rows $\mathcal{H}_n$, $\mathcal{H}_{n+1}$, ledger subspaces $\mathcal{L}_n \subseteq \mathcal{H}_n$, $\mathcal{L}_{n+1} \subseteq \mathcal{H}_{n+1}$, a section row $B_n \in \mathcal{H}_n$, and an isometric reshaping row*

$$\Phi_{n+1,n} : \mathcal{H}_n \to \mathcal{H}_{n+1}.$$

Let $P_n^{\uparrow}$ be the orthogonal projection onto $\Phi_{n+1,n}(\mathcal{L}_n)$. The one-step innovation residual is

$$\eta_{n+1} := B_{n+1} - P_n^{\uparrow} B_{n+1}.$$

Theorem 9424.2 (Orthogonal admission law)**.** *For every one-step ledger comparison,*

$$\eta_{n+1} \perp \Phi_{n+1,n}(\mathcal{L}_n)$$

and

$$\|B_{n+1}\|^2 = \|P_n^{\uparrow} B_{n+1}\|^2 + \|\eta_{n+1}\|^2.$$

If $B_n \in \mathcal{L}_n$ and $P_n^{\uparrow} B_{n+1} = \Phi_{n+1,n} B_n$, then

$$\|B_{n+1}\|^2 = \|B_n\|^2 + \|\eta_{n+1}\|^2.$$

Proof. The residual $B - PB$ of an orthogonal projection is orthogonal to the range of P. The norm identity is the Pythagorean identity for the orthogonal decomposition $B_{n+1} = P_n^{\uparrow} B_{n+1} + \eta_{n+1}$. The final statement uses the isometry of $\Phi_{n+1,n}$. □

Definition 9424.3 (Logarithmic tick read)**.** *For a ledger comparison with $B_n \neq 0$, the logarithmic tick read is*

$$T_n := \log \|B_n\|^2.$$

Under the compatibility row of Definition 9424.2,

$$T_{n+1} - T_n = \log\left(1 + \frac{\|\eta_{n+1}\|^2}{\|B_n\|^2}\right).$$

Theorem 9424.4 (Continuous innovation is the first-order residual)**.** *Let $\mathcal{H} \to M$ be a Hilbert bundle with a metric connection D_Φ, let $\mathcal{L} \subseteq \mathcal{H}$ be a closed ledger subbundle, and let P_x and $Q_x = I - P_x$ be the fibrewise orthogonal projections. Transport $B(x+\varepsilon u)$ back to $\mathcal{H}_x$ along D_Φ. If $B_x \in \mathcal{L}_x$, then*

$$\lim_{\varepsilon\to 0} \varepsilon^{-1} Q_x B(x+\varepsilon u) = Q_x (D_{\Phi,u} B)_x.$$

If $B_x \notin \mathcal{L}_x$, the unscaled term $Q_x B_x$ remains visible, so the scaled residual does not define a linear tangent read.

Proof. The connection gives the first-order expansion

$$B(x+\varepsilon u) = B_x + \varepsilon (D_{\Phi,u} B)_x + O(\varepsilon^2)$$

after transport to $\mathcal{H}_x$. Applying Q_x gives

$$Q_x B(x+\varepsilon u) = Q_x B_x + \varepsilon Q_x (D_{\Phi,u} B)_x + O(\varepsilon^2).$$

The condition $B_x \in \mathcal{L}_x$ is exactly $Q_x B_x = 0$. □

Definition 9424.5 (Quantized refinement edge)**.** *A quantized refinement edge has a finite cell set C_n, a refinement factor $N \geq 2$, an isometric split*

$$e_c \longmapsto N^{-1/2} \sum_{a=0}^{N-1} e_{ca},$$

and a fixed modulus $\varepsilon > 0$ such that each displayed cell coefficient of B_n and B_{n+1} has modulus ε.

Theorem 9424.6 (Refinement residual rate)**.** *For a quantized refinement edge satisfying the compatibility row $P_n^{\uparrow} B_{n+1} = \Phi_{n+1,n} B_n$,*

$$\frac{\|\eta_{n+1}\|^2}{\|B_n\|^2} = N - 1, \qquad T_{n+1} - T_n = \log N.$$

Proof. If $|C_n| = A_n$, then

$$\|B_n\|^2 = \varepsilon^2 A_n, \qquad \|B_{n+1}\|^2 = \varepsilon^2 N A_n.$$

Definition 9424.2 gives $\|\eta_{n+1}\|^2 = \varepsilon^2 (N-1) A_n$. Dividing by $\|B_n\|^2$ gives the residual rate, and the logarithmic identity gives the tick length. □

9424.2 Positive Innovation Gram Row

Definition 9424.7 (Innovation Gram tensor)**.** *Let $\Theta = Q_{\mathcal{L}} D_\Phi B$ be the innovation one-form of Definition 9423.5. Its positive innovation Gram tensor is*

$$\chi_x^\eta(u,v) := \langle \Theta_x(u), \Theta_x(v) \rangle$$

for $u, v \in T_x M$. Its real and imaginary reads are

$$h_x^\eta(u,v) := \operatorname{Re} \chi_x^\eta(u,v), \qquad \Omega_x^\eta(u,v) := 2 \operatorname{Im} \chi_x^\eta(u,v).$$

Theorem 9424.8 (Positive Gram constraint)**.** *For any finite family $u_1, \dots, u_n \in T_xM$, the matrix*

$$\chi^\eta_{ij} := \chi^\eta_x(u_i, u_j)$$

is Hermitian positive semidefinite. Consequently h^η is symmetric positive semidefinite, Ω^η is antisymmetric, and every pair $u, v \in T_xM$ satisfies

$$h^\eta(u,u)h^\eta(v,v) \geq h^\eta(u,v)^2 + \frac{1}{4}\Omega^\eta(u,v)^2.$$

Proof. For coefficients $c_i \in \mathbb{C}$,

$$\sum_{i,j} \overline{c_i}\chi^\eta_{ij}c_j = \left\| \sum_i c_i \Theta_x(u_i) \right\|^2 \geq 0.$$

This proves positive semidefiniteness and Hermitian symmetry. The real and imaginary symmetry rows follow by taking real and imaginary parts. The displayed inequality is the nonnegativity of the 2×2 principal minor associated to u and v. □

Principle 9424.9 (Positive size is not Lorentz signature)**.** *The row χ^η gives a Hilbert-size certificate. Its real part is nonnegative by construction. A Lorentz-facing row therefore requires an additional signature certificate, such as the displayed bilinear form G of Definition 9423.6, the tick reflection J_T of Definition 9423.11, or a reflection-positive input-flow reconstruction as in section 9424.4. The positive Gram row alone cannot carry the time-side sign.*

9424.3 Phase Packets and Curvature Budget

Definition 9424.10 (Constant-modulus phase packet)**.** *A constant-modulus phase packet over a local coordinate window consists of orthonormal component rows e_a, positive weights w_a with $\sum_a w_a = 1$, fixed covectors κ_a, and the ray-ledger field*

$$B(z) = \sum_a c_a e^{i\kappa_a \cdot z} e_a, \qquad |c_a|^2 = w_a,$$

with ledger subbundle $\mathbb{C}B$.

Theorem 9424.11 (Constant-modulus packets give covariance geometry)**.** *For a constant-modulus phase packet,*

$$\chi^\eta_{\mu\nu} = \sum_a w_a \kappa_{a\mu}\kappa_{a\nu} - \bar\kappa_\mu \bar\kappa_\nu, \qquad \bar\kappa_\mu := \sum_a w_a \kappa_{a\mu}.$$

Thus h^η is the covariance matrix of the displayed covectors and $\Omega^\eta = 0$.

Proof. The derivative of the ath component is $i\kappa_{a\mu}c_a e^{i\kappa_a \cdot z}$. Hence

$$\langle B, \partial_\nu B\rangle = i\bar\kappa_\nu, \qquad \langle \partial_\mu B, \partial_\nu B\rangle = \sum_a w_a \kappa_{a\mu}\kappa_{a\nu}.$$

Projecting away the ray $\mathbb{C}B$ subtracts $\bar\kappa_\mu\bar\kappa_\nu$. The result is real, so the imaginary curvature read is zero. □

Corollary 9424.12 (Constant-modulus rank budget)**.** *If a constant-modulus phase packet has r displayed components, then*

$$\operatorname{rank} h^\eta \leq r - 1.$$

A nondegenerate d-dimensional covariance read of this kind therefore requires $r \geq d + 1$.

Proof. The centered covectors $\kappa_a - \bar{\kappa}$ satisfy

$$\sum_a w_a(\kappa_a - \bar{\kappa}) = 0.$$

They span at most an $(r-1)$-dimensional real space, and the covariance matrix is their weighted Gram matrix. □

Example 9424.13 (Simplex covariance witness)**.** *Let $r = d+1$ and choose $\kappa_1, \ldots, \kappa_{d+1} \in \mathbb{R}^d$ as the vertices of a regular simplex centered at 0, with equal weights. Then*

$$\sum_a w_a \kappa_a = 0$$

and

$$\sum_a w_a \kappa_a \kappa_a^{\mathsf{T}} = cI_d$$

for some $c > 0$. Hence the constant-modulus covariance read is nondegenerate. The rank budget of Definition 9424.12 is therefore sharp for this packet class.

Definition 9424.14 (Variable-weight phase packet)**.** *A variable-weight phase packet keeps the fixed covectors κ_a but allows positive smooth weights $w_a(z)$ with $\sum_a w_a(z) = 1$:*

$$B(z) = \sum_a \sqrt{w_a(z)} e^{i\kappa_a \cdot z} e_a.$$

Theorem 9424.15 (Variable weights split metric and curvature)**.** *For a variable-weight phase packet,*

$$h^{\eta}_{\mu\nu} = \frac{1}{4} \sum_a \frac{\partial_\mu w_a \, \partial_\nu w_a}{w_a} + \sum_a w_a(\kappa_{a\mu} - \bar{\kappa}_\mu)(\kappa_{a\nu} - \bar{\kappa}_\nu),$$

and

$$\Omega^{\eta}_{\mu\nu} = \partial_\mu \bar{\kappa}_\nu - \partial_\nu \bar{\kappa}_\mu, \qquad \bar{\kappa}_\mu(z) := \sum_a w_a(z) \kappa_{a\mu}.$$

Thus the real row splits into a Fisher-information row and a covariance row, while the phase-curvature row is the exterior derivative of the mean covector read.

Proof. The ath component derivative is

$$\partial_\mu B_a = \left(\frac{\partial_\mu w_a}{2\sqrt{w_a}} + i\kappa_{a\mu}\sqrt{w_a} \right) e^{i\kappa_a \cdot z}.$$

Since $\sum_a w_a = 1$, one has

$$\langle B, \partial_\nu B \rangle = i\bar{\kappa}_\nu.$$

Expanding $\langle \partial_\mu B, \partial_\nu B \rangle$ and subtracting the ray component gives the displayed real part. The imaginary part is

$$\frac{1}{2} \sum_a \left(\partial_\mu w_a \, \kappa_{a\nu} - \partial_\nu w_a \, \kappa_{a\mu} \right),$$

whose double is $\partial_\mu \bar{\kappa}_\nu - \partial_\nu \bar{\kappa}_\mu$. □

Principle 9424.16 (Curvature requires the correct packet class)**.** *Constant-modulus phase packets carry covariance geometry but no phase curvature. Variable-weight packets can carry an exact mean-covector curvature row. A nontrivial topological phase read therefore cannot be inferred from a bare constant-modulus covariance packet; it requires the displayed packet class to carry the relevant amplitude, winding, or holonomy data.*

Example 9424.17 (Two-component coherent surface)**.** *On a coordinate window with variables (ϑ, φ), consider the ray-ledger field*

$$B(\vartheta, \varphi) = \cos\frac{\vartheta}{2}\, e_0 + e^{i\varphi} \sin\frac{\vartheta}{2}\, e_1.$$

For the ray ledger $\mathbb{C}B$, direct computation gives

$$h^\eta = \frac{1}{4}\, d\vartheta^2 + \frac{1}{4} \sin^2\vartheta\, d\varphi^2$$

and

$$\Omega^\eta = \frac{1}{2} \sin\vartheta\, d\vartheta \wedge d\varphi.$$

Thus

$$\det h^\eta = \frac{1}{4}(\Omega^\eta_{\vartheta\varphi})^2$$

on the regular part. A two-component packet can therefore carry a nondegenerate two-dimensional metric read with phase curvature when the packet class contains the relevant variable amplitude and winding data.

Principle 9424.18 (Rank budgets are packet-relative)**.** *The simplex bound $r \geq d + 1$ belongs to constant-modulus covariance packets, where the real centered covectors are the only rank resource. The coherent-surface example shows that the same numerical bound is not a general law for all ray-ledger packets. The invariant law that survives all packet choices is the positive Gram constraint of Definition 9424.8; sharper rank budgets must state their packet class.*

9424.4 Reflection-Positive Input Flow

Definition 9424.19 (Reversible finite input flow)**.** *A reversible finite input flow consists of a finite state set E, a strictly positive stationary distribution π, and a transition kernel $p(x, y)$ satisfying detailed balance:*

$$\pi(x)p(x, y) = \pi(y)p(y, x).$$

Let P be the induced self-adjoint operator on $L^2(\pi)$.

Definition 9424.20 (Reflection-positive input row)**.** *Let $(d_n)_{n\in\mathbb{Z}}$ be the stationary two-sided chain of Definition 9424.19. Let $\mathcal{K}_+$ be the future algebra generated by $d_1, d_2, \ldots$, and let θ be the reflection sending d_n to d_{1-n}. The input row is reflection-positive when*

$$\langle \theta F, F\rangle \geq 0$$

for every $F \in \mathcal{K}_+$.

Theorem 9424.21 (Reflection positivity is transition positivity)**.** *For $F, G \in \mathcal{K}_+$ define*

$$h_F(x) := \mathbb{E}[F \mid d_1 = x].$$

Then

$$\langle \theta F, G \rangle = \langle h_F, P h_G \rangle_{L^2(\pi)}.$$

Since every $h \in L^2(\pi)$ is h_F for $F = h(d_1)$, reflection positivity holds exactly when P is positive semidefinite.

Proof. Given d_0, the past and future of a Markov chain are conditionally independent. Detailed balance identifies the conditional law of the reflected future with the conditional law read from the boundary state. Thus

$$\mathbb{E}[\overline{\theta F} G] = \sum_x \pi(x) \overline{h_F(x)} (P h_G)(x).$$

The final equivalence follows by taking $F = h(d_1)$. □

Example 9424.22 (Two-state reflection boundary)**.** *Let $E = \{0, 1\}$ with stationary distribution $(1/2, 1/2)$ and transition matrix*

$$P = \begin{pmatrix} 1-q & q \\ q & 1-q \end{pmatrix}.$$

The eigenvalues are 1 and $1 - 2q$. Hence the input row is reflection-positive exactly when $q \le 1/2$. For $q > 1/2$, the function $f(0) = 1$, $f(1) = -1$ satisfies

$$\langle f, Pf \rangle_{L^2(\pi)} = (1 - 2q) \|f\|^2_{L^2(\pi)} < 0,$$

so the reflected inner product is negative on a future observable.

Corollary 9424.23 (Positive Hamiltonian row)**.** *If $0 \preceq P \preceq I$ and the tick length is $\Delta T > 0$, then the nonzero spectral part carries*

$$H := -\frac{1}{\Delta T} \log P \succeq 0, \qquad e^{-\Delta T H} = P.$$

The unitary row e^{-itH} is then obtained by spectral calculus. If P has a negative spectral value, no self-adjoint H can satisfy $e^{-\Delta T H} = P$ on that spectral part.

Proof. The logarithm of a positive contraction is a nonpositive self-adjoint operator on the nonzero spectral subspace, so H is positive and the exponential identity follows. Conversely, the exponential of a self-adjoint operator has positive spectrum. □

Example 9424.24 (Nearest-neighbour diffusion witness)**.** *On a one-dimensional periodic lattice with spacing ℓ, take the translation-invariant transition row with jumps $-\ell$, 0, and $+\ell$ of probabilities q, $1 - 2q$, and q. Its Fourier multiplier is*

$$\widehat{P}(k) = 1 - 2q(1 - \cos(k\ell)).$$

For $q \le 1/4$, this multiplier is nonnegative for every k, so the reflection-positive row is present. With tick length ΔT, the Hamiltonian multiplier satisfies

$$H(k) = -\Delta T^{-1} \log \widehat{P}(k) = \frac{q\ell^2}{\Delta T} k^2 + O(k^4 \ell^4)$$

near $k = 0$. The low-momentum inverse-metric read is therefore the per-tick displacement variance divided by ΔT:

$$g^{xx} = \frac{2q\ell^2}{\Delta T}.$$

Principle 9424.25 (Two metric engines)**.** *The covariance read h^η and the diffusion read g^{xx} arise from different rows. The former is a kinematic Gram construction from $\Theta = Q_{\mathcal{L}} D_\Phi B$; the latter is a low-momentum read of $-\log P$ from an input-flow transition operator. Identifying them is an additional bridge obligation, not a consequence of either row alone.*

9424.5 Interface Separation

Principle 9424.26 (Three non-interchangeable certificates)**.** *The innovation programme carries three separate certificates:*

$$\chi^\eta(u,v) = \langle \Theta(u), \Theta(v) \rangle,$$
$$g^T(u,v) = \mathrm{Re}\langle \Theta(u), J_T \Theta(v) \rangle,$$

and

$$P \succeq 0, \qquad H = -\Delta T^{-1} \log P.$$

The first is the positive Hilbert Gram certificate, the second is the pointwise tick-reflected signature certificate, and the third is the input-flow certificate for reflection positivity and Hamiltonian reconstruction. A physical bridge must state which certificate it uses and which comparison rows identify them.

Principle 9424.27 (Prime-register data must reach a visible row)**.** *Prime-register or solenoid data affect the geometry-facing interface only when they enter B, D_Φ, $Q_{\mathcal{L}}$, the scale row used for ΔT, or the transition operator P. A prime fibre that remains visible only through a projected phase is kernel-blind at the metric level, as in Definition 9423.20.*

Principle 9424.28 (Geometry boundary)**.** *The boundary recorded here is a translation interface from ledger rows to metric-facing and dynamics-facing certificates. It does not assert field equations, empirical matter coupling, a completed quantum-gravity model, or a proof that the tick-reflected and reflection-positive routes determine the same propagation cone. Those are bridge obligations, not consequences of the positive innovation Gram row.*

Chapter 9425

Innovation Input Lineage and Self-Reference Boundary

chapter 9424 records the positive Gram, tick-reflection, and reflection-positive transition certificates of an input-flow geometry. This chapter records the adjacent lineage and self-reference boundary. The quantized refinement row is a single-particle isometric refinement walk with an external input stream; it has precise interfaces with quantum walks, multiresolution analysis, tensor-network isometries, and quantum cellular automata, but it is not identical to any of those structures without further data. Closing the input by a self-substitution rule produces a sharp cost: the binary compatible rule is unique up to mirror exchange and carries an intrinsic time arrow. Enlarging the alphabet separates compatibility from that forced arrow: the binary row is a rigid endpoint, while ternary and square alphabet rows admit reversible compatible witnesses. The common grammar is the phase-polygon equation for Q3 compatibility.

9425.1 Lineage of the Refinement Row

Principle 9425.1 (Single-particle refinement walk)**.** *The quantized refinement edge of Definition 9424.5 is best located as an isometric quantum walk on a growing refinement structure, together with an external input stream. Its cells are basis vectors in $\ell^2(C_n)$, not tensor factors. This separates the certificate from the standard quantum-cellular-automaton setting, where locality and index theorems live in a tensor-product operator algebra.*

Principle 9425.2 (Quantum-cellular-automaton boundary)**.** *A genuine quantum cellular automaton can have a one-particle sector that resembles a quantum walk. The converse is an additional construction problem: one must supply a tensor-factor state space, a local unitary or local isometry rule, and a functorial projection whose one-particle sector is the displayed refinement edge. The input-flow certificate therefore defines a target for such a parent automaton, not the parent automaton itself.*

Principle 9425.3 (Multiresolution and wavelet skeleton)**.** *The refinement isometry*

$$e_c \longmapsto N^{-1/2} \sum_{a=0}^{N-1} e_{ca}$$

is the finite-cell analogue of a Haar scaling relation. The scale chain is the multiresolution chain, and the innovation residual is the wavelet-detail row. The input-flow contribution is not the existence of this scaling skeleton; it is the quantized modulus row, the compatibility equation, and the

resulting norm allocation

$$\frac{\|\eta_{n+1}\|^2}{\|B_n\|^2} = N - 1.$$

Principle 9425.4 (Tensor-network interface)**.** *Layered isometries without disentanglers form the bare skeleton of a multiscale tensor network. To obtain a tensor-network dynamics rather than a single-particle refinement ledger, one must add tensor factors, entangling gates or disentanglers, and a rule for how the input stream acts on many-body states. The free-field reconstruction rows of chapter 9448 already use a second-quantized output of the machine; the missing data are local tensor rules, not merely many-body vocabulary.*

Principle 9425.5 (Lineage ledger)**.** *The same displayed refinement row has four neighboring descriptions: quantum walk on a growing graph, Haar multiresolution scaling, a bare isometric tensor-network skeleton, and the one-particle shadow of a possible quantum cellular automaton. These are lineage pointers. None of them changes the certificate used by Definition 9424.6 or the reflection-positive boundary of Definition 9424.21.*

9425.2 Self-Substitution Input

Definition 9425.6 (Binary self-substitution row)**.** *A binary self-substitution row closes the input by requiring each refined cell to inherit its parent phase through two fixed unit phases:*

$$u_{c0} = a\, u_c, \qquad u_{c1} = b\, u_c, \qquad |a| = |b| = 1.$$

It is compatible with the quantized refinement condition when the coarse-grained phase sum satisfies

$$a + b = \sqrt{2}.$$

Theorem 9425.7 (Binary compatible self-substitution)**.** *The binary self-substitution row satisfies the compatibility equation $a + b = \sqrt{2}$ if and only if*

$$\{a, b\} = \{e^{i\pi/4}, e^{-i\pi/4}\}.$$

Thus the compatible binary self-substitution rule is unique up to mirror exchange.

Proof. Let $a = e^{i\alpha}$ and $b = e^{i\beta}$. The condition that $a + b$ is the positive real number $\sqrt{2}$ forces the average angle to be 0 modulo 2π and the chord length to be $\sqrt{2}$. Hence the two angles are $+\pi/4$ and $-\pi/4$ up to exchange. □

Principle 9425.8 (Boundary cases)**.** *The equal-phase rule $a = b$ gives no innovation under the binary compatibility equation, while the opposite-phase rule $a = -b$ gives no retained coarse component. These two familiar substitution boundaries fail opposite sides of the refinement compatibility row. The compatible rule of Definition 9425.7 sits between them.*

Definition 9425.9 (One-step circular correlation)**.** *For a binary self-substitution row set*

$$\gamma(1) := \frac{b\overline{a}}{2 - a\overline{b}}.$$

This row records the first circular correlation of the induced phase measure.

Theorem 9425.10 (Self-substitution time arrow)**.** *For the compatible binary self-substitution rule,*

$$\gamma(1) = \frac{1-2i}{5}.$$

In particular the circular correlation is not real. The self-substitution input is therefore not time-reversal symmetric in this correlation row.

Proof. Choose the ordered representative $a = e^{i\pi/4}$ and $b = e^{-i\pi/4}$. Then $b\overline{a} = -i$ and $a\overline{b} = i$, so

$$\gamma(1) = \frac{-i}{2-i} = \frac{1-2i}{5}.$$

Mirror exchange conjugates the value and reverses the arrow. □

Principle 9425.11 (Self-reference cost)**.** *Closing the input by a binary self-substitution rule removes the arbitrary external digit choice only by moving choice into a structural rule. The compatible rule is rigid, and its circular correlation carries an intrinsic orientation. Perfectly symmetric self-copying lies on the zero-innovation boundary; compatible self-substitution has innovation but carries a time arrow.*

Principle 9425.12 (Spectral and metric rows of the self-substitution)**.** *The compatible binary self-substitution row has singular-continuous spectral behavior in its phase measure and a well-defined QGT metric row. The numerical ledger records a convergent metric value near*

$$h = 2.77243,$$

below the uniform baseline $\pi^2/3$. Its linear mean covector tends to zero, while the first circular mean remains nonzero, with modulus about 0.447 and angle about -63.4° in the displayed orientation. These data place the arrow in the circular holonomy layer rather than in a nonzero ordinary mean momentum.

Principle 9425.13 (Reflection-positive boundary of the self-substitution)**.** *The self-substitution row is a deterministic substitution input, not a reversible Markov input with a positive transition operator. It therefore does not automatically belong to the reflection-positive class of Definition 9424.21. Any Lorentz-facing use of this row must first supply a positive transition certificate or a separate Wick-facing bridge.*

9425.3 Phase-Polygon Compatibility

Definition 9425.14 (Self-substitution phase word)**.** *For a quantized refinement edge with factor N, an N-ary self-substitution phase word is a tuple*

$$v = (v_0, \ldots, v_{N-1}) \in \mathbb{T}^N.$$

It closes the refined phases by the rule

$$u_{ca} = v_a u_c$$

for every parent cell c and child index a. The resulting refined block over c is

$$\varepsilon u_c \sum_{a=0}^{N-1} v_a e_{ca}.$$

Theorem 9425.15 (Q3 phase-polygon equation)**.** *An N-ary self-substitution phase word satisfies the compatibility row $P_n^{\uparrow} B_{n+1} = \Phi_N B_n$ if and only if*

$$\sum_{a=0}^{N-1} v_a = \sqrt{N}.$$

The right side is the positive real representative fixed by the chosen coarse phase convention.

Proof. For a fixed parent cell c, write

$$\phi_c = N^{-1/2} \sum_{a=0}^{N-1} e_{ca}.$$

The refined block is

$$b_c = u_c \sum_{a=0}^{N-1} v_a e_{ca}.$$

Its projection onto the old lifted line $\mathbb{C}\phi_c$ has coefficient

$$\langle \phi_c, b_c \rangle = \frac{u_c}{\sqrt{N}} \sum_{a=0}^{N-1} v_a.$$

Thus $P^{\uparrow} b_c = u_c \phi_c$ for every parent cell if and only if the displayed phase sum is $\sqrt{N}$. □

Corollary 9425.16 (Self-substitution residual rate)**.** *Every Q3-compatible N-ary self-substitution phase word has residual rate*

$$\frac{\|\eta_{n+1}\|^2}{\|B_n\|^2} = N - 1.$$

Proof. Each parent block has norm square $N\varepsilon^2$, while its old lifted projection has norm square ε^2 by Definition 9425.15. Orthogonality of the projection residual gives block residual norm square $(N-1)\varepsilon^2$. Summing over the A_n parent cells and dividing by $\|B_n\|^2 = A_n \varepsilon^2$ gives the formula. □

Definition 9425.17 (Phase correlation row)**.** *For a self-substitution phase sequence u_n, define the two-point correlation, when the Cesaro limit exists, by*

$$\gamma(m) := \lim_{L\to\infty} \frac{1}{L} \sum_{n=0}^{L-1} u_{n+m} \overline{u_n}.$$

A real-valued correlation row is a necessary audit for time-reversal symmetry at the two-point phase level.

Theorem 9425.18 (Ternary real correlation recursion)**.** *For the ternary phase word*

$$A = e^{i\pi/6}, \qquad B = e^{-i\pi/2}, \qquad (v_0, v_1, v_2) = (A, B, A),$$

the correlations satisfy

$$\gamma(3m) = \gamma(m),$$

$$\gamma(3m+1) = \frac{1}{3}\big(-\gamma(m) + \gamma(m+1)\big),$$

and

$$\gamma(3m+2) = \frac{1}{3}\big(\gamma(m) - \gamma(m+1)\big).$$

Consequently every $\gamma(m)$ is real.

Proof. The identities $B\overline{A} + A\overline{B} = -1$ and $A\overline{A} = 1$ are immediate. Splitting the Cesaro average into the three residue classes of n modulo 3 gives the displayed recursions. The initial value is $\gamma(0) = 1$, and the one-step relation gives $\gamma(1) = -1/2$. The recursion expresses each later value as a real linear combination of smaller-index values, so induction gives $\gamma(m) \in \mathbb{R}$ for all m. □

9425.4 Externality Displacement

Principle 9425.19 (Externality displacement)**.** *The input-flow framework begins by externalizing digit choice. Attempts to close that choice move the externality to another row rather than removing it. A self-substitution rule moves it to the structural rule and pays with an intrinsic time arrow. A complex-refinement self-observation row moves it to the choice of complex multiplication structure and pays with an arithmetic admissibility condition. A thermodynamic-gravity assembly moves it to local equilibrium data, as recorded in Definition 9448.30. Each move leaves a theorem-level constraint behind.*

Principle 9425.20 (No hidden unification claim)**.** *The lineage and self-reference rows do not turn the input-flow grammar into a completed quantum-gravity or consciousness theory. They record where neighboring structures attach, which data are still external, and which constraints appear when external choice is pushed into the machine. This is a boundary ledger, not a unification theorem.*

9425.5 Self-Observation and Arithmetic Habitat

Definition 9425.21 (Self-similar observation row)**.** *A self-similar observation row is a refinement row in which the refined machine remains similar to the coarse machine. In a Gaussian refinement tower, this means that the refining sublattice is obtained by multiplication by a Gaussian integer.*

Theorem 9425.22 (Two-square admissibility)**.** *In the Gaussian refinement tower, a rational prime p admits a conformal index-p self-similar refinement exactly when*

$$p = a^2 + b^2$$

for integers a, b. Inert primes enter conformal Gaussian refinement only through even powers.

Proof. This is the conformal-refinement reading of Definition 9452.9. Multiplication by a Gaussian integer of norm p gives an index-p similar sublattice, and Fermat's two-square theorem characterizes exactly the rational primes that occur as such norms. □

Principle 9425.23 (Heegner habitat for universal shape blindness)**.** *If self-similar observation is required for all ideal refinements in an imaginary quadratic order, universal shape blindness holds exactly in the class-number-one habitat recorded by Definition 9452.16. Outside that habitat, the class group becomes a visible shape register. Perfect self-observation therefore lives only where the class group imposes no shape memory.*

Principle 9425.24 (Arithmetic constraint from self-observation)**.** *The two-square and class-number-one restrictions are not empirical claims about all possible input streams. They are conditional constraints produced by a self-similar observation requirement. In the unrestricted input-flow grammar the prime set remains external; under self-similar observation it is cut by the arithmetic of the selected complex structure.*

9425.6 Parent Automaton and Larger Alphabets

Principle 9425.25 (Parent automaton target)**.** *The parent-automaton target asks for a tensor-product, local, quantum-cellular-automaton realization whose one-particle sector is the quantized refinement input row. A solution would have to preserve the residual-rate law, the reflection-positive boundary, and the solenoid arithmetic rows after projection to the one-particle sector. The present chapter only states the target surface.*

Principle 9425.26 (Larger alphabet self-substitution)**.** *For an N-ary self-substitution row the compatibility equation becomes*

$$\sum_{a=0}^{N-1} e^{i\theta_a} = \sqrt{N}.$$

For $N = 2$ the compatibility equation is rigid and forces the oriented pair of Definition 9425.7. For $N \geq 3$ the solution set has positive dimension, so reversibility is a separate constraint on the self-substitution row rather than a consequence of compatibility alone.

Theorem 9425.27 (Higher-alphabet reversible self-substitution)**.** *The binary incompatibility between compatible self-substitution and time-reversal symmetry is not stable under enlargement of the alphabet. For $N = 3$ the phase row*

$$\theta = \left(\frac{\pi}{6}, -\frac{\pi}{2}, \frac{\pi}{6}\right)$$

satisfies

$$e^{i\pi/6} + e^{-i\pi/2} + e^{i\pi/6} = \sqrt{3}$$

and its circular-correlation recursion has real block coefficients. For every square alphabet size $N = k^2$, a compatible real-sign row exists: choose

$$\#\{+\} = \frac{k(k+1)}{2}, \qquad \#\{-\} = \frac{k(k-1)}{2}.$$

Then the sum of the signs is $k = \sqrt{N}$.

Proof. The ternary identity is immediate from $2e^{i\pi/6} - i = \sqrt{3}$. After factoring out the common rotation, the phase pattern is a third-root pattern with conjugate block products; the correlation recursion therefore has real coefficients at every finite depth. For the square alphabet row, the two displayed cardinalities are integers because $k(k+1)$ is even, their sum is k^2, and their signed difference is k. □

Principle 9425.28 (Binary endpoint)**.** *The forced time arrow of Definition 9425.10 is a binary endpoint. With two phases, the equation $a + b = \sqrt{2}$ leaves only the mirror pair $e^{\pm i\pi/4}$, and the first circular coefficient is nonreal. With three or more phases, compatibility can coexist with a real correlation audit. The arrow is therefore forced in the binary row and becomes a selectable feature in larger alphabets.*

Principle 9425.29 (Feasibility audit for phase searches)**.** *Any numerical or parametrized search for reversible self-substitution rows must keep*

$$\left|\sum_{a=0}^{N-1} e^{i\theta_a}\right| = \sqrt{N}$$

as a displayed constraint. A projection that maps infeasible trial values back into an inverse-trigonometric domain can create apparent zero-defect rows whose phase sum does not satisfy the compatibility equation. The feasibility constraint is part of the certificate, not a post-processing choice.

Principle 9425.30 (Lineage correspondence ledger)**.** *The correspondence checks for this boundary include quantum walks and quantum cellular automata, causal graph dynamics, multiresolution analysis and Haar wavelets, multiscale tensor networks, generalized Thue–Morse diffraction, complex multiplication, and class-number-one shape theory. These are source disciplines for the interface claims. The input-flow contribution is the exact placement of each discipline against the refinement, positivity, solenoid, and self-reference rows.*

Chapter 9426

Innovation Input Self-Substitution Correlation Boundary

chapter 9425 isolates the Q3 phase-polygon equation for self-substitution rows and exhibits the binary, ternary, and square-alphabet boundary cases. This chapter records the correlation machine behind those examples. The two-point arrow is not carried by Q3 itself; it is carried by the imaginary part of the word-level correlation coefficients that enter the carry recursion. The constructions below are stated for an arbitrary phase word; the Q3 equation

$$\sum_{a=0}^{N-1} v_a = \sqrt{N}$$

then selects the self-substitution rows compatible with the innovation input projection.

9426.1 Layered Phase Correlations

Definition 9426.1 (Layered phase sequence)**.** *Let $v = (v_0, \dots, v_{N-1}) \in \mathbb{T}^N$ be a self-substitution phase word as in Definition 9425.14. For*

$$n = a_0 + a_1 N + \cdots + a_{K-1} N^{K-1}, \qquad a_j \in \{0, \dots, N-1\},$$

define the level-K phase by

$$u_n^{(K)} := v_{a_0} v_{a_1} \cdots v_{a_{K-1}}.$$

Equivalently,

$$u_{Nq+a}^{(K)} = v_a u_q^{(K-1)}.$$

This is the one-index form of the parent-cell rule $u_{ca} = v_a u_c$.

Definition 9426.2 (Level correlation and two-point weak reversibility)**.** *For $m \geq 0$, set*

$$\gamma_K(m) := \frac{1}{N^K} \sum_{n=0}^{N^K-1-m} u_{n+m}^{(K)} \overline{u_n^{(K)}}.$$

When the limit exists, write

$$\gamma(m) := \lim_{K \to \infty} \gamma_K(m).$$

The phase word is two-point weakly reversible when

$$\gamma(m) \in \mathbb{R} \qquad \textit{for all } m \geq 0.$$

Equivalently, after extending the row by

$$\gamma(-m) := \overline{\gamma(m)},$$

the two-point row satisfies $\gamma(-m) = \gamma(m)$. Thus the row is invisible to reversal at the level of two-point phase correlations. This condition is weaker than reflection positivity. It only states that the two-point phase correlations do not by themselves distinguish a time orientation.

9426.2 Carry Recursion

Definition 9426.3 (Word-level correlation coefficients)**.** *For $0 \leq r < N$, define*

$$s_r(v) := \sum_{a=0}^{N-1-r} v_{a+r}\overline{v_a},$$

and

$$t_r(v) := \sum_{a=N-r}^{N-1} v_{a+r-N}\overline{v_a}.$$

For $r = 0$ this means $s_0 = N$ and $t_0 = 0$. For $r \geq 1$,

$$t_r(v) = \overline{s_{N-r}(v)}.$$

Lemma 9426.4 (Carry-complement identity)**.** *For $1 \leq r < N$, the carry coefficient satisfies*

$$t_r(v) = \overline{s_{N-r}(v)}.$$

Proof. Starting from the carry part and setting $b = a + r - N$ gives

$$t_r(v) = \sum_{a=N-r}^{N-1} v_{a+r-N}\overline{v_a} = \sum_{b=0}^{r-1} v_b\overline{v_{b+N-r}}.$$

Taking complex conjugates gives

$$\sum_{b=0}^{r-1} v_b\overline{v_{b+N-r}} = \overline{\sum_{b=0}^{r-1} v_{b+N-r}\overline{v_b}} = \overline{s_{N-r}(v)}.$$

□

Theorem 9426.5 (Carry recursion for self-substitution correlations)**.** *Let $m = Nq + r$ with $0 \leq r < N$. Then*

$$\gamma(Nq + r) = \frac{1}{N}\big(s_r(v)\gamma(q) + t_r(v)\gamma(q+1)\big).$$

In particular,

$$\gamma(Nq) = \gamma(q).$$

Proof. Write $n = Nb + a$. If $a + r < N$, then

$$n + m = N(b + q) + (a + r),$$

and the local coefficient is $v_{a+r}\overline{v_a}$. If $a + r \geq N$, then

$$n + m = N(b + q + 1) + (a + r - N),$$

and the local coefficient is $v_{a+r-N}\overline{v_a}$. Summing first over the child index a gives the coefficients s_r and t_r. At finite level this has the form

$$\gamma_K(Nq + r) = \frac{1}{N}\big(s_r(v)\gamma_{K-1}(q) + t_r(v)\gamma_{K-1}(q + 1)\big) + O(N^{-K}).$$

The boundary terms in the finite level average have relative size $O(N^{-K})$ and vanish as $K \to \infty$. □

Theorem 9426.6 (Existence and first correlation)**.** *For every phase word $v \in \mathbb{T}^N$, the limit $\gamma(m)$ exists for each fixed $m \geq 0$ and is uniquely determined by Definition 9426.5. Moreover*

$$\gamma(1) = \frac{s_1(v)}{N - t_1(v)}.$$

Proof. The value $\gamma(0) = 1$ is immediate. For $m = 1$, the finite-level recursion has the form

$$\gamma_K(1) = \frac{s_1}{N} + \frac{t_1}{N}\gamma_{K-1}(1) + O(N^{-K}).$$

Since $|t_1| \leq 1 < N$, this is a contraction and gives the displayed fixed point. For $m > 1$, write $m = Nq + r$. If $r = 0$, the value is $\gamma(q)$ with $q < m$. If $r > 0$, the recursion uses only $\gamma(q)$ and $\gamma(q + 1)$, and these have smaller indices except in the already treated case $m = 1$. Induction gives existence and uniqueness. □

9426.3 Weak Reversibility Criterion

Definition 9426.7 (Real word-level correlation condition)**.** *A phase word satisfies the real word-level correlation condition when*

$$s_r(v) \in \mathbb{R} \qquad 1 \leq r < N.$$

By Definition 9426.4, this is equivalent to requiring all coefficients $s_r(v)$ and $t_r(v)$ in the carry recursion to be real.

Theorem 9426.8 (Real word-level criterion)**.** *If*

$$s_r(v) \in \mathbb{R} \qquad 1 \leq r < N,$$

then

$$\gamma(m) \in \mathbb{R} \qquad \textit{for all } m \geq 0.$$

Proof. The condition implies $t_r(v) \in \mathbb{R}$ for all r. The first correlation is real by Definition 9426.6. For general m, use induction in the carry recursion: when $m = Nq + r$, the right side is a real linear combination of already real correlations. □

Corollary 9426.9 (Real-sign words)**.** *If $v_a \in \{+1, -1\}$ for every a, then the self-substitution phase word is two-point weakly reversible. In particular, the square-alphabet Q3 construction of Definition 9425.27 has no two-point phase arrow.*

Proof. For a real-sign word each product $v_{a+r}\overline{v_a}$ is ± 1. Hence every $s_r(v)$ is an integer, and Definition 9426.8 applies. □

Theorem 9426.10 (Square-alphabet real-sign Q3 rows)**.** *Let $N = k^2$. Choose*

$$P = \frac{k^2 + k}{2} \qquad \text{and} \qquad M = \frac{k^2 - k}{2}$$

entries equal to $+1$ and -1, respectively. The resulting phase word is Q3-compatible and two-point weakly reversible.

Proof. The cardinalities are integers because $k(k+1)$ and $k(k-1)$ are even, and $P + M = k^2 = N$. The phase sum is

$$\sum_a v_a = P - M = k = \sqrt{N},$$

so the Q3 phase-polygon equation holds. Since all entries are real signs, Definition 9426.9 gives two-point weak reversibility. □

9426.4 Boundary Examples

Principle 9426.11 (Binary coefficient source of the arrow)**.** *For the binary Q3 word*

$$v = (e^{i\pi/4}, e^{-i\pi/4}),$$

one has

$$s_1 = -i, \qquad t_1 = i.$$

Thus

$$\gamma(1) = \frac{s_1}{2 - t_1} = \frac{1 - 2i}{5}.$$

Hence

$$\operatorname{Im} \gamma(1) = -\frac{2}{5} \neq 0.$$

The binary arrow is therefore read at the word-level coefficient s_1, before any long-range limit is taken. In particular the binary Q3 self-substitution row is not two-point weakly reversible.

Principle 9426.12 (Ternary weakly reversible word)**.** *For the ternary Q3 word*

$$v = (e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6}),$$

the Q3 sum is

$$2e^{i\pi/6} - i = \sqrt{3}.$$

The word-level coefficients are

$$s_1 = -1, \qquad s_2 = 1.$$

The real word-level criterion therefore gives $\gamma(m) \in \mathbb{R}$ for all m. The explicit recursion is

$$\gamma(3q) = \gamma(q),$$

$$\gamma(3q+1) = \frac{1}{3}\big(-\gamma(q) + \gamma(q+1)\big),$$

and

$$\gamma(3q+2) = \frac{1}{3}\big(\gamma(q) - \gamma(q+1)\big),$$

matching Definition 9425.18. The first values are

$$\gamma(1) = -\frac{1}{2}, \qquad \gamma(2) = \frac{1}{2}.$$

Principle 9426.13 (Quartic real-sign word)**.** *For the real-sign Q3 word*

$$v = (1, 1, 1, -1),$$

one has

$$1 + 1 + 1 - 1 = 2 = \sqrt{4}.$$

The coefficients are

$$s_1 = 1, \qquad s_2 = 0, \qquad s_3 = -1.$$

The carry coefficients are therefore

$$t_1 = -1, \qquad t_2 = 0, \qquad t_3 = 1.$$

Hence

$$\gamma(4q) = \gamma(q),$$
$$\gamma(4q+1) = \frac{1}{4}\big(\gamma(q) - \gamma(q+1)\big),$$
$$\gamma(4q+2) = 0,$$

and

$$\gamma(4q+3) = \frac{1}{4}\big(-\gamma(q) + \gamma(q+1)\big).$$

In particular $\gamma(1) = 1/5$, $\gamma(2) = 0$, *and* $\gamma(3) = -1/5$.

Principle 9426.14 (Location of the two-point arrow)**.** *The two-point phase arrow is not forced by the Q3 phase-polygon equation alone. It is carried by the imaginary parts of the word-level coefficients* $s_r(v)$. *The binary Q3 equation has no freedom to make those coefficients real, while the ternary and real-sign square-alphabet rows do.*

Principle 9426.15 (Coefficient readout)**.** *The boundary between the basic examples is already visible in the first word-level coefficients:*

N	*Q3 row*	*word-level readout*	*two-point row*
2	$(e^{i\pi/4}, e^{-i\pi/4})$	$s_1 = -i$	$\gamma(1) = \frac{1-2i}{5}$
3	$(e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6})$	$s_1 = -1,\ s_2 = 1$	$\gamma(m) \in \mathbb{R}$
4	$(1, 1, 1, -1)$	$s_1 = 1,\ s_2 = 0,\ s_3 = -1$	$\gamma(m) \in \mathbb{R}$
k^2	± 1 *with* $\#(+) - \#(-) = k$	$s_r \in \mathbb{R}$	$\gamma(m) \in \mathbb{R}$

Thus two-point weak reversibility is controlled by the realness of the coefficients $s_r(v)$, *not by Q3 compatibility alone.*

Principle 9426.16 (Finite-block boundary)**.** *Two-point weak reversibility is only the level detected by the pair correlations* $\gamma(m)$. *The finite-block layer is separated in chapter 9427. The present chapter closes only the two-point criterion.*

Chapter 9427

Innovation Input Finite-Block Reversibility Boundary

chapter 9426 closes the two-point correlation recursion for self-substitution phase words. This chapter separates that two-point result from the stronger finite-block question. The ternary Q3 row has real two-point correlations, but a four-point balanced block still detects a chiral residue.

9427.1 Signed Blocks

Definition 9427.1 (Signed block)**.** *A signed block is a finite integer combination*

$$\alpha = \sum_{j=1}^{r} e_j \delta_{m_j},$$

where

$$m_j \in \mathbb{Z}_{\geq 0}, \qquad e_j \in \mathbb{Z} \setminus \{0\}.$$

Its phase monomial is

$$U_\alpha(n) := \prod_{j=1}^{r} u_{n+m_j}^{e_j}.$$

Since $|u_n| = 1$, negative exponents are interpreted as conjugate powers, so $u_n^{-1} = \overline{u_n}$.

Definition 9427.2 (Charge and balanced blocks)**.** *The charge of a signed block is*

$$Q(\alpha) := \sum_{j=1}^{r} e_j.$$

The block is balanced when $Q(\alpha) = 0$. Balanced blocks are the correlation observables that pair phase and conjugate phase contributions; unbalanced blocks carry a net phase charge and are not the finite-block analogue of the two-point row.

Definition 9427.3 (Finite-block correlation)**.** *Let $M(\alpha) = \max_j m_j$. When the limit exists, define*

$$\Gamma(\alpha) := \lim_{K\to\infty} \frac{1}{N^K} \sum_{n=0}^{N^K-1-M(\alpha)} U_\alpha(n).$$

The two-point row is the special case

$$\Gamma(\delta_0 - \delta_m) = \overline{\gamma(m)}.$$

When $\gamma(m)$ is real, this agrees with $\gamma(m)$.

Definition 9427.4 (Translation of a block)**.** *For $c \in \mathbb{Z}_{\geq 0}$, set*

$$\tau_c \alpha := \sum_{j=1}^{r} e_j \delta_{m_j + c}.$$

Whenever both limits exist,

$$\Gamma(\tau_c \alpha) = \Gamma(\alpha).$$

Thus blocks that differ by a common translation represent the same finite-block correlation.

9427.2 Weak Reversibility Layers

Definition 9427.5 (Order of a signed block)**.** *The order of a signed block is*

$$|\alpha| := \sum_j |e_j|.$$

Definition 9427.6 (Order-bounded weak reversibility)**.** *A self-substitution phase word is d-order weakly reversible when every balanced signed block with $|\alpha| \leq d$ satisfies*

$$\Gamma(\alpha) \in \mathbb{R}.$$

The case $d = 2$ is exactly two-point weak reversibility.

Definition 9427.7 (Finite-block weak reversibility)**.** *A self-substitution phase word is finite-block weakly reversible when*

$$\Gamma(\alpha) \in \mathbb{R}$$

for every balanced signed block α for which the correlation exists.

Principle 9427.8 (Reversibility hierarchy)**.** *The weak reversibility layers satisfy*

$$\textit{finite-block weak reversibility} \Longrightarrow d\textit{-order weak reversibility} \Longrightarrow 2\textit{-order weak reversibility}.$$

The implications are one-way assertions. The ternary computation below shows that the last implication cannot be reversed.

9427.3 Finite-Block Carry Recursion

Definition 9427.9 (Carry branch of a signed block)**.** *For a signed block*

$$\alpha = \sum_j e_j \delta_{m_j}$$

and a residue $a \in \{0, \ldots, N-1\}$, write

$$a + m_j = N q_{j,a} + r_{j,a}, \qquad 0 \leq r_{j,a} < N.$$

The branch coefficient and branch block are

$$C_a(\alpha) := \prod_j v_{r_{j,a}}^{e_j},$$

and

$$\alpha_a := \sum_j e_j \delta_{q_{j,a}}.$$

After the branch is formed, a common translation may be removed by Definition 9427.4.

Lemma 9427.10 (Charge preservation under carry branches)**.** *For every residue a,*

$$Q(\alpha_a) = Q(\alpha).$$

In particular, balanced blocks have balanced carry branches.

Proof. The carry branch changes only the locations of the atoms:

$$\alpha_a = \sum_j e_j \delta_{q_{j,a}}.$$

The integer coefficients e_j are unchanged, so their sum is unchanged. □

Theorem 9427.11 (Finite-block carry recursion)**.** *If $\Gamma(\alpha)$ and all branch correlations $\Gamma(\alpha_a)$ exist, then*

$$\Gamma(\alpha) = \frac{1}{N} \sum_{a=0}^{N-1} C_a(\alpha)\Gamma(\alpha_a).$$

Proof. Split the finite-level average by writing $n = Nb + a$. For each atom,

$$n + m_j = Nb + a + m_j = N(b + q_{j,a}) + r_{j,a}.$$

The self-substitution rule gives

$$u_{n+m_j} = v_{r_{j,a}} u_{b+q_{j,a}},$$

hence

$$u_{n+m_j}^{e_j} = v_{r_{j,a}}^{e_j} u_{b+q_{j,a}}^{e_j}.$$

Multiplying over j gives

$$U_\alpha(Nb + a) = C_a(\alpha) U_{\alpha_a}(b).$$

Averaging first over residues and then letting $K \to \infty$ gives the displayed recursion; boundary terms have vanishing relative size. □

9427.4 Ternary Four-Point Test

Definition 9427.12 (Ternary Q3 row)**.** *Let*

$$A = e^{i\pi/6}, \qquad B = e^{-i\pi/2}, \qquad v = (A, B, A).$$

Then $A + B + A = \sqrt{3}$, so this is a ternary Q3-compatible self-substitution phase word. By Definition 9426.12, all its two-point correlations are real.

Definition 9427.13 (Four-point test block)**.** *Set*

$$\alpha_\star := \delta_0 + \delta_1 - \delta_3 - \delta_5.$$

It is balanced, since $Q(\alpha_\star) = 1 + 1 - 1 - 1 = 0$*, and has order* $|\alpha_\star| = 4$*. Its correlation is*

$$\Gamma(\alpha_\star) = \langle u_n u_{n+1} \overline{u_{n+3} u_{n+5}} \rangle .$$

Definition 9427.14 (Ternary auxiliary correlations)**.** *Let*

$$\omega := e^{2\pi i/3} = -\frac{1}{2} + \frac{\sqrt{3}}{2} i.$$

For the ternary row, set

$$X := \Gamma(2\delta_0 - 2\delta_1),$$
$$Y := \Gamma(\delta_0 - \delta_1),$$
$$V := \Gamma(\delta_0 - \delta_2),$$
$$W := \Gamma(2\delta_0 - \delta_1 - \delta_2),$$

and

$$Z := \Gamma(\delta_0 + \delta_1 - \delta_3 - \delta_5).$$

Lemma 9427.15 (Ternary two-point and squared two-point values)**.** *For the ternary row,*

$$Y = -\frac{1}{2}, \qquad V = \frac{1}{2}, \qquad X = -\frac{1}{2}.$$

Proof. For $Y = \Gamma(\delta_0 - \delta_1)$, the carry branches give

$$Y = \frac{1}{3}(\omega + \overline{\omega} + Y) = \frac{1}{3}(-1 + Y),$$

so $Y = -1/2$.

For $V = \Gamma(\delta_0 - \delta_2)$, the carry branches give

$$V = \frac{1}{3}(1 + (\omega + \overline{\omega})Y) = \frac{1}{3}(1 - Y).$$

Substituting $Y = -1/2$ gives $V = 1/2$.

For $X = \Gamma(2\delta_0 - 2\delta_1)$, the carry branches give

$$X = \frac{1}{3}(\overline{\omega} + \omega + X) = \frac{1}{3}(-1 + X).$$

Thus $X = -1/2$. □

Lemma 9427.16 (Ternary three-point auxiliary cancellation)**.** *For the ternary row,*

$$W = \Gamma(2\delta_0 - \delta_1 - \delta_2) = 0.$$

Proof. For the block $2\delta_0 - \delta_1 - \delta_2$, all three carry branch coefficients are ω, and the branch correlations are 1, Y, and X. Therefore

$$W = \frac{1}{3}\omega(1 + Y + X).$$

By Definition 9427.15,

$$1 + Y + X = 1 - \frac{1}{2} - \frac{1}{2} = 0.$$

Hence $W = 0$. □

Theorem 9427.17 (Ternary four-point chirality)**.** *For the ternary Q3 row*

$$v = (e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6}),$$

one has

$$\Gamma(\delta_0 + \delta_1 - \delta_3 - \delta_5) = \frac{i\sqrt{3}}{6}.$$

Consequently this row is two-point weakly reversible but not 4-order weakly reversible.

Proof. Write

$$Z := \Gamma(\delta_0 + \delta_1 - \delta_3 - \delta_5).$$

The three carry branches of $\alpha_\star$ give

$$a = 0 : \qquad \overline{\omega}X,$$

$$a = 1 : \qquad W,$$

and

$$a = 2 : \qquad \omega V.$$

Thus

$$Z = \frac{1}{3}\left(\overline{\omega}X + W + \omega V\right).$$

Using Definition 9427.15 and Definition 9427.16,

$$Z = \frac{1}{3}\left(-\frac{1}{2}\overline{\omega} + \frac{1}{2}\omega\right) = \frac{1}{6}(\omega - \overline{\omega}).$$

Since

$$\omega - \overline{\omega} = i\sqrt{3},$$

the claimed value follows. □

Corollary 9427.18 (Two-point reversibility does not force finite-block reversibility)**.** *There exists a Q3-compatible self-substitution phase word such that*

$$\gamma(m) \in \mathbb{R} \qquad \textit{for all } m \geq 0,$$

while some balanced finite-block correlation is not real.

Proof. The ternary row of Definition 9427.12 has real two-point correlations by Definition 9426.12. The balanced block $\alpha_\star$ of Definition 9427.13 has nonreal correlation by Definition 9427.17. □

9427.5 Layer Separation

Principle 9427.19 (Chirality moves upward)**.** *For the ternary row, the two-point carry coefficients*

$$s_1 = -1, \qquad s_2 = 1$$

are real, so the two-point row sees no phase arrow. The four-point block with sites $0, 1, 3, 5$ *crosses the ternary digit boundaries differently: its carry branches leave the asymmetric residue*

$$\frac{1}{6}(\omega - \overline{\omega}) = \frac{i\sqrt{3}}{6}.$$

Thus the ternary row removes the arrow from the two-point layer but does not remove it from all finite-block layers.

Principle 9427.20 (Reversibility audit table)**.** *The basic Q3 rows occupy different levels of the audit hierarchy:*

audit layer	*object*	$N = 2$ *Q3 row*	$N = 3$ *Q3 row*
first two-point	$\operatorname{Im}\gamma(1)$	$\neq 0$	0
all two-point	$\gamma(m) \in \mathbb{R}\ \forall m$	*no*	*yes*
four-point	$\Gamma(\delta_0 + \delta_1 - \delta_3 - \delta_5)$	*not needed*	$\frac{i\sqrt{3}}{6}$
finite-block weak	$\Gamma(\alpha) \in \mathbb{R}\ \forall Q(\alpha) = 0$	*no*	*no*
RP/OS	*reflection-positive matrices*	*undecided*	*undecided*

The table separates two-point weak reversibility, finite-block weak reversibility, and RP/OS positivity. None of the stronger layers may be inferred from real two-point correlations alone.

Principle 9427.21 (Reflection-positive boundary)**.** *Finite-block realness is still weaker than reflection positivity. The finite-window reflection-positive audit is separated in chapter 9428. The four-point computation above is therefore a layer-separation result, not an RP certificate.*

Chapter 9428

Innovation Input Finite-Window Reflection-Positive Boundary

chapter 9427 separates two-point realness from finite-block realness. Reflection positivity is still stronger: it asks for nonnegative quadratic forms for reflected future observables. This chapter records a finite-window audit for self-substitution phase rows and applies it to the smallest Q3 representatives already isolated above.

9428.1 Finite-Window Reflection

Definition 9428.1 (Discrete reflection)**.** *Let the discrete reflection act on integer sites by*

$$\theta(j) = 1 - j.$$

Thus $1 \mapsto 0$, $2 \mapsto -1$, *and* $3 \mapsto -2$. *On signed block atoms, set*

$$\theta\delta_j := \delta_{1-j}.$$

For a signed block

$$\alpha = \sum_j e_j \delta_j,$$

define

$$\theta\alpha := \sum_j e_j \delta_{1-j}.$$

Definition 9428.2 (Future monomial)**.** *A future signed block in a window of length* L *is an anchored block of the form*

$$\alpha = \sum_{j=1}^{L} e_j \delta_j, \qquad e_j \in \mathbb{Z}.$$

The sites $1, \ldots, L$ *are the actual future positions relative to the reflection plane. The block is not translated before reflection. It determines the future monomial*

$$U_\alpha(n) := \prod_{j=1}^{L} u_{n+j}^{e_j}.$$

When $Q(\alpha) = \sum_j e_j = 0$, *the monomial is neutral.*

Definition 9428.3 (Finite-window RP matrix)**.** *Given anchored future signed blocks $\alpha_0, \ldots, \alpha_m$, define*

$$M_{ij} := \langle \theta U_{\alpha_i}, U_{\alpha_j} \rangle := \Gamma(\alpha_j - \theta\alpha_i).$$

The order of operations is fixed: keep the future blocks at their anchored sites, reflect α_i, form $\alpha_j - \theta\alpha_i$, and only then translate all sites by a common integer if negative sites occur, using Definition 9427.4. The window passes the reflection-positive check when

$$M \succeq 0.$$

Proposition 9428.4 (Translation and reflection anti-commute)**.** *For $T_s\delta_j := \delta_{j+s}$,*

$$\theta T_s = T_{-s}\theta.$$

Thus finite-window RP entries depend on the anchored placement of the future blocks before reflection, even though Γ itself is invariant under common translation after the reflected difference is formed.

Proof. On atoms,

$$\theta T_s \delta_j = \theta\delta_{j+s} = \delta_{1-j-s},$$

while

$$T_{-s}\theta\delta_j = T_{-s}\delta_{1-j} = \delta_{1-j-s}.$$

The identity follows by linearity. □

Definition 9428.5 (Charged and neutral RP windows)**.** *The charged RP audit allows arbitrary future monomials. The neutral RP audit restricts to future monomials with $Q(\alpha) = 0$. Therefore*

$$\textit{charged RP} \Longrightarrow \textit{neutral RP}.$$

The neutral audit is the projective or gauge-invariant version of the same finite-window test.

Theorem 9428.6 (Finite-window Gram criterion)**.** *Let $F_i = U_{\alpha_i}$ be a finite list of future monomials. For*

$$F = \sum_i c_i F_i,$$

one has

$$\langle \theta F, F \rangle = \sum_{i,j} \overline{c_i} M_{ij} c_j.$$

Consequently the finite window satisfies reflection positivity exactly when $M \succeq 0$.

Proof. Expand the quadratic form:

$$\langle \theta F, F \rangle = \left\langle \theta \left(\sum_i c_i F_i \right), \sum_j c_j F_j \right\rangle.$$

The reflection acts on the observables, while the first slot of the correlation pairing is conjugate-linear. Hence

$$\langle \theta F, F \rangle = \sum_{i,j} \overline{c_i} c_j \langle \theta F_i, F_j \rangle = \sum_{i,j} \overline{c_i} M_{ij} c_j.$$

Nonnegativity for every coefficient vector c is exactly positive semidefiniteness of the Gram matrix. □

9428.2 Charged One-Site Obstruction

Theorem 9428.7 (Charged one-site necessary condition)**.** *If the charged finite-window RP audit holds, then*

$$\gamma(1) \in \mathbb{R}_{\geq 0}.$$

Proof. Take the future monomial $F(n) = u_{n+1}$. Its reflection is $\theta F(n) = u_n$. Therefore

$$\langle \theta F, F \rangle = \langle u_n, u_{n+1} \rangle = \langle \overline{u_n} u_{n+1} \rangle = \gamma(1).$$

Charged RP requires this value to be nonnegative. □

Corollary 9428.8 (Binary charged RP obstruction)**.** *The binary Q3 self-substitution row*

$$v = (e^{i\pi/4}, e^{-i\pi/4})$$

fails charged finite-window RP at the one-site window.

Proof. By Definition 9426.11,

$$\gamma(1) = \frac{1-2i}{5}.$$

This is not real, so it cannot be a nonnegative real number. □

Corollary 9428.9 (Ternary charged RP obstruction)**.** *The ternary Q3 self-substitution row*

$$v = (e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6})$$

fails charged finite-window RP at the one-site window.

Proof. By Definition 9426.12,

$$\gamma(1) = -\frac{1}{2}.$$

The value is real but negative, contradicting Definition 9428.7. □

Principle 9428.10 (Quartic one-site survival)**.** *For the real-sign quartic Q3 row $v = (1, 1, 1, -1)$,*

$$\gamma(1) = \frac{1}{5} > 0.$$

Thus the row passes the charged one-site test, but this does not certify reflection positivity.

9428.3 Ternary Neutral RP Failure

Lemma 9428.11 (Ternary neutral diagonal value)**.** *For the ternary row, one has*

$$\gamma(2) = \frac{1}{2}$$

and

$$D_{13} := \Gamma(\delta_0 - \delta_2 + \delta_3 - \delta_5) = \frac{1}{6}.$$

Proof. The value $\gamma(2) = 1/2$ is Definition 9426.12. For the block $\delta_0 - \delta_2 + \delta_3 - \delta_5$, the ternary carry recursion has three branches:

$$a = 0: \qquad 1 \cdot 1,$$

$$a = 1: \qquad \omega\,\Gamma(\delta_0 - \delta_2),$$

and

$$a = 2: \qquad \overline{\omega}\,\Gamma(\delta_0 - \delta_2),$$

where $\omega = e^{2\pi i/3}$. Therefore

$$D_{13} = \frac{1}{3}\left(1 + (\omega + \overline{\omega})\gamma(2)\right).$$

Since $\omega + \overline{\omega} = -1$ and $\gamma(2) = 1/2$,

$$D_{13} = \frac{1}{3}\left(1 - \frac{1}{2}\right) = \frac{1}{6}.$$

□

Theorem 9428.12 (Ternary neutral RP obstruction)**.** *For the ternary Q3 row*

$$v = (e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6}),$$

the neutral future observables

$$F_0 = 1, \qquad F_1 = u_{n+1}\overline{u_{n+3}}$$

have finite-window RP matrix

$$M = \begin{pmatrix} 1 & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{6} \end{pmatrix}.$$

Its determinant is

$$\det M = \frac{1}{6} - \frac{1}{4} = -\frac{1}{12} < 0.$$

Hence the ternary row fails neutral finite-window RP.

Proof. The constant entry is $M_{00} = 1$. The off-diagonal entry is

$$M_{01} = \langle F_1 \rangle = \langle u_{n+1}\overline{u_{n+3}} \rangle = \gamma(2) = \frac{1}{2}.$$

The same value gives M_{10}. For the diagonal entry, set

$$\alpha = \delta_1 - \delta_3.$$

Then

$$\theta\alpha = \delta_0 - \delta_{-2}.$$

Thus

$$\alpha - \theta\alpha = (\delta_1 - \delta_3) - (\delta_0 - \delta_{-2}).$$

After translating by 2, this becomes

$$\delta_0 - \delta_2 + \delta_3 - \delta_5.$$

Therefore

$$M_{11} = \Gamma(\delta_0 - \delta_2 + \delta_3 - \delta_5) = D_{13} = \frac{1}{6}$$

by Definition 9428.11. The displayed determinant is negative, so M is not positive semidefinite. □

Corollary 9428.13 (Two-point realness does not imply neutral RP)**.** *Two-point weak reversibility does not imply neutral finite-window RP.*

Proof. The ternary Q3 row has real two-point correlations by Definition 9426.12, but fails neutral finite-window RP by Definition 9428.12. □

9428.4 Quartic Neutral RP Failure

Lemma 9428.14 (Quartic neutral diagonal value)**.** *For the quartic real-sign row* $v = (1, 1, 1, -1)$ *and*

$$F(n) = u_{n+1}\overline{u_{n+2}},$$

one has

$$\langle \theta F, F\rangle = -\frac{3}{5}.$$

Proof. The observable corresponds to $\alpha = \delta_1 - \delta_2$. Since

$$\theta\alpha = \delta_0 - \delta_{-1},$$

the reflected diagonal block is

$$\alpha - \theta\alpha = (\delta_1 - \delta_2) - (\delta_0 - \delta_{-1}).$$

After translating by 1, this becomes

$$\delta_0 - \delta_1 + \delta_2 - \delta_3.$$

Set

$$D_{12} := \Gamma(\delta_0 - \delta_1 + \delta_2 - \delta_3).$$

For $v = (1, 1, 1, -1)$, the four carry branches contribute

$$a = 0 : \qquad -1 \cdot 1,$$

$$a = 1 : \qquad -1 \cdot \gamma(1),$$

$$a = 2 : \qquad -1 \cdot 1,$$

and

$$a = 3 : \qquad -1 \cdot \gamma(1).$$

Therefore

$$D_{12} = -\frac{1}{4}\,(2 + 2\gamma(1)) = -\frac{1}{2}(1 + \gamma(1)).$$

Using $\gamma(1) = 1/5$ from Definition 9426.13,

$$D_{12} = -\frac{1}{2}\left(1 + \frac{1}{5}\right) = -\frac{3}{5}.$$

□

Theorem 9428.15 (Quartic neutral RP obstruction)**.** *The quartic real-sign Q3 row*

$$v = (1, 1, 1, -1)$$

fails neutral finite-window RP.

Proof. The neutral future observable $F(n) = u_{n+1}\overline{u_{n+2}}$ has

$$\langle \theta F, F\rangle = -\frac{3}{5} < 0$$

by Definition 9428.14. A positive semidefinite reflection-positive matrix cannot have a negative diagonal entry. □

Corollary 9428.16 (Real-sign correlations do not imply RP)**.** *Real-sign Q3 words can have real two-point correlations while failing neutral finite-window RP.*

Proof. The quartic row is real-sign and Q3-compatible by Definition 9426.13; its two-point correlations are real by Definition 9426.9. It fails neutral finite-window RP by Definition 9428.15. □

9428.5 Strict Layering

Theorem 9428.17 (Self-substitution reversibility layers)**.** *For Q3 self-substitution phase rows, finite-window reflection positivity is strictly stronger than real two-point correlations and real word-level correlations.*

Proof. The ternary row has real two-point correlations but fails neutral finite-window RP by Definition 9428.12. The quartic real-sign row has real word-level correlations but fails neutral finite-window RP by Definition 9428.15. The binary row fails even the charged one-site condition by Definition 9428.8. □

Principle 9428.18 (Terminology separation)**.** *The self-substitution rows require three distinct terms. Correlation reversibility means*

$$\gamma(m) \in \mathbb{R} \qquad \textit{for all } m.$$

Finite-block real reversibility means

$$\Gamma(\alpha) \in \mathbb{R}$$

for every balanced block α. RP reversibility means that every finite-window reflection-positive matrix is positive semidefinite, with the limiting row matching the OS/RP positivity used by Definition 9424.21. The ternary row belongs to the first class but not to the second or third. The quartic row belongs to the first class but fails the third.

Principle 9428.19 (Window audit table)**.** *The smallest Q3 representatives have the following RP-facing status:*

N	*representative Q3 row*	*two-point row*	*neutral RP*	*charged RP*
2	$(e^{i\pi/4}, e^{-i\pi/4})$	*nonreal*	*fail*	*fail*
3	$(e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6})$	*real*	*fail*	*fail*
4	$(1, 1, 1, -1)$	*real*	*fail*	*one-site pass*

Thus Q3 self-reference can coexist with the absence of a two-point arrow, but these minimal representatives do not provide an OS/RP-compatible self-substitution row.

Definition 9428.20 (Neutral RP deficit)**.** *For a bounded neutral future window, let $M^{\mathrm{neu}}_{N,L}(v)$ denote the finite-window RP matrix formed from the neutral monomials supported in $\{1, \ldots, L\}$. The neutral RP deficit is the least eigenvalue*

$$\rho^{\mathrm{neu}}_{N,L}(v) := \lambda_{\min} M^{\mathrm{neu}}_{N,L}(v).$$

Nonnegative values are necessary finite-window evidence for RP compatibility; negative values are finite-window obstruction certificates.

Chapter 9429

Innovation Input Minimal RP Deficit Search Boundary

chapter 9428 gives finite-window reflection positivity as a matrix condition. This chapter turns that condition into a search object: the Q3 constraint is kept exact, RP failure is measured by least eigenvalues and link deficits, and negative finite-window certificates become local obstructions to OS/RP-compatible self-substitution.

9429.1 Q3 Search Space

Definition 9429.1 (Q3 phase-word space)**.** *For $N \geq 2$, define*

$$\mathcal{Q}_N := \left\{ v = (v_0, \ldots, v_{N-1}) \in \mathbb{T}^N : \sum_{a=0}^{N-1} v_a = \sqrt{N} \right\}.$$

An element $v \in \mathcal{Q}_N$ determines the self-substitution rule

$$u_{Nn+a} = v_a u_n.$$

Proposition 9429.2 (Expected dimension of the Q3 space)**.** *At a nonsingular point, $\mathcal{Q}_N$ is a real manifold of dimension $N-2$.*

Proof. The torus $\mathbb{T}^N$ has real dimension N. The Q3 equation

$$\sum_a v_a = \sqrt{N}$$

is one complex equation, equivalently the two real equations

$$\operatorname{Re} \sum_a v_a = \sqrt{N},$$

and

$$\operatorname{Im} \sum_a v_a = 0.$$

At points where these two constraints have differential rank 2, the regular value theorem gives dimension $N-2$. □

Definition 9429.3 (Last-two-side closure)**.** *Choose $v_0, \dots, v_{N-3} \in \mathbb{T}$ and set*

$$R := \sqrt{N} - \sum_{a=0}^{N-3} v_a.$$

If $|R| \le 2$, write $R = \rho e^{i\phi}$ with $0 \le \rho \le 2$ and choose

$$v_{N-2} = e^{i\phi} e^{i\alpha},$$

$$v_{N-1} = e^{i\phi} e^{-i\alpha},$$

where

$$\cos\alpha = \frac{\rho}{2}.$$

Theorem 9429.4 (Exact Q3 closure)**.** *Every phase word constructed by Definition 9429.3 lies in $\mathcal{Q}_N$.*

Proof. The construction gives $v_{N-2} + v_{N-1} = R$. Therefore

$$\sum_{a=0}^{N-1} v_a = \sum_{a=0}^{N-3} v_a + v_{N-2} + v_{N-1} = \sum_{a=0}^{N-3} v_a + R = \sqrt{N}.$$

□

Principle 9429.5 (No projection after the fact)**.** *Searches for RP-compatible self-substitution rows must keep*

$$\sum_a v_a = \sqrt{N}$$

as an exact constraint. Projecting or clipping an infeasible phase row back toward Q3 after optimization can create apparent zero-defect rows whose phase sum is not a certificate. Exact closure or explicitly constrained optimization is part of the search object.

9429.2 Neutral Window Deficits

Definition 9429.6 (Neutral future block set)**.** *For a window length $L \ge 1$ and exponent bound $R \ge 1$, let $\mathcal{B}^{\mathrm{neu}}_{L,R}$ be the set of anchored future signed blocks*

$$\alpha = \sum_{j=1}^{L} e_j \delta_j$$

with

$$e_j \in \{-R, -R+1, \dots, R\}$$

and

$$\sum_{j=1}^{L} e_j = 0.$$

The zero block is included. The sites $1, \dots, L$ remain anchored until the reflected difference in the RP matrix has been formed.

Definition 9429.7 (Neutral finite-window RP matrix)**.** *For an enumeration*

$$\mathcal{B} = \{\alpha_0, \ldots, \alpha_m\} \subset \mathcal{B}^{\mathrm{neu}}_{L,R},$$

with $\alpha_0 = 0$*, define*

$$M_{\mathcal{B}}(v)_{ij} := \Gamma(\alpha_j - \theta\alpha_i).$$

The reflection is the one from Definition 9428.1; the anchoring discipline is the one in Definition 9428.3. The row passes the window $\mathcal{B}$ *when* $M_{\mathcal{B}}(v) \succeq 0$*.*

Definition 9429.8 (Hermitian defect and RP deficit)**.** *For a neutral window* $\mathcal{B}$*, define the Hermitian defect*

$$\eta_{\mathcal{B}}(v) := \|M_{\mathcal{B}}(v) - M_{\mathcal{B}}(v)^*\|.$$

Define the RP deficit by

$$\rho_{\mathcal{B}}(v) := \lambda_{\min}\left(\frac{M_{\mathcal{B}}(v) + M_{\mathcal{B}}(v)^*}{2}\right).$$

An RP candidate must have $\eta_{\mathcal{B}}(v) = 0$ *and* $\rho_{\mathcal{B}}(v) \geq 0$ *for every finite window.*

Definition 9429.9 (Optimal neutral window deficit)**.** *The optimal neutral deficit at window* (N, L, R) *is*

$$\rho^{\mathrm{neu}}_{N,L,R} := \sup_{v \in \mathcal{Q}_N} \rho_{\mathcal{B}^{\mathrm{neu}}_{L,R}}(v).$$

If $\rho^{\mathrm{neu}}_{N,L,R} < 0$*, no* N*-ary Q3 self-substitution row passes that neutral RP window. If it is nonnegative, the result is only a finite-window candidate condition, not a complete RP certificate.*

9429.3 Link Deficit Gate

Definition 9429.10 (Link observable)**.** *For* $d \geq 1$*, define the neutral future observable*

$$F_d(n) := u_{n+1}\overline{u_{n+1+d}}.$$

Its signed block is

$$\alpha_d := \delta_1 - \delta_{1+d}.$$

Definition 9429.11 (Link mean and reflected diagonal)**.** *Set*

$$\mu_d := \langle F_d \rangle = \Gamma(\delta_1 - \delta_{1+d}) = \Gamma(\delta_0 - \delta_d).$$

With the convention

$$\gamma(d) = \Gamma(\delta_d - \delta_0),$$

this means $\mu_d = \overline{\gamma(d)}$*. Also set*

$$D_d := \langle \theta F_d, F_d \rangle.$$

Directly,

$$D_d = \Gamma(\delta_0 - \delta_d + \delta_{d+1} - \delta_{2d+1}).$$

Theorem 9429.12 (Link two-by-two necessary condition)**.** *If neutral RP holds, then for every $d \geq 1$,*

$$D_d \in \mathbb{R}_{\geq 0}$$

and

$$D_d \geq |\mu_d|^2.$$

Equivalently, the link deficit

$$\Delta_d(v) := D_d - |\mu_d|^2$$

must satisfy $\Delta_d(v) \geq 0$.

Proof. Use the two future observables $F_0 = 1$ and $F_1 = F_d$. Their RP matrix is

$$M_d = \begin{pmatrix} 1 & \mu_d \\ \overline{\mu_d} & D_d \end{pmatrix}.$$

Under neutral RP this matrix is Hermitian positive semidefinite. Therefore its diagonal entry D_d is nonnegative real, and its determinant satisfies

$$\det M_d = D_d - |\mu_d|^2 \geq 0.$$

□

Corollary 9429.13 (Negative link deficit obstruction)**.** *If $D_d \notin \mathbb{R}$ or $\Delta_d(v) < 0$ for some $d \geq 1$, then the phase word does not satisfy neutral RP.*

Proof. This is the contrapositive of Definition 9429.12. □

9429.4 Known Link Obstructions

Principle 9429.14 (Ternary link obstruction)**.** *For the ternary Q3 row*

$$v = (e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6}),$$

one has $\mu_2 = 1/2$ and

$$D_2 = \Gamma(\delta_0 - \delta_2 + \delta_3 - \delta_5) = \frac{1}{6}.$$

Therefore

$$\Delta_2 = D_2 - |\mu_2|^2 = \frac{1}{6} - \frac{1}{4} = -\frac{1}{12}.$$

The ternary row is excluded by the $d = 2$ link window.

Principle 9429.15 (Quartic link obstruction)**.** *For the quartic real-sign Q3 row*

$$v = (1, 1, 1, -1),$$

one has $\mu_1 = 1/5$ and

$$D_1 = \Gamma(\delta_0 - \delta_1 + \delta_2 - \delta_3) = -\frac{3}{5}.$$

Therefore

$$\Delta_1 = D_1 - |\mu_1|^2 = -\frac{3}{5} - \frac{1}{25} = -\frac{16}{25}.$$

The quartic row is excluded by the $d = 1$ link window.

Principle 9429.16 (First RP screen)**.** *The link deficits form the first screen for RP-compatible self-substitution. A candidate must satisfy*

$$\Delta_d(v) \geq 0$$

for all checked links. A single negative link deficit is already a finite-window neutral RP obstruction, before any larger RP matrix is assembled.

9429.5 Exact Correlation Evaluation

Definition 9429.17 (Block diameter)**.** *For a signed block*

$$\alpha = \sum_j e_j \delta_{m_j},$$

define

$$\operatorname{diam}(\alpha) := \max_j m_j - \min_j m_j.$$

After a common translation, one may assume $\min_j m_j = 0$.

Definition 9429.18 (Carry closure)**.** *For a finite set $\mathcal{A}$ of signed blocks, the one-step carry closure contains every branch block α_a of Definition 9427.9, for $\alpha \in \mathcal{A}$ and $0 \leq a < N$, normalized by translation. Iterating this operation gives the carry closure*

$$\overline{\mathcal{A}}^{\text{carry}}.$$

Proposition 9429.19 (Finite-window correlations reduce to a finite linear system)**.** *For a fixed finite RP window and a fixed exponent bound, the block correlations appearing in its matrix entries reduce, under carry closure, to a finite linear system*

$$X = A(v)X + b(v).$$

The entries of $A(v)$ and $b(v)$ are averages of Laurent monomials in the phase word entries v_a.

Proof. For a fixed block $\alpha = \sum_j e_j \delta_{m_j}$, the carry branch at residue a replaces each index by

$$q_{j,a} = \left\lfloor \frac{a + m_j}{N} \right\rfloor.$$

Hence branch diameters obey the coarse bound

$$\operatorname{diam}(\alpha_a) \leq \left\lceil \frac{\operatorname{diam}(\alpha)}{N} \right\rceil.$$

All persistent self-cycles are confined to finitely many small-diameter blocks. Starting from a finite window and repeatedly applying carry branches therefore produces finitely many normalized block types. Writing Definition 9427.11 for each block gives the displayed finite linear system. □

Principle 9429.20 (Exact evaluator contract)**.** *For search purposes, the exact evaluator is the carry-closure linear system attached to the requested window. Long finite words are not the primary certificate. A negative eigenvalue or negative link deficit should be reported with the Q3 residual, the block window, the carry-closure system, and the resulting exact or high-precision matrix entry.*

9429.6 Search Objects

Definition 9429.21 (Link-screen feasible set)**.** *For $N \geq 2$ and $d_{\max} \geq 1$, define*

$$\mathcal{C}_{N,d_{\max}} := \{v \in \mathcal{Q}_N : \Delta_d(v) \geq 0 \text{ and } D_d(v) \in \mathbb{R} \quad 1 \leq d \leq d_{\max}\}.$$

Definition 9429.22 (Window RP feasible set)**.** *For L, R, define*

$$\mathcal{R}_{N,L,R} := \left\{v \in \mathcal{Q}_N : M_{\mathcal{B}^{\text{neu}}_{L,R}}(v) \succeq 0\right\}.$$

Whenever the window contains the link observables F_d for $d \leq d_{\max}$,

$$\mathcal{R}_{N,L,R} \subseteq \mathcal{C}_{N,d_{\max}}.$$

Principle 9429.23 (Minimal RP candidate problem)**.** *Find the least alphabet size N for which there is a Q3 phase word $v \in \mathcal{Q}_N$ that remains in $\mathcal{R}_{N,L,R}$ through increasing neutral windows, beginning with*

$$(L, R) = (2, 1), (3, 1), (4, 1).$$

The complete neutral RP problem asks whether some $v \in \mathcal{Q}_N$ passes every neutral finite window. The charged RP problem asks the same without the neutrality restriction.

Principle 9429.24 (Search route)**.** *A reliable search route has four gates. First, sample exactly inside $\mathcal{Q}_N$ using Definition 9429.3 or an explicitly constrained parameterization. Second, compute $\Delta_d(v)$ for $1 \leq d \leq d_{\max}$ and reject any negative link deficit. Third, form small neutral RP windows such as $\mathcal{B}^{\text{neu}}_{2,1}$ and $\mathcal{B}^{\text{neu}}_{3,1}$ and compute their least eigenvalues. Fourth, optimize the window value*

$$\sup_{v \in \mathcal{Q}_N} \lambda_{\min} M_{\mathcal{B}^{\text{neu}}_{L,1}}(v)$$

as the window grows, rather than fixing a small-window candidate and assuming it remains optimal.

Principle 9429.25 (Layered search table)**.** *The known smallest representatives occupy the following search states:*

N	*representative row*	*Q3*	*two-point row*	*link deficit*
2	$(e^{i\pi/4}, e^{-i\pi/4})$	*yes*	*nonreal*	*charged obstruction*
3	$(e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6})$	*yes*	*real*	$\Delta_2 = -1/12$
4	$(1, 1, 1, -1)$	*yes*	*real*	$\Delta_1 = -16/25$
$N \geq 5$	*undetermined*	*open*	*open*	*open*

Thus the live search problem begins after the three smallest representatives have already been filtered by charged or neutral finite-window obstructions.

Principle 9429.26 (Candidate families for the next screen)**.** *Two low-dimensional $N = 5$ families give natural first screens. The symmetric pentary family has*

$$v = (a, b, c, b, a), \qquad 2a + 2b + c = \sqrt{5}.$$

The unit-root correction family has the form

$$v_a = e^{i\phi} w_a,$$

where the w_a are drawn from fifth-root phase patterns and the common rotation is chosen only when the Q3 sum is exactly $\sqrt{5}$. In either family, the first nontrivial target is simultaneous nonnegativity of Δ_1 and Δ_2.

Chapter 9430

Innovation Input Anchored RP Golden Palindrome Boundary

chapter 9428 fixes the finite-window RP matrix as an anchored future-window construction. This chapter applies that anchored audit to the lowest-complexity pentary palindrome family. The family removes the two-point arrow, but the smallest neutral anchored RP window still detects failure.

9430.1 Anchored Window Discipline

Principle 9430.1 (Anchored RP workflow)**.** *Finite-window RP entries are not functions of future-block translation classes before reflection. The workflow is*

$$\textit{anchored future block} \to \textit{reflection} \to \textit{difference} \to \textit{common translation} \to \Gamma \textit{ evaluation.}$$

Only the last step uses translation invariance of finite-block correlations.

Principle 9430.2 (Ternary anchored status)**.** *For the ternary Q3 row*

$$v = (e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6}),$$

the anchored $L = 2$ neutral window generated by

$$1, \qquad u_{n+1}\overline{u_{n+2}}, \qquad \overline{u_{n+1}}u_{n+2}$$

has matrix

$$\begin{pmatrix} 1 & -\frac{1}{2} & -\frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} & 0 \\ -\frac{1}{2} & 0 & \frac{1}{2} \end{pmatrix},$$

with eigenvalues 0, $1/2$, and $3/2$. Hence the ternary row passes the anchored $L = 2$ neutral window. It still fails at anchored $L = 3$ by Definition 9428.12.

Principle 9430.3 (Quartic anchored status)**.** *For the quartic real-sign row $v = (1, 1, 1, -1)$, the anchored observable*

$$F = u_{n+1}\overline{u_{n+2}}$$

has

$$\langle \theta F, F \rangle = \Gamma(\delta_0 - \delta_1 + \delta_2 - \delta_3) = -\frac{3}{5}.$$

Thus the quartic representative fails the anchored $L = 2$ neutral window.

9430.2 Pentary Palindromes

Definition 9430.4 (Pentary palindrome phase word)**.** *A pentary palindrome phase word is a row*

$$v = (a, b, c, b, a) \in \mathbb{T}^5.$$

It is Q3-compatible exactly when

$$2a + 2b + c = \sqrt{5}.$$

Theorem 9430.5 (Pentary palindromes have real two-point coefficients)**.** *For every pentary palindrome $v = (a, b, c, b, a)$, the word-level two-point coefficients*

$$s_r = \sum_{j=0}^{4-r} v_{j+r}\overline{v_j}$$

are real for $1 \le r \le 4$. Consequently every Q3-compatible pentary palindrome is two-point weakly reversible.

Proof. Directly,

$$s_1 = b\overline{a} + c\overline{b} + b\overline{c} + a\overline{b} = 2\,\mathrm{Re}(b\overline{a}) + 2\,\mathrm{Re}(c\overline{b}),$$

so s_1 is real. Also

$$s_2 = c\overline{a} + b\overline{b} + a\overline{c} = 1 + 2\,\mathrm{Re}(c\overline{a}),$$

$$s_3 = b\overline{a} + a\overline{b} = 2\,\mathrm{Re}(b\overline{a}),$$

and

$$s_4 = a\overline{a} = 1.$$

Thus all s_r are real, and Definition 9426.8 gives real two-point correlations. □

Corollary 9430.6 (Pentary palindrome two-point reversibility)**.** *Every Q3-compatible pentary palindrome satisfies*

$$\gamma(m) \in \mathbb{R} \qquad \textit{for all } m \ge 0.$$

9430.3 Golden Palindrome Branches

Definition 9430.7 (Golden palindrome branches)**.** *Let*

$$\xi := e^{\pi i/5}, \qquad \zeta := e^{2\pi i/5}.$$

Define

$$v_5^{(+)} := (\xi, \xi^{-1}, -1, \xi^{-1}, \xi)$$

and

$$v_5^{(-)} := (\zeta, \zeta^{-1}, 1, \zeta^{-1}, \zeta).$$

Theorem 9430.8 (Golden palindrome Q3 rows)**.** *Both golden palindrome branches lie in $\mathcal{Q}_5$, and both have real two-point correlations.*

Proof. The trigonometric identities

$$\cos\frac{\pi}{5} = \frac{\sqrt{5}+1}{4}$$

and

$$\cos\frac{2\pi}{5} = \frac{\sqrt{5}-1}{4}$$

give

$$2\xi + 2\xi^{-1} - 1 = 4\cos\frac{\pi}{5} - 1 = \sqrt{5},$$

and

$$2\zeta + 2\zeta^{-1} + 1 = 4\cos\frac{2\pi}{5} + 1 = \sqrt{5}.$$

Thus both rows satisfy Q3. They are palindromes, so Definition 9430.5 gives real two-point correlations. □

9430.4 Anchored Neutral Window Audit

Definition 9430.9 (Pentary anchored neutral window)**.** *Use the anchored $L = 2$ neutral observables*

$$F_0 = 1,$$

$$F_1 = u_{n+1}\overline{u_{n+2}},$$

and

$$F_2 = \overline{u_{n+1}}u_{n+2}.$$

Their future blocks are

$$\alpha_0 = 0, \qquad \alpha_1 = \delta_1 - \delta_2, \qquad \alpha_2 = -\delta_1 + \delta_2.$$

Lemma 9430.10 (First golden branch window values)**.** *For*

$$v_5^{(+)} = (\xi, \xi^{-1}, -1, \xi^{-1}, \xi), \qquad \xi = e^{\pi i/5},$$

the anchored $L = 2$ neutral window has

$$\mu_1 := \langle F_1 \rangle = -\frac{1}{4},$$

$$D_1 := \langle \theta F_1, F_1 \rangle = \frac{1+\sqrt{5}}{8},$$

and

$$C_1 := \langle \theta F_1, F_2 \rangle = -\frac{1+\sqrt{5}}{8} + i\frac{\sqrt{10-2\sqrt{5}}}{8}.$$

In particular, $|C_1| = 1/2$.

Proof. The values are obtained by applying Definition 9427.11 to the anchored blocks defining μ_1, D_1, and C_1, then solving the finite carry-closure linear system described in Definition 9429.19. The cross term has modulus

$$|C_1|^2 = \frac{(1+\sqrt{5})^2}{64} + \frac{10-2\sqrt{5}}{64} = \frac{1}{4},$$

so $|C_1| = 1/2$. □

Theorem 9430.11 (First golden branch fails anchored neutral RP)**.** *The branch $v_5^{(+)}$ fails the anchored $L = 2$ neutral RP window.*

Proof. The (F_1, F_2) principal submatrix has the form

$$\begin{pmatrix} D_1 & C_1 \\ \overline{C_1} & D_1 \end{pmatrix}.$$

Its eigenvalues are $D_1 \pm |C_1|$. By Definition 9430.10,

$$D_1 - |C_1| = \frac{1+\sqrt{5}}{8} - \frac{1}{2} = \frac{\sqrt{5}-3}{8} < 0.$$

The principal submatrix is not positive semidefinite. □

Lemma 9430.12 (Second golden branch negative diagonal)**.** *For*

$$v_5^{(-)} = (\zeta, \zeta^{-1}, 1, \zeta^{-1}, \zeta), \qquad \zeta = e^{2\pi i/5},$$

one has

$$\langle \theta F_1, F_1 \rangle = \frac{1-\sqrt{5}}{8} < 0.$$

Proof. For $F_1 = u_{n+1}\overline{u_{n+2}}$, the reflected diagonal block is

$$\delta_0 - \delta_1 + \delta_2 - \delta_3.$$

Applying the finite-block carry recursion and solving its finite closure system for the second golden branch gives

$$\Gamma(\delta_0 - \delta_1 + \delta_2 - \delta_3) = \frac{1-\sqrt{5}}{8}.$$

This is negative. □

Theorem 9430.13 (Second golden branch fails anchored neutral RP)**.** *The branch $v_5^{(-)}$ fails the anchored $L = 2$ neutral RP window.*

Proof. By Definition 9430.12, the RP quadratic form is negative on the neutral future observable F_1. Hence the anchored $L = 2$ window is not positive semidefinite. □

Theorem 9430.14 (Golden palindromes are not RP candidates)**.** *The two golden palindrome Q3 rows $v_5^{(+)}$ and $v_5^{(-)}$ have real two-point correlations, but neither passes the anchored $L = 2$ neutral RP window.*

Proof. Q3 compatibility and real two-point correlations follow from Definition 9430.8. The first branch fails by Definition 9430.11; the second branch fails by Definition 9430.13. □

Principle 9430.15 (Anchored RP status table)**.** *The low-complexity Q3 representatives now have the following anchored RP status:*

N	*representative row*	*two-point row*	*anchored RP status*
2	$(e^{i\pi/4}, e^{-i\pi/4})$	*nonreal*	*charged one-site fail*
3	$(e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6})$	*real*	$L = 3$ *neutral fail*
4	$(1, 1, 1, -1)$	*real*	$L = 2$ *neutral fail*
5	$v_5^{(+)}$	*real*	$L = 2$ *neutral fail*
5	$v_5^{(-)}$	*real*	$L = 2$ *neutral fail*

The pentary golden branches show that additional phase freedom can remove the two-point arrow without producing an OS/RP-compatible self-substitution row.

Principle 9430.16 (Pentary full-window target)**.** *The remaining pentary question is global over $\mathcal{Q}_5$: determine whether some $v \in \mathcal{Q}_5$ passes the anchored $L = 2$ neutral RP matrix. For*

$$F = u_{n+1}\overline{u_{n+2}},$$

the basic entries are

$$\mu = \langle F \rangle, \qquad D = \langle \theta F, F \rangle, \qquad C = \langle \theta F, \overline{F} \rangle.$$

The anchored $L = 2$ matrix is

$$M_2(v) = \begin{pmatrix} 1 & \mu & \overline{\mu} \\ \overline{\mu} & D & C \\ \mu & \overline{C} & \overline{D} \end{pmatrix}.$$

In the Hermitian case, the first necessary conditions are $D \geq 0$, $D \geq |C|$, and $\det M_2(v) \geq 0$.

Chapter 9431

Innovation Input Pentary Anchored Window Boundary

chapter 9430 shows that the golden pentary palindrome endpoints fail the anchored $L = 2$ neutral RP window. This chapter records a different pentary Q3 row: it passes the anchored $L = 2$ neutral window, but fails when the window is enlarged to include the next anchored link. The obstruction is therefore not only a local link shape, but also its position relative to the reflection plane.

9431.1 Anchored Pentary Window

Definition 9431.1 (Pentary anchored $L = 2$ window)**.** *Let $v = (v_0, \dots, v_4) \in \mathcal{Q}_5$ and let*

$$u_{5n+a} = v_a u_n.$$

For

$$F = u_{n+1}\overline{u_{n+2}},$$

write

$$\alpha = \delta_1 - \delta_2.$$

The anchored $L = 2$ neutral window is

$$\mathcal{B}_2 = \{0, \alpha, -\alpha\}.$$

Its RP matrix is

$$M_2(v)_{ij} = \Gamma(\alpha_j - \theta\alpha_i),$$

where the future blocks remain anchored before reflection.

Definition 9431.2 (Anchored $L = 2$ structure quantities)**.** *Set*

$$\mu := \Gamma(\delta_0 - \delta_1),$$

$$D := \Gamma(\delta_0 - \delta_1 + \delta_2 - \delta_3),$$

and

$$C := \Gamma(\delta_0 - \delta_1 - \delta_2 + \delta_3).$$

Then

$$M_2(v) = \begin{pmatrix} 1 & \mu & \overline{\mu} \\ \mu & D & C \\ \overline{\mu} & \overline{C} & \overline{D} \end{pmatrix}$$

whenever the anchored window is Hermitian.

Theorem 9431.3 (Pentary anchored $L = 2$ formulas)**.** *For $v = (v_0, \ldots, v_4) \in \mathbb{T}^5$,*

$$\mu = \frac{v_0\overline{v}_1 + v_1\overline{v}_2 + v_2\overline{v}_3 + v_3\overline{v}_4}{5 - v_4\overline{v}_0}.$$

Moreover

$$D = \frac{1}{5}\left[d_0 + d_1 + d_3 + (d_2 + d_4)\mu\right],$$

where

$$d_0 = v_0\overline{v}_1 v_2\overline{v}_3, \qquad d_1 = v_1\overline{v}_2 v_3\overline{v}_4,$$

$$d_2 = v_2\overline{v}_3 v_4\overline{v}_0, \qquad d_3 = v_3\overline{v}_4 v_0\overline{v}_1,$$

and

$$d_4 = v_4\overline{v}_0 v_1\overline{v}_2.$$

Finally,

$$C = \frac{1}{5}\left[c_0 + c_1 + c_3 + c_2\overline{\mu} + c_4\mu\right],$$

where

$$c_0 = v_0\overline{v}_1\overline{v}_2 v_3, \qquad c_1 = v_1\overline{v}_2\overline{v}_3 v_4,$$

$$c_2 = v_2\overline{v}_3\overline{v}_4 v_0, \qquad c_3 = v_3\overline{v}_4\overline{v}_0 v_1,$$

and

$$c_4 = v_4\overline{v}_0\overline{v}_1 v_2.$$

Proof. For $\mu = \Gamma(\delta_0 - \delta_1)$, split the average by $n = 5q + a$. For $0 \le a \le 3$ there is no carry, giving $v_a\overline{v}_{a+1}$. For $a = 4$ the carry contributes $v_4\overline{v}_0\mu$. Thus

$$\mu = \frac{1}{5}\left(\sum_{a=0}^{3} v_a\overline{v}_{a+1} + v_4\overline{v}_0\mu\right),$$

which gives the displayed formula.

For D, the residues $a = 0, 1, 3$ collapse to the zero block and contribute d_0, d_1, d_3. The residues $a = 2, 4$ leave the branch block $\delta_0 - \delta_1$, whose correlation is μ. This gives the displayed formula for D.

For C, the residues $a = 0, 1, 3$ collapse to the zero block and contribute c_0, c_1, c_3. The residue $a = 2$ leaves $-\delta_0 + \delta_1$, whose correlation is $\overline{\mu}$, and the residue $a = 4$ leaves $\delta_0 - \delta_1$, whose correlation is μ. □

9431.2 Pythagorean Pentary Row

Definition 9431.4 (Pythagorean pentary phase word)**.** *Let*

$$a := \frac{1+2i}{\sqrt{5}}, \qquad b := \frac{2-i}{\sqrt{5}}.$$

Define

$$v_\star := (a, b, -a, b, a).$$

Theorem 9431.5 (Pythagorean row is Q3)**.** *The row $v_\star$ lies in $\mathcal{Q}_5$.*

Proof. Directly,

$$a + 2b = \frac{1+2i}{\sqrt{5}} + 2\frac{2-i}{\sqrt{5}} = \frac{5}{\sqrt{5}} = \sqrt{5}.$$

Since the row sum of $(a, b, -a, b, a)$ is $a + 2b$, the Q3 equation holds. □

Lemma 9431.6 (Pythagorean products)**.** *For $a = (1+2i)/\sqrt{5}$ and $b = (2-i)/\sqrt{5}$,*

$$a\overline{b} = i, \qquad b\overline{a} = -i.$$

Proof. Since $\overline{b} = (2+i)/\sqrt{5}$,

$$a\overline{b} = \frac{(1+2i)(2+i)}{5} = \frac{5i}{5} = i.$$

The second identity is the complex conjugate. □

9431.3 Anchored $L = 2$ Passage

Theorem 9431.7 (Pythagorean anchored $L = 2$ structure)**.** *For $v_\star = (a, b, -a, b, a)$,*

$$\mu = 0, \qquad D = \frac{3}{5}, \qquad C = -\frac{3}{5}.$$

Therefore

$$M_2(v_\star) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{3}{5} & -\frac{3}{5} \\ 0 & -\frac{3}{5} & \frac{3}{5} \end{pmatrix}.$$

Proof. Using Definition 9431.6,

$$v_0\overline{v}_1 = i, \qquad v_1\overline{v}_2 = i, \qquad v_2\overline{v}_3 = -i, \qquad v_3\overline{v}_4 = -i.$$

The numerator in the formula for μ is therefore zero, so $\mu = 0$.

For D, the terms involving μ vanish. The remaining products are

$$d_0 = (a\overline{b})((-a)\overline{b}) = 1,$$

$$d_1 = (b\overline{(-a)})(b\overline{a}) = 1,$$

and

$$d_3 = (b\overline{a})(a\overline{b}) = 1.$$

Thus $D = (1+1+1)/5 = 3/5$.

For C, again the terms involving μ vanish. The remaining products are

$$c_0 = (a\overline{b})(\overline{(-a)}b) = -1,$$

$$c_1 = (b\overline{(-a)})(\overline{b}a) = -1,$$

and

$$c_3 = (b\overline{a})(\overline{a}b) = -1.$$

Thus $C = -3/5$. □

Corollary 9431.8 (Pythagorean row passes anchored $L = 2$ neutral RP)**.** *The anchored $L = 2$ neutral RP matrix of $v_\star$ is positive semidefinite.*

Proof. The lower-right block is

$$\frac{3}{5}\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix},$$

with eigenvalues 0 and 6/5. Together with the top-left entry 1, the matrix eigenvalues are 1, 0, and 6/5. □

9431.4 Anchored $L = 3$ Failure

Definition 9431.9 (Second anchored link)**.** *Set*

$$F_{23}(n) := \overline{u_{n+2}}u_{n+3}.$$

Its future block is

$$\alpha_{23} := -\delta_2 + \delta_3.$$

The reflected diagonal quantity is

$$D_{23} := \langle \theta F_{23}, F_{23} \rangle.$$

Since $\theta\delta_2 = \delta_{-1}$ and $\theta\delta_3 = \delta_{-2}$,

$$\alpha_{23} - \theta\alpha_{23} = -\delta_2 + \delta_3 + \delta_{-1} - \delta_{-2}.$$

After translating by 2, this is the block

$$-\delta_0 + \delta_1 - \delta_4 + \delta_5.$$

Theorem 9431.10 (Pythagorean anchored $L = 3$ failure)**.** *For $v_\star = (a, b, -a, b, a)$,*

$$D_{23} = \Gamma(-\delta_0 + \delta_1 - \delta_4 + \delta_5) = -\frac{1}{5}.$$

Thus $v_\star$ fails the anchored $L = 3$ neutral RP window.

Proof. Let $\beta = -\delta_0 + \delta_1 - \delta_4 + \delta_5$. Split the recursion by residue $r = 0, \ldots, 4$.

For $r = 0$, the coefficient is

$$\overline{v}_0 v_1 \overline{v}_4 v_0 = \overline{a}b\overline{a}a = -i,$$

and the branch block is $-\delta_0 + \delta_1$, whose correlation is $\overline{\mu} = 0$.

For $r = 1$, the coefficient is

$$\overline{v}_1 v_2 \overline{v}_0 v_1 = \overline{b}(-a)\overline{a}b = -1,$$

and the branch is the zero block.

For $r = 2$, the coefficient is

$$\overline{v}_2 v_3 \overline{v}_1 v_2 = \overline{(-a)} b \overline{b} (-a) = 1,$$

and the branch is the zero block.

For $r = 3$, the coefficient is

$$\overline{v}_3 v_4 \overline{v}_2 v_3 = \overline{b} a \overline{(-a)} b = -1,$$

and the branch is the zero block.

For $r = 4$, the coefficient is

$$\overline{v}_4 v_0 \overline{v}_3 v_4 = \overline{a} a \overline{b} a = i,$$

and the branch block is again $-\delta_0 + \delta_1$, whose correlation is $\overline{\mu} = 0$.

Therefore

$$D_{23} = \frac{1}{5}(0 - 1 + 1 - 1 + 0) = -\frac{1}{5}.$$

The negative diagonal entry violates neutral RP. □

Corollary 9431.11 (Anchored $L = 2$ does not imply anchored $L = 3$)**.** *There exists $v \in \mathcal{Q}_5$ such that its anchored $L = 2$ neutral RP matrix is positive semidefinite, while its anchored $L = 3$ neutral RP window fails.*

Proof. Use $v = v_\star$. The anchored $L = 2$ matrix is positive semidefinite by Definition 9431.8, while Definition 9431.10 gives a negative anchored $L = 3$ diagonal entry. □

9431.5 Anchor Dependence

Definition 9431.12 (Anchored link diagonal)**.** *For $1 \le i < j$, define*

$$F_{ij} := u_{n+i} \overline{u_{n+j}},$$

and

$$D_{ij} := \langle \theta F_{ij}, F_{ij} \rangle.$$

Theorem 9431.13 (Link diagonal depends on anchor)**.** *For the Pythagorean row,*

$$D_{12} = \frac{3}{5}, \qquad D_{23} = -\frac{1}{5}.$$

Proof. The value $D_{12} = 3/5$ is the D value in Definition 9431.7. The value $D_{23} = -1/5$ is Definition 9431.10. □

Principle 9431.14 (Anchor-sensitive RP audit)**.** *Ordinary finite-block correlations satisfy*

$$\Gamma(T_s \alpha) = \Gamma(\alpha),$$

but RP diagonals are of the form

$$\Gamma(\alpha - \theta\alpha).$$

Because $\theta T_s = T_{-s}\theta$, translating a future block changes its relative position to the reflection plane. A complete finite-window audit must therefore check every anchored link, not only each translation shape.

Principle 9431.15 (Pentary anchored status table)**.** *The pentary anchored search status is:*

N	*row*	*Q3*	$L = 2$ *neutral RP*	$L = 3$ *neutral RP*
3	$(e^{i\pi/6}, e^{-i\pi/2}, e^{i\pi/6})$	*yes*	*pass*	*fail*
4	$(1, 1, 1, -1)$	*yes*	*fail*	*not needed*
5	$v_5^{(+)}$	*yes*	*fail*	*not needed*
5	$v_5^{(-)}$	*yes*	*fail*	*not needed*
5	$v_\star = (a, b, -a, b, a)$	*yes*	*pass*	*fail*

Thus the pentary search space contains rows that pass the nearest anchored neutral RP window, but the next anchor can still obstruct reflection positivity.

Principle 9431.16 (Pentary $L = 3$ target)**.** *The full pentary target is the $\mathcal{Q}_5$ feasibility problem for anchored $L = 3$ neutral RP. At minimum one must have*

$$D_{12} \geq 0, \qquad D_{13} \geq 0, \qquad D_{23} \geq 0.$$

The Pythagorean row has $D_{12} = 3/5$ but $D_{23} = -1/5$, so improving the candidate requires moving the second anchored link diagonal to the nonnegative side without destroying the anchored $L = 2$ matrix.

Chapter 9432

Innovation Input Pentary Hermitian Link Boundary

chapter 9431 separates anchored $L = 2$ passage from anchored $L = 3$ failure for one pentary Q3 row. This chapter isolates the first $L = 3$ algebraic filters: the three anchored link diagonals, the endpoint gate carried by the middle link, and the correlation inequality forced by the second link.

9432.1 Pentary Edge Ratios

Definition 9432.1 (Pentary edge ratios)**.** *Let*

$$v = (v_0, v_1, v_2, v_3, v_4) \in \mathbb{T}^5.$$

Define the cyclic edge ratios

$$x_a := v_a \overline{v_{a+1}}, \qquad a = 0, 1, 2, 3, 4,$$

where indices are read modulo 5*. Thus*

$$x_4 = v_4 \overline{v_0}.$$

Then

$$|x_a| = 1$$

and

$$x_0 x_1 x_2 x_3 x_4 = 1.$$

Definition 9432.2 (First and second ordinary correlations)**.** *For the self-substitution row v, write*

$$\mu := \Gamma(\delta_0 - \delta_1)$$

and

$$\nu := \Gamma(\delta_0 - \delta_2).$$

Equivalently, μ is the ordinary distance-one average $\langle u_n \overline{u_{n+1}} \rangle$, while ν is the ordinary distance-two average $\langle u_n \overline{u_{n+2}} \rangle$.

Theorem 9432.3 (Pentary first correlation formula)**.** *For every pentary self-substitution row,*

$$\mu = \frac{x_0 + x_1 + x_2 + x_3}{5 - x_4}.$$

Proof. Split the average defining $\Gamma(\delta_0 - \delta_1)$ by $n = 5q + a$. For $a = 0, 1, 2, 3$ there is no carry, and the contribution is x_a. For $a = 4$ the carry leaves the same distance-one block and contributes $x_4\mu$. Hence

$$\mu = \frac{1}{5}\left(x_0 + x_1 + x_2 + x_3 + x_4\mu\right),$$

which is the stated formula. □

Theorem 9432.4 (Pentary second correlation formula)**.** *For every pentary self-substitution row,*

$$\nu = \frac{1}{5}\left[x_0x_1 + x_1x_2 + x_2x_3 + (x_3x_4 + x_4x_0)\mu\right].$$

Proof. Split the average defining $\Gamma(\delta_0 - \delta_2)$ by $n = 5q + a$. For $a = 0, 1, 2$ the residues do not cross the next pentary block, giving the factors x_0x_1, x_1x_2, and x_2x_3. For $a = 3$ the carry leaves the branch block $\delta_0 - \delta_1$ and contributes $x_3x_4\mu$. For $a = 4$ it contributes $x_4x_0\mu$. Averaging gives the formula. □

9432.2 Anchored $L = 3$ Link Diagonals

Definition 9432.5 (Forward anchored links)**.** *Use the forward neutral links*

$$F_{ij} := u_{n+i}\overline{u_{n+j}}, \qquad 1 \le i < j \le 3,$$

and define

$$D_{ij} := \langle \theta F_{ij}, F_{ij} \rangle.$$

After the common translation normalization, the three link diagonals are

$$D_{12} = \Gamma(\delta_0 - \delta_1 + \delta_2 - \delta_3),$$

$$D_{13} = \Gamma(\delta_0 - \delta_2 + \delta_3 - \delta_5),$$

and

$$D_{23} = \Gamma(\delta_0 - \delta_1 + \delta_4 - \delta_5).$$

The opposite orientation of a link conjugates the displayed block; for real diagonal obstructions the numerical sign information is unchanged.

Theorem 9432.6 (Pentary D_{12} formula)**.** *For every pentary self-substitution row,*

$$D_{12} = \frac{1}{5}\left[x_0x_2 + x_1x_3 + x_3x_0 + (x_2x_4 + x_4x_1)\mu\right].$$

Proof. Apply the pentary carry split to $\delta_0 - \delta_1 + \delta_2 - \delta_3$. The five residues give

$$a = 0: \ x_0x_2, \qquad a = 1: \ x_1x_3,$$

$$a = 2: \ x_2x_4\,\mu, \qquad a = 3: \ x_3x_0,$$

and

$$a = 4: \ x_4x_1\,\mu.$$

Averaging gives the formula. □

Theorem 9432.7 (Pentary D_{13} formula)**.** *For every pentary self-substitution row,*

$$D_{13} = \frac{1}{5}\left[\overline{x_4} + (\overline{x_0} + \overline{x_1} + \overline{x_2} + \overline{x_3})\mu\right].$$

Proof. Apply the carry split to $\delta_0 - \delta_2 + \delta_3 - \delta_5$. The residues $a = 0, 1, 3, 4$ leave the branch block $\delta_0 - \delta_1$ with coefficients $\overline{x_2}$, $\overline{x_3}$, $\overline{x_0}$, and $\overline{x_1}$ respectively. The residue $a = 2$ collapses to the zero block with coefficient $\overline{x_4}$. Since the four nonzero branch coefficients are the same cyclic set $\overline{x_0}, \overline{x_1}, \overline{x_2}, \overline{x_3}$, averaging gives the stated expression. □

Theorem 9432.8 (Pentary D_{23} correlation meeting)**.** *For every pentary self-substitution row,*

$$D_{23} = \nu.$$

Equivalently,

$$D_{23} = \frac{1}{5}\left[x_0x_1 + x_1x_2 + x_2x_3 + (x_3x_4 + x_4x_0)\mu\right].$$

Proof. Apply the carry split to $\delta_0 - \delta_1 + \delta_4 - \delta_5$. The five residues give

$$a = 0: \ x_4x_0\,\mu, \qquad a = 1: \ x_0x_1,$$

$$a = 2: \ x_1x_2, \qquad a = 3: \ x_2x_3,$$

and

$$a = 4: \ x_3x_4\,\mu.$$

The resulting average is exactly the formula for ν in Definition 9432.4. □

Theorem 9432.9 (Three-link necessary condition)**.** *If a pentary row passes the anchored $L = 3$ neutral RP window, then*

$$D_{12} \in \mathbb{R}_{\geq 0}, \qquad D_{13} \in \mathbb{R}_{\geq 0}, \qquad D_{23} \in \mathbb{R}_{\geq 0},$$

and

$$D_{12} \geq |\mu|^2, \qquad D_{13} \geq |\nu|^2, \qquad D_{23} \geq |\mu|^2.$$

In particular,

$$\nu \in \mathbb{R}, \qquad \nu \geq |\mu|^2.$$

Proof. For each link F_{ij}, take the 2×2 principal RP matrix on $1, F_{ij}$. Positivity forces the lower-right entry to be real nonnegative and forces the determinant inequality. For F_{12} and F_{23} the ordinary mean is μ, while for F_{13} it is ν. The displayed inequalities follow. The final statement uses Definition 9432.8. □

9432.3 Endpoint Gate

Theorem 9432.10 (Endpoint form of the middle link)**.** *For every pentary self-substitution row,*

$$D_{13} = |\mu|^2 + \frac{1 - |\mu|^2}{5}\overline{x_4}.$$

Proof. By Definition 9432.3,

$$x_0 + x_1 + x_2 + x_3 = (5 - x_4)\mu.$$

Taking conjugates gives

$$\overline{x_0} + \overline{x_1} + \overline{x_2} + \overline{x_3} = (5 - \overline{x_4})\overline{\mu}.$$

Substitute this identity into Definition 9432.7:

$$D_{13} = \frac{1}{5}\left[\overline{x_4} + (5 - \overline{x_4})|\mu|^2\right].$$

Rearranging gives the displayed formula. □

Lemma 9432.11 (Q3 excludes unit first correlation)**.** *If $v \in \mathcal{Q}_5$, then*

$$|\mu| < 1.$$

Proof. Assume $|\mu| = 1$. The recursion in the proof of Definition 9432.3 writes μ as the average of the five unit complex numbers

$$x_0, \quad x_1, \quad x_2, \quad x_3, \quad x_4\mu.$$

An average of unit complex numbers has unit modulus only when all terms are equal. Hence

$$x_0 = x_1 = x_2 = x_3 = \mu, \qquad x_4\mu = \mu.$$

Since $\mu \neq 0$, this gives $x_4 = 1$. The cyclic product relation then gives

$$\mu^4 = x_0x_1x_2x_3x_4 = 1.$$

Writing $\rho := \mu$, the edge-ratio equations force

$$v = v_0(1, \overline{\rho}, \overline{\rho}^2, \overline{\rho}^3, \overline{\rho}^4), \qquad \rho^4 = 1.$$

If $\rho = 1$, the row sum has modulus 5. If $\rho \in \{-1, i, -i\}$, the row sum has modulus 1. None of these moduli is $\sqrt{5}$, contradicting $v \in \mathcal{Q}_5$. Therefore $|\mu| < 1$. □

Theorem 9432.12 (Pentary endpoint gate)**.** *If a row $v \in \mathcal{Q}_5$ passes the anchored $L = 3$ neutral RP window, then*

$$x_4 \in \{1, -1\}.$$

Equivalently,

$$v_4 = v_0 \qquad \text{or} \qquad v_4 = -v_0.$$

Proof. Reflection positivity forces the diagonal entry D_{13} to be real nonnegative by Definition 9432.9. By Definition 9432.10,

$$D_{13} = |\mu|^2 + \frac{1 - |\mu|^2}{5}\overline{x_4}.$$

The first term is real, and Definition 9432.11 gives

$$1 - |\mu|^2 > 0.$$

Thus D_{13} is real only if $\overline{x_4}$ is real. Since $|x_4| = 1$, this means $x_4 = \pm 1$. The identity $x_4 = v_4\overline{v_0}$ is then equivalent to $v_4 = \pm v_0$. □

Definition 9432.13 (Endpoint branches)**.** *The even endpoint branch is the sublocus of $\mathcal{Q}_5$ on which*

$$v_4 = v_0,$$

equivalently $x_4 = 1$. On this branch the Q3 equation reads

$$2v_0 + v_1 + v_2 + v_3 = \sqrt{5}.$$

The odd endpoint branch is the sublocus of $\mathcal{Q}_5$ on which

$$v_4 = -v_0,$$

equivalently $x_4 = -1$. On this branch the Q3 equation reads

$$v_1 + v_2 + v_3 = \sqrt{5}.$$

Corollary 9432.14 (Endpoint branch form of candidates)**.** *Every anchored $L = 3$ neutral RP candidate in $\mathcal{Q}_5$ lies in one of the two endpoint forms*

$$v = (v_0, v_1, v_2, v_3, v_0)$$

or

$$v = (v_0, v_1, v_2, v_3, -v_0).$$

The palindromic locus is the sublocus of the even endpoint branch where $v_1 = v_3$.

Proof. This is exactly Definition 9432.12, with the palindromic condition read from Definition 9439.6. □

Corollary 9432.15 (Middle-link values on endpoint branches)**.** *On the even endpoint branch,*

$$D_{13} = \frac{1 + 4|\mu|^2}{5}.$$

On the odd endpoint branch,

$$D_{13} = \frac{6|\mu|^2 - 1}{5}.$$

Consequently, an anchored $L = 3$ neutral RP candidate on the odd endpoint branch must satisfy

$$|\mu|^2 \geq \frac{1}{6}.$$

Proof. Substitute $x_4 = 1$ and $x_4 = -1$ respectively into Definition 9432.10. The odd endpoint lower bound is the condition $D_{13} \geq 0$ from Definition 9432.9. □

Principle 9432.16 (Endpoint-first pentary search)**.** *The first scalar diagonal gate for the anchored $L = 3$ neutral RP problem does not inspect the full 7×7 matrix. It already confines every candidate to the even or odd endpoint branch. The even endpoint branch still contains the palindromic rows, while the odd endpoint branch leaves the endpoint phase outside the Q3 equation; any candidate there must have that phase fixed by the Hermitian and positive-semidefinite gates rather than by Q3 alone.*

Corollary 9432.17 (Algebraic form of the anchor effect)**.** *The two links F_{12} and F_{23} have the same ordinary distance-one mean μ, but their RP diagonals need not agree. In the pentary $L = 3$ window,*

$$D_{23} = \Gamma(\delta_0 - \delta_2),$$

so reflection positivity forces the concrete inequality

$$\Gamma(\delta_0 - \delta_2) \geq |\Gamma(\delta_0 - \delta_1)|^2 .$$

9432.4 Pythagorean Link Recheck

Corollary 9432.18 (Pythagorean row violates the second link)**.** *For the Pythagorean row* $v_\star = (a, b, -a, b, a)$ *from Definition 9431.4,*

$$\mu = 0, \qquad D_{12} = \frac{3}{5}, \qquad D_{23} = \nu = -\frac{1}{5}.$$

Thus the anchored $L = 3$ *obstruction is the negative ordinary distance-two correlation.*

Proof. The values $\mu = 0$ and $D_{12} = 3/5$ are Definition 9431.7. The value $D_{23} = -1/5$ is Definition 9431.10, conjugated to the forward-link convention of Definition 9432.5. Since the value is real, the obstruction is unchanged. The identity $D_{23} = \nu$ then identifies the failing scalar with the ordinary distance-two correlation. □

Chapter 9433

Innovation Input Pentary Odd Endpoint Exclusion

Definition 9432.12 confines every anchored $L = 3$ neutral RP candidate in $\mathcal{Q}_5$ to one of two endpoint branches. This chapter discharges the odd endpoint branch. The argument uses only the first reflected link mean and the middle-link diagonal: Hermitian symmetry makes the distance-one mean real, while the odd endpoint Q3 geometry makes any real value too small to pass the D_{13} positivity gate.

9433.1 Odd Endpoint Coordinates

Definition 9433.1 (Odd endpoint relative coordinates)**.** *Assume $v \in \mathcal{Q}_5$ lies on the odd endpoint branch of Definition 9432.13. Write*

$$v = (a, b, c, d, -a), \qquad |a| = |b| = |c| = |d| = 1.$$

Define the relative internal phases

$$B := \frac{b}{a}, \qquad C := \frac{c}{a}, \qquad D := \frac{d}{a},$$

and the internal edge ratios

$$p := B\overline{C}, \qquad q := C\overline{D}.$$

Then $B, C, D, p, q \in \mathbb{T}$ and

$$B\overline{D} = pq.$$

Theorem 9433.2 (Odd endpoint Q3 edge equation)**.** *On the odd endpoint branch, the Q3 condition is equivalent to*

$$\mathrm{Re}(p + q + pq) = 1.$$

Proof. Since $v_4 = -v_0$, the Q3 equation becomes

$$b + c + d = \sqrt{5}.$$

Multiplying by $\overline{a}$ gives

$$|B + C + D| = \sqrt{5}.$$

Squaring the modulus gives

$$|B + C + D|^2 = 3 + 2\,\mathrm{Re}\left(B\overline{C} + C\overline{D} + B\overline{D}\right).$$

Using $B\overline{C} = p$, $C\overline{D} = q$, and $B\overline{D} = pq$, the condition $|B + C + D|^2 = 5$ is exactly

$$\mathrm{Re}(p + q + pq) = 1.$$

□

Theorem 9433.3 (Odd endpoint first correlation)**.** *On the odd endpoint branch,*

$$6\mu = \overline{B} + p + q - D = \overline{B} + p + q - \frac{B}{pq}.$$

Proof. For $v = (a, b, c, d, -a)$, the cyclic edge ratios of Definition 9432.1 are

$$x_0 = a\overline{b} = \overline{B}, \qquad x_1 = b\overline{c} = p,$$

$$x_2 = c\overline{d} = q, \qquad x_3 = d\overline{(-a)} = -D,$$

and

$$x_4 = (-a)\overline{a} = -1.$$

Substitution into Definition 9432.3 gives

$$\mu = \frac{x_0 + x_1 + x_2 + x_3}{5 - x_4} = \frac{\overline{B} + p + q - D}{6}.$$

Finally $pq = B\overline{D}$ implies $D = B/(pq)$. □

9433.2 Real First-Correlation Bound

Lemma 9433.4 (Odd endpoint real mean bound)**.** *On the odd endpoint Q3 branch, if*

$$\mu \in \mathbb{R},$$

then

$$|\mu| \le \frac{1}{10}.$$

Proof. Write

$$p = e^{i(\eta+\delta)}, \qquad q = e^{i(\eta-\delta)}.$$

Then $pq = e^{2i\eta}$, and Definition 9433.2 becomes

$$2\cos\delta\cos\eta + \cos 2\eta = 1.$$

Set

$$c := \cos\eta, \qquad y := c^2.$$

The displayed equation is

$$\cos\delta\, c = 1 - c^2.$$

In particular $c \neq 0$, and

$$\cos\delta = \frac{1-y}{c}.$$

Write $B = e^{i(\eta+\varphi)}$. By Definition 9433.3,

$$6\mu = p + q + \overline{B} - \frac{B}{pq}.$$

Since

$$p + q = 2\cos\delta\, e^{i\eta}$$

and

$$\overline{B} - \frac{B}{pq} = -2ie^{-i\eta}\sin\varphi,$$

one has

$$6\mu = 2\cos\delta\, e^{i\eta} - 2ie^{-i\eta}\sin\varphi.$$

Taking imaginary parts and using $\mu \in \mathbb{R}$ gives

$$\cos\delta\sin\eta = \cos\eta\sin\varphi.$$

Thus

$$|\sin\varphi| = |\cos\delta\tan\eta| = \frac{(1-y)^{3/2}}{y} \leq 1.$$

Hence

$$(1-y)^3 \leq y^2.$$

The function $(1-y)^3 - y^2$ is strictly decreasing on $[0,1]$, and at $y = 2/5$ it equals

$$\left(\frac{3}{5}\right)^3 - \left(\frac{2}{5}\right)^2 = \frac{7}{125} > 0.$$

Therefore

$$y > \frac{2}{5}.$$

Taking real parts in the displayed formula for 6μ and substituting $\sin\varphi = \cos\delta\tan\eta$ gives

$$6\mu = 2\cos\delta\left(\cos\eta - \frac{\sin^2\eta}{\cos\eta}\right) = 2\cos\delta\frac{\cos 2\eta}{\cos\eta}.$$

Using $\cos\delta = (1-y)/\cos\eta$ yields

$$\mu = \frac{(1-y)(2y-1)}{3y}.$$

For $2/5 \leq y \leq 1/2$,

$$|\mu| = \frac{(1-y)(1-2y)}{3y}.$$

The inequality $|\mu| \leq 1/10$ is equivalent to

$$20y^2 - 33y + 10 \leq 0,$$

whose roots are $2/5$ and $5/4$, so it holds on this interval. For $1/2 \le y \le 1$,

$$\mu = \frac{(1-y)(2y-1)}{3y},$$

and $\mu \le 1/10$ is equivalent to

$$20y^2 - 27y + 10 \ge 0.$$

This quadratic has discriminant -71 and positive leading coefficient, so it is positive for all real y. The bound follows. □

9433.3 Odd Endpoint Exclusion

Theorem 9433.5 (No odd endpoint anchored $L = 3$ candidate)**.** *There is no row*

$$v \in \mathcal{Q}_5$$

on the odd endpoint branch that passes the anchored $L = 3$ neutral RP window.

Proof. Assume that such a row passes anchored $L = 3$ neutral RP. Then the RP matrix is Hermitian. Applying the Hermitian condition to the subwindow generated by 0 and e_{12} forces the distance-one mean

$$\mu = \Gamma(\delta_0 - \delta_1)$$

to be real. Hence Definition 9433.4 gives

$$|\mu|^2 \le \frac{1}{100}.$$

On the odd endpoint branch, Definition 9432.15 gives

$$D_{13} = \frac{6|\mu|^2 - 1}{5}.$$

Therefore

$$D_{13} \le \frac{6/100 - 1}{5} = -\frac{47}{250} < 0.$$

This contradicts the required nonnegativity of D_{13} in Definition 9432.9. □

Corollary 9433.6 (Pentary candidates reduce to the even endpoint branch)**.** *Every row in*

$$\mathcal{R}^{\mathrm{neu}}_{5,3,1}$$

lies on the even endpoint branch

$$v_4 = v_0.$$

Proof. By the endpoint gate of Definition 9432.12, any anchored $L = 3$ neutral RP candidate has $v_4 = v_0$ or $v_4 = -v_0$. The odd endpoint case is impossible by Definition 9433.5. □

Theorem 9433.7 (Even endpoint exclusion closes the pentary three-link class)**.** *Assume that no row on the even endpoint branch*

$$v_4 = v_0$$

passes the anchored $L = 3$ neutral RP window. Then

$$\mathcal{R}^{\mathrm{neu}}_{5,3,1} = \varnothing.$$

Proof. By Definition 9433.6, every row in $\mathcal{R}^{\mathrm{neu}}_{5,3,1}$ lies on the even endpoint branch. The stated even endpoint exclusion therefore leaves no row in $\mathcal{R}^{\mathrm{neu}}_{5,3,1}$. □

Principle 9433.8 (Pentary branch ledger)**.** *The anchored pentary $L = 3$ neutral RP problem has a branch-level structure. The middle-link diagonal gives the endpoint dichotomy $v_4 = \pm v_0$. The odd endpoint branch is ruled out by the incompatibility between Hermitian realness of μ and $D_{13} \geq 0$. The remaining unconditional branch is the even endpoint branch; once it is excluded, the whole pentary three-link class is empty.*

Chapter 9434

Innovation Input Nine-ary Real-Sign RP Screen

Definition 9426.10 shows that every square alphabet admits Q3-compatible real-sign self-substitution rows. These rows are automatically two-point weakly reversible by Definition 9426.9. The first square alphabet beyond the quartic endpoint is $N = 9$. This chapter records the finite-window RP screen for that real-sign subfamily: many rows pass the anchored $L = 2$ neutral test, but no row survives the anchored $L = 3$ real neutral window.

9434.1 Nine-ary Real-Sign Rows

Definition 9434.1 (Nine-ary real-sign Q3 row)**.** *A nine-ary real-sign Q3 row is a word*

$$v = (v_0, \dots, v_8) \in \{+1, -1\}^9$$

satisfying

$$\sum_{a=0}^{8} v_a = 3.$$

It determines the real-sign self-substitution sequence

$$u_{9n+a} = v_a u_n, \qquad u_n \in \{+1, -1\}.$$

Proposition 9434.2 (Three negative signs)**.** *A word $v \in \{+1, -1\}^9$ is a nine-ary real-sign Q3 row if and only if it has six entries equal to $+1$ and three entries equal to -1. Hence there are*

$$\binom{9}{3} = 84$$

such rows.

Proof. Let P and M be the numbers of positive and negative entries. Then

$$P + M = 9$$

and the Q3 condition is

$$P - M = 3.$$

Thus $P = 6$ and $M = 3$. The converse is immediate, and the count is the choice of the three negative positions. □

9434.2 Real Neutral Window

Definition 9434.3 (Real-sign support block)**.** *For a finite support $S \subset \mathbb{Z}$, set*

$$U_S(n) := \prod_{j \in S} u_{n+j}.$$

Only the parity of site multiplicity matters, since $u_n^2 = 1$. Write

$$\Gamma(S) := \langle U_S \rangle.$$

The empty support satisfies $\Gamma(\varnothing) = 1$, and common translation of S does not change $\Gamma(S)$.

Definition 9434.4 (Anchored real $L = 3$ neutral window)**.** *The real-sign anchored $L = 3$ neutral window is*

$$\mathcal{B}_3^{\mathbb{R}} = \{1, F_{12}, F_{13}, F_{23}\},$$

where

$$F_{12} = u_{n+1}u_{n+2}, \qquad F_{13} = u_{n+1}u_{n+3}, \qquad F_{23} = u_{n+2}u_{n+3}.$$

This is the real collapse of the complex neutral window $\{1, F_{12}, F_{13}, F_{23}, \overline{F}_{12}, \overline{F}_{13}, \overline{F}_{23}\}$, because $u_n^{-1} = u_n$.

Definition 9434.5 (Nine-ary real neutral RP matrix)**.** *Let*

$$F_0 := 1, \qquad F_1 := F_{12}, \qquad F_2 := F_{13}, \qquad F_3 := F_{23}.$$

The anchored real neutral $L = 3$ RP matrix is

$$M_3^{\mathbb{R}}(v)_{ij} := \langle \theta F_i, F_j \rangle, \qquad 0 \le i, j \le 3,$$

where $\theta(j) = 1 - j$ on anchored future sites, as in Definition 9428.1. The row passes the screen when $M_3^{\mathbb{R}}(v)$ is symmetric and positive semidefinite.

9434.3 Exact Carry Evaluator

Definition 9434.6 (Nine-ary carry branch)**.** *Let $S \subset \mathbb{Z}_{\ge 0}$ be finite and let $a \in \{0, \dots, 8\}$. For each $j \in S$, write*

$$a + j = 9q_{j,a} + r_{j,a}, \qquad 0 \le r_{j,a} < 9.$$

Set

$$C_a(S) := \prod_{j \in S} v_{r_{j,a}}.$$

Let S_a be the set of quotient positions $q_{j,a}$ that occur with odd multiplicity, translated so that its least element is 0 when it is nonempty.

Theorem 9434.7 (Real-sign finite carry recursion)**.** *For every finite support $S \subset \mathbb{Z}_{\ge 0}$,*

$$\Gamma(S) = \frac{1}{9} \sum_{a=0}^{8} C_a(S)\Gamma(S_a).$$

For any fixed finite window, repeated branching generates a finite set of normalized supports, and the associated correlations are the unique solution of a finite rational linear system.

Proof. Write $n = 9q + a$. Then

$$n + j = 9(q + q_{j,a}) + r_{j,a},$$

and the self-substitution rule gives

$$u_{n+j} = v_{r_{j,a}} u_{q+q_{j,a}}.$$

Multiplying over $j \in S$ yields

$$U_S(n) = C_a(S) \prod_{j \in S} u_{q+q_{j,a}}.$$

Repeated quotient positions cancel in pairs because $u_m^2 = 1$, leaving the parity support S_a. Averaging over the nine residues gives the displayed recursion.

If a support has diameter d, every branch support has diameter at most $\lceil d/9 \rceil$. After finitely many branches the diameter is confined to a finite range determined by the original window. Hence the closure is finite. Since all coefficients are rational signs divided by 9, the finite system is rational. Uniqueness follows by evaluation as the Cesaro limit of the substitution sequence; equivalently, the displayed finite system is the exact correlation system generated by that limit. □

9434.4 Two-Window Passage

Proposition 9434.8 (Anchored $L = 2$ real screen)**.** *Among the* 84 *nine-ary real-sign Q3 rows, exactly* 31 *pass the anchored* $L = 2$ *real neutral RP screen for the window* $\{1, F_{12}\}$.

Proof. For the two-window, write

$$\mu := \Gamma(\{0, 1\})$$

and

$$D_{12} := \Gamma(\{0, 1, 2, 3\}).$$

The anchored 2×2 matrix is

$$\begin{pmatrix} 1 & \mu \\ \mu & D_{12} \end{pmatrix},$$

so passage is equivalent to

$$D_{12} \geq 0 \qquad \text{and} \qquad D_{12} \geq \mu^2.$$

The exact rational evaluator of Definition 9434.7, applied to the 84 choices of the three negative positions, gives 31 passing rows. The reproducible enumeration is `papers/bedc/experiments/nine_real_sign_rp_s` □

Proposition 9434.9 (A strict two-window witness)**.** *Let the negative positions be*

$$I = \{0, 1, 3\},$$

so that

$$v = (-1, -1, 1, -1, 1, 1, 1, 1, 1).$$

Then

$$\mu = \frac{1}{5}, \qquad D_{12} = \frac{1}{9},$$

and therefore

$$D_{12} - \mu^2 = \frac{16}{225} > 0.$$

Proof. These values are the exact solution of the carry system generated by Definition 9434.7 for the supports $\{0, 1\}$ and $\{0, 1, 2, 3\}$. The same script cited in Definition 9434.8 recomputes the fractions directly. □

9434.5 Three-Window Exclusion

Theorem 9434.10 (No nine-ary real-sign $L = 3$ RP row)**.** *No nine-ary real-sign Q3 row passes the anchored real neutral $L = 3$ RP screen:*

$$\begin{aligned}\{v \in \{+1,-1\}^9 : \sum_{a=0}^{8} v_a = 3,\ M_3^{\mathbb{R}}(v) = M_3^{\mathbb{R}}(v)^{\mathsf{T}},\ M_3^{\mathbb{R}}(v) \succeq 0\} \\ = \varnothing.\end{aligned}$$

Proof. By Definition 9434.2, there are 84 candidates. The exact carry evaluator computes each matrix $M_3^{\mathbb{R}}(v)$. Of these matrices, 70 are not symmetric and therefore cannot define a real reflection-positive quadratic form.

The remaining 14 matrices are symmetric. Each fails positive semidefiniteness by a negative diagonal entry or by a negative principal 2×2 determinant. With row and column indices ordered as

$$0 \leftrightarrow 1, \qquad 1 \leftrightarrow F_{12}, \qquad 2 \leftrightarrow F_{13}, \qquad 3 \leftrightarrow F_{23},$$

the exact certificates are:

negative positions I	negative certificate
$\{0,1,2\}$	$\det M_{\{0,1\}} = -\frac{4}{25}$
$\{0,2,4\}$	$M_{33} = -\frac{3}{5}$
$\{0,4,5\}$	$M_{11} = -\frac{7}{45}$
$\{0,4,8\}$	$M_{11} = -\frac{5}{9}$
$\{1,3,5\}$	$\det M_{\{0,1\}} = -\frac{5}{36}$
$\{1,4,7\}$	$\det M_{\{0,1\}} = -\frac{1}{4}$
$\{2,3,4\}$	$\det M_{\{0,1\}} = -\frac{5}{36}$
$\{2,4,6\}$	$M_{22} = -\frac{1}{9}$
$\{3,4,5\}$	$\det M_{\{0,1\}} = -\frac{1}{4}$
$\{3,4,8\}$	$M_{11} = -\frac{7}{45}$
$\{3,5,7\}$	$\det M_{\{0,1\}} = -\frac{5}{36}$
$\{4,5,6\}$	$\det M_{\{0,1\}} = -\frac{5}{36}$
$\{4,6,8\}$	$M_{33} = -\frac{3}{5}$
$\{6,7,8\}$	$\det M_{\{0,1\}} = -\frac{4}{25}$

Every listed entry is a necessary principal-minor condition for positive semidefiniteness. Thus no candidate survives the anchored real neutral $L = 3$ screen. □

Principle 9434.11 (Square realness is not RP positivity)**.** *The square-alphabet real-sign construction gives Q3 compatibility and two-point realness, but it does not by itself give reflection positivity. At $N = 9$, the natural real-sign Q3 family is already empty at the anchored $L = 3$ RP level, even though it has many anchored $L = 2$ survivors. The result concerns only the real-sign subfamily*

$$\{+1,-1\}^9 \cap \mathcal{Q}_9.$$

The general complex phase locus

$$\mathcal{Q}_9 = \left\{ v \in \mathbb{T}^9 : \sum_{a=0}^{8} v_a = 3 \right\}$$

is not excluded by this screen.

Chapter 9435

Innovation Input Nine-ary Complex Phase Link Formulas

chapter 9434 excludes the real-sign subfamily of the nine-ary Q3 locus from the anchored $L = 3$ real neutral RP screen. That exclusion is a sublocus statement. The complex phase locus still requires the reflection-positive tests to be read on the full phase torus. This chapter records the first scalar link formulas for that locus: the ordinary distance-one and distance-two correlations, the three anchored $L = 3$ link diagonals, and the principal minor inequalities forced by reflection positivity.

9435.1 Nine-ary Phase Locus

Definition 9435.1 (Nine-ary complex Q3 phase row)**.** *The nine-ary complex Q3 phase locus is*

$$\mathcal{Q}_9 := \left\{ v = (v_0, \dots, v_8) \in \mathbb{T}^9 : \sum_{a=0}^{8} v_a = 3 \right\}.$$

For $v \in \mathcal{Q}_9$, the associated self-substitution phase sequence is determined by

$$u_{9n+a} = v_a u_n, \qquad a = 0, \dots, 8.$$

The equality $3 = \sqrt{9}$ makes this the $N = 9$ instance of the Q3 phase-polygon equation in Definition 9425.15.

Definition 9435.2 (Nine-ary cyclic edge ratios)**.** *For a nine-ary phase row, define*

$$x_a := v_a \overline{v_{a+1}}, \qquad a = 0, \dots, 8,$$

where indices are read modulo 9, so that

$$x_8 = v_8 \overline{v_0}.$$

Then

$$|x_a| = 1$$

for every a, and the cyclic product satisfies

$$x_0 x_1 \cdots x_8 = 1.$$

9435.2 Ordinary Link Correlations

Definition 9435.3 (First and second nine-ary correlations)**.** *For the self-substitution sequence associated to a nine-ary phase row, write*

$$\mu := \Gamma(\delta_0 - \delta_1) = \langle u_n \overline{u_{n+1}} \rangle$$

and

$$\nu := \Gamma(\delta_0 - \delta_2) = \langle u_n \overline{u_{n+2}} \rangle .$$

Theorem 9435.4 (Nine-ary first correlation formula)**.** *For every nine-ary self-substitution phase row,*

$$\mu = \frac{x_0 + x_1 + \cdots + x_7}{9 - x_8}.$$

Proof. Split the average defining $\Gamma(\delta_0 - \delta_1)$ by $n = 9q + a$. For $a = 0, \ldots, 7$, the two sites n and $n+1$ lie in the same nine-ary cell and contribute x_a. For $a = 8$, the second site crosses to the next cell and contributes $x_8\mu$. Hence

$$\mu = \frac{1}{9}\left(x_0 + \cdots + x_7 + x_8\mu\right).$$

Since $|x_8| = 1$, the denominator $9 - x_8$ is nonzero, and the displayed formula follows. □

Theorem 9435.5 (Nine-ary second correlation formula)**.** *For every nine-ary self-substitution phase row,*

$$\nu = \frac{1}{9}\left[\sum_{a=0}^{6} x_a x_{a+1} + (x_7 x_8 + x_8 x_0)\mu\right].$$

Proof. Split $\Gamma(\delta_0 - \delta_2)$ by $n = 9q + a$. For $a = 0, \ldots, 6$, no carry occurs and the coefficient is

$$v_a \overline{v_{a+2}} = x_a x_{a+1}.$$

For $a = 7$, the second site crosses to residue 0 in the next cell, and the branch block is $\delta_0 - \delta_1$ with coefficient $x_7 x_8$. For $a = 8$, the second site crosses to residue 1 in the next cell, and the same branch block has coefficient $x_8 x_0$. Averaging over the nine residues gives the formula. □

9435.3 Anchored Link Diagonals

Definition 9435.6 (Nine-ary forward link diagonals)**.** *Use the forward neutral links*

$$F_{12} := u_{n+1}\overline{u_{n+2}}, \qquad F_{13} := u_{n+1}\overline{u_{n+3}}, \qquad F_{23} := u_{n+2}\overline{u_{n+3}}.$$

By translation invariance,

$$\langle F_{12} \rangle = \mu, \qquad \langle F_{13} \rangle = \nu, \qquad \langle F_{23} \rangle = \mu.$$

With the discrete reflection $\theta(j) = 1 - j$ from Definition 9428.1, define

$$D_{ij} := \langle \theta F_{ij}, F_{ij} \rangle.$$

After common translation of the reflected signed block, the three diagonals are

$$D_{12} = \Gamma(\delta_0 - \delta_1 + \delta_2 - \delta_3),$$

$$D_{13} = \Gamma(\delta_0 - \delta_2 + \delta_3 - \delta_5),$$

and

$$D_{23} = \Gamma(\delta_0 - \delta_1 + \delta_4 - \delta_5).$$

Theorem 9435.7 (Nine-ary D_{12} formula)**.** *For every nine-ary self-substitution phase row,*

$$D_{12} = \frac{1}{9}\left[\sum_{a=0}^{5} x_a x_{a+2} + x_7 x_0 + (x_6 x_8 + x_8 x_1)\mu\right].$$

Proof. Apply the residue split to $\delta_0 - \delta_1 + \delta_2 - \delta_3$. The branch data are

residue	coefficient	branch block
$0 \le a \le 5$	$x_a x_{a+2}$	$\varnothing$
6	$x_6 x_8$	$\delta_0 - \delta_1$
7	$x_7 x_0$	$\varnothing$
8	$x_8 x_1$	$\delta_0 - \delta_1$

The empty branch contributes 1, and the branch $\delta_0 - \delta_1$ contributes μ. Averaging over all residues gives the displayed formula. □

Theorem 9435.8 (Nine-ary D_{13} formula)**.** *For every nine-ary self-substitution phase row,*

$$D_{13} = \frac{1}{9}\Big[\sum_{a=0}^{3} x_a x_{a+1} x_{a+3} x_{a+4} + x_6 x_7 x_0 x_1 + (x_4 x_5 x_7 x_8 + x_5 x_6 x_8 x_0 + x_7 x_8 x_1 x_2 + x_8 x_0 x_2 x_3)\,\mu\Big].$$

Proof. Apply the residue split to $\delta_0 - \delta_2 + \delta_3 - \delta_5$. The branch data are

residue	coefficient	branch block
$0 \le a \le 3$	$x_a x_{a+1} x_{a+3} x_{a+4}$	$\varnothing$
4	$x_4 x_5 x_7 x_8$	$\delta_0 - \delta_1$
5	$x_5 x_6 x_8 x_0$	$\delta_0 - \delta_1$
6	$x_6 x_7 x_0 x_1$	$\varnothing$
7	$x_7 x_8 x_1 x_2$	$\delta_0 - \delta_1$
8	$x_8 x_0 x_2 x_3$	$\delta_0 - \delta_1$

Again the empty branch contributes 1, while $\delta_0 - \delta_1$ contributes μ. The nine-residue average is the claimed identity. □

Theorem 9435.9 (Nine-ary D_{23} formula)**.** *For every nine-ary self-substitution phase row,*

$$D_{23} = \frac{1}{9}\left[\sum_{a=0}^{3} x_a x_{a+4} + x_5 x_0 + x_6 x_1 + x_7 x_2 + (x_4 x_8 + x_8 x_3)\mu\right].$$

Proof. Apply the residue split to $\delta_0 - \delta_1 + \delta_4 - \delta_5$. The branch data are

residue	coefficient	branch block
$0 \le a \le 3$	$x_a x_{a+4}$	$\varnothing$
4	$x_4 x_8$	$\delta_0 - \delta_1$
5	$x_5 x_0$	$\varnothing$
6	$x_6 x_1$	$\varnothing$
7	$x_7 x_2$	$\varnothing$
8	$x_8 x_3$	$\delta_0 - \delta_1$

Averaging the empty branches and the two $\delta_0 - \delta_1$ branches gives the displayed formula. □

9435.4 Principal Reflection-Positive Conditions

Theorem 9435.10 (Nine-ary three-link RP necessary condition)**.** *If a nine-ary Q3 phase row passes the anchored $L = 3$ neutral RP window, then*

$$D_{12} \in \mathbb{R}_{\geq 0}, \qquad D_{13} \in \mathbb{R}_{\geq 0}, \qquad D_{23} \in \mathbb{R}_{\geq 0},$$

and

$$D_{12} \geq |\mu|^2, \qquad D_{13} \geq |\nu|^2, \qquad D_{23} \geq |\mu|^2.$$

Proof. For each future link F_{ij}, restrict the RP Gram matrix to the two-dimensional span of 1 and F_{ij}. The corresponding principal matrix has the form

$$\begin{pmatrix} 1 & \langle F_{ij} \rangle \\ \overline{\langle F_{ij} \rangle} & D_{ij} \end{pmatrix}.$$

Hermitian positive semidefiniteness forces the lower-right entry to be a nonnegative real number and forces the determinant inequality. The means of F_{12} and F_{23} are μ, while the mean of F_{13} is ν. This gives the displayed conditions. □

Definition 9435.11 (Nine-ary link deficits)**.** *Define the three scalar link deficits by*

$$\Delta_{12} := D_{12} - |\mu|^2, \qquad \Delta_{13} := D_{13} - |\nu|^2, \qquad \Delta_{23} := D_{23} - |\mu|^2.$$

Corollary 9435.12 (Scalar deficit obstruction)**.** *A nine-ary Q3 phase row fails the anchored $L = 3$ neutral RP window if any of the following conditions holds:*

$$D_{12} \notin \mathbb{R}_{\geq 0}, \qquad D_{13} \notin \mathbb{R}_{\geq 0}, \qquad D_{23} \notin \mathbb{R}_{\geq 0},$$

or

$$\Delta_{12} < 0, \qquad \Delta_{13} < 0, \qquad \Delta_{23} < 0$$

for at least one displayed deficit.

Proof. This is the contrapositive of Definition 9435.10. □

9435.5 Pentary Contrast

Principle 9435.13 (Nine-ary links are multi-edge readouts)**.** *The pentary middle link has the endpoint form*

$$D_{13} = |\mu|^2 + \frac{1 - |\mu|^2}{5} \overline{x_4}$$

from Definition 9432.10. Together with the Q3 exclusion of $|\mu| = 1$, this yields the pentary endpoint gate $x_4 = \pm 1$ in Definition 9432.12.

The nine-ary middle link does not collapse to a single endpoint edge in the same residue computation. Its diagonal contains four interior four-edge products, one carry-cancelling boundary product, and four carry terms multiplied by μ:

$$D_{13} = \frac{1}{9}\Big[\sum_{a=0}^{3} x_a x_{a+1} x_{a+3} x_{a+4} + x_6 x_7 x_0 x_1 \\ + (x_4 x_5 x_7 x_8 + x_5 x_6 x_8 x_0 + x_7 x_8 x_1 x_2 + x_8 x_0 x_2 x_3)\,\mu\Big].$$

Thus the scalar $L = 3$ readout for $N = 9$ is governed by several local phase paths rather than by a single endpoint ratio. The real-sign exclusion of Definition 9434.10 therefore does not exclude the complex phase locus $\mathcal{Q}_9$.

Principle 9435.14 (Cell-scale interpretation)**.** *For $N = 5$, the anchored $L = 3$ middle link reaches the digit boundary strongly enough that the scalar diagonal reduces to an endpoint gate. For $N = 9$, the same window is shorter relative to the digit cell. Several residue branches remain inside the cell, and boundary crossings enter as distributed carry corrections. Reflection positivity at this scale is therefore a coupled condition on interior four-edge paths and carry terms, not an endpoint-only condition.*

Chapter 9436

Innovation Input Square Real-Sign Four-Window Bottleneck

Definition 9426.10 gives Q3-compatible real-sign rows for every square alphabet. The nine-ary screen in chapter 9434 shows that the first such square alphabet has no anchored $L = 3$ real neutral RP row. The larger square alphabets exhibit a sharper phenomenon: real-sign rows can pass the anchored $L = 3$ RP matrix in substantial numbers, but the anchored $L = 4$ real neutral matrix remains empty for the computed square families.

9436.1 Twenty-five-ary Real-Sign Locus

Definition 9436.1 (Twenty-five-ary real-sign Q3 row)**.** *A twenty-five-ary real-sign Q3 row is a word*

$$v = (v_0, \ldots, v_{24}) \in \{+1, -1\}^{25}$$

satisfying

$$\sum_{a=0}^{24} v_a = 5.$$

It determines the real-sign self-substitution sequence

$$u_{25n+a} = v_a u_n.$$

Proposition 9436.2 (Twenty-five-ary real-sign count)**.** *A twenty-five-ary real-sign row is Q3-compatible exactly when it has fifteen positive signs and ten negative signs. Hence the search space has*

$$\binom{25}{10} = 3268760$$

rows.

Proof. Let P and M be the numbers of positive and negative entries. Then

$$P + M = 25, \qquad P - M = 5.$$

Thus $P = 15$ and $M = 10$. Conversely, those two cardinalities give the required row sum. The number of rows is the choice of the ten negative positions. □

9436.2 Four-Window Screen

Definition 9436.3 (Anchored real $L = 4$ neutral window)**.** *The anchored real $L = 4$ neutral window is ordered as*

index	*support*
0	$\varnothing$
1	$(1, 2)$
2	$(1, 3)$
3	$(1, 4)$
4	$(2, 3)$
5	$(2, 4)$
6	$(3, 4)$
7	$(1, 2, 3, 4)$.

The last support represents the four-body observable

$$F_{1234} = u_{n+1}u_{n+2}u_{n+3}u_{n+4}.$$

Theorem 9436.4 (Twenty-five-ary real-sign four-window exclusion)**.** *Among the* 3268760 *twenty-five-ary real-sign Q3 rows, exactly* 2784 *pass the anchored $L = 3$ real neutral RP screen. None passes the anchored $L = 4$ real neutral RP screen:*

$$\#\mathcal{R}^{\mathbb{R},\mathrm{neu}}_{25,3} = 2784, \qquad \#\mathcal{R}^{\mathbb{R},\mathrm{neu}}_{25,4} = 0.$$

Proof. The exact carry evaluator is the same finite parity recursion as Definition 9434.7, with 9 replaced by 25. For the $L = 4$ window, every reflected support has diameter at most 7, so a single carry branch lands in either the empty support or the distance-one support. Thus each matrix entry is an exact rational function of the row signs and the distance-one correlation.

The reproducible enumeration is `papers/bedc/experiments/square_real_sign_rp_screen.py`. It enumerates all $\binom{25}{10}$ rows, solves the exact carry values for the anchored $L = 3$ and $L = 4$ real neutral windows, and checks Hermitian symmetry together with the displayed principal-minor certificates. The script asserts the two counts above. □

Theorem 9436.5 (Twenty-five-ary four-window failure split)**.** *Of the* 2784 *twenty-five-ary real-sign rows passing anchored $L = 3$ real neutral RP, the anchored $L = 4$ failures split as follows:*

$$2612 \quad \textit{fail Hermitian symmetry,}$$

and

$$172 \quad \textit{are Hermitian but fail positive semidefiniteness.}$$

Consequently

$$L = 3 \textit{ real neutral RP} \not\Rightarrow L = 4 \textit{ real neutral Hermitian symmetry,}$$

and therefore also

$$L = 3 \textit{ real neutral RP} \not\Rightarrow L = 4 \textit{ real neutral RP.}$$

Proof. This is the refined classification produced by the exact enumeration in Definition 9436.4. A non-Hermitian matrix cannot define a reflection-positive real quadratic form. On the Hermitian subfamily, the script searches diagonal entries and 2×2 principal minors for the first negative certificate; the certificates in Definition 9436.6 exhaust the 172 remaining failures. □

Proposition 9436.6 (Hermitian positive-semidefinite failure certificates)**.** *For the* 172 *twenty-five-ary rows whose anchored* $L = 4$ *matrix is Hermitian but not positive semidefinite, the first low-order certificate has the following distribution:*

certificate	*count*
$\det(0,3) < 0$	8
$\det(0,5) < 0$	20
$\det(0,7) < 0$	4
$\det(1,3) < 0$	6
$\det(1,5) < 0$	4
$\det(1,6) < 0$	8
$\det(2,3) < 0$	2
$\det(3,4) < 0$	4
$\det(5,7) < 0$	2
$M_{33} < 0$	76
$M_{55} < 0$	32
$M_{77} < 0$	6

Proof. The table is the exact certificate counter emitted by `papers/bedc/experiments/square_real_sign_rp_sc` Each listed entry is a necessary condition for positive semidefiniteness of the Hermitian anchored $L = 4$ matrix. □

9436.3 Concrete Witnesses

Proposition 9436.7 (Strict three-window row with four-body failure)**.** *Let the negative positions be*

$$I = \{9, 11, 12, 14, 16, 18, 20, 21, 22, 23\}.$$

Then the row $v_a = -1$ *exactly on* I *is a twenty-five-ary real-sign Q3 row. Its anchored* $L = 3$ *real neutral RP matrix is*

$$M_3 = \begin{pmatrix} 1 & 0 & 13/25 & 0 \\ 0 & 7/25 & 0 & 3/25 \\ 13/25 & 0 & 9/25 & 0 \\ 0 & 3/25 & 0 & 7/25 \end{pmatrix}.$$

This matrix is positive definite, with least eigenvalue

$$\lambda_{\min}(M_3) = \frac{17 - \sqrt{233}}{25} \approx 0.0694264991.$$

However, in the anchored $L = 4$ *real neutral window,*

$$\langle \theta F_{1234}, F_{1234} \rangle = -\frac{1}{25}.$$

Proof. The row has ten negative signs, hence is Q3-compatible by Definition 9436.2. The displayed matrix entries are the exact carry values recomputed by `papers/bedc/experiments/square_real_sign_rp_scree` The two nontrivial blocks have spectra

$$\left\{ \frac{34 \pm 2\sqrt{233}}{50} \right\}$$

and

$$\left\{\frac{4}{25}, \frac{10}{25}\right\},$$

so the least eigenvalue is $(17-\sqrt{233})/25 > 0$. The same exact carry evaluation gives the four-body diagonal $-1/25$, which is already a negative diagonal certificate for the $L = 4$ matrix. □

Proposition 9436.8 (Near-Hermitian survivor still fails symmetry)**.** *Let the negative positions be*

$$I = \{0, 1, 2, 3, 12, 13, 17, 18, 21, 22\}.$$

This row passes anchored $L = 3$ real neutral RP. In the anchored $L = 4$ matrix,

$$M_{3,5} = -\frac{31}{325}, \qquad M_{5,3} = \frac{41}{325}.$$

Therefore

$$M_{3,5} \neq M_{5,3},$$

with discrepancy

$$M_{5,3} - M_{3,5} = \frac{72}{325}.$$

Proof. The row has ten negative signs, hence is Q3-compatible. The exact enumerator confirms anchored $L = 3$ passage and computes the two displayed $L = 4$ entries. Since Hermitian symmetry already fails, no positive-semidefinite RP interpretation is available for this row at window length 4. □

9436.4 Square-Family Pattern

Theorem 9436.9 (Computed square real-sign bottleneck)**.** *For the computed square real-sign Q3 subfamilies, the anchored real neutral RP counts are*

N	*real-sign Q3 rows*	$L = 3$ *pass*	$L = 4$ *pass*
9	84	0	0
16	8008	7	0
25	3268760	2784	0

Proof. The $N = 9$ row is the exact screen of Definition 9434.10. The $N = 16$ and $N = 25$ rows are recomputed by `papers/bedc/experiments/square_real_sign_rp_screen.py`, using the same real-sign carry recursion and the same anchored neutral window conventions. □

Principle 9436.10 (Local positivity is not stable RP)**.** *The square real-sign construction supplies Q3 compatibility and real two-point correlations, and for $N = 16$ and $N = 25$ it also supplies genuine anchored $L = 3$ reflection-positive examples. The same construction has no computed survivor at anchored $L = 4$ for $N = 9, 16, 25$. Thus the empirical obstruction has moved from the existence of low-window RP to the stability of RP across the next neutral window. The four-body observable F_{1234} is a distinguished part of that obstruction, because it already gives the exact negative diagonal $-1/25$ for the strict twenty-five-ary $L = 3$ witness above.*

Chapter 9437

Innovation Input RP Solenoid Limit Conjecture

chapter 9428 separates Q3 self-reference from finite-window reflection positivity. chapter 9436 then shows the square real-sign phenomenon more sharply: larger alphabets can create genuine low-window RP, while the next displayed neutral window still supplies an obstruction. The OS/Hamiltonian gate of chapter 9443 makes the consequence rigid: a finite-window obstruction blocks the input Hamiltonian source. The solenoid arithmetic row of chapter 9451 therefore supplies the natural ambient object for a stronger conjectural reading: complete RP belongs to a cofinal prime-register tower, not to a single finite substitution alphabet.

9437.1 Finite-Window Horizon

Definition 9437.1 (Anchored neutral RP horizon)**.** *For a finite alphabet size N, define*

$$L_{\max}^{\mathrm{neu}}(N) := \sup\left\{ L \in \mathbb{N} : \exists v \in \mathcal{Q}_N,\ v \in \bigcap_{\ell=1}^{L} \mathcal{R}_{N,\ell,1}^{\mathrm{neu}} \right\}.$$

If the displayed set is empty, set $L_{\max}^{\mathrm{neu}}(N) = 0$. The parameter $R = 1$ fixes the anchored window convention used by the finite-window audit. Requiring all reflection-centered placements can only lower the horizon.

Principle 9437.2 (Horizon reading)**.** *The number $L_{\max}^{\mathrm{neu}}(N)$ measures how long a single alphabet size can postpone a neutral RP obstruction. It is not a complete RP certificate. Complete neutral RP is the stronger assertion*

$$\mathcal{R}_N^{\mathrm{neu}} = \bigcap_{L,R} \mathcal{R}_{N,L,R}^{\mathrm{neu}} \neq \varnothing,$$

as in Definition 9441.14.

Principle 9437.3 (Finite-layer evidence ledger)**.** *The displayed Q3 searches support a monotone-*

looking but obstruction-rich pattern:

N	*locus*	*displayed passage*	*displayed obstruction*
2	*binary row*	*none charged*	$L = 1$ *charged*
3	*unit-root row*	*two-point real*	*neutral determinant*
4	*real-sign square*	$L = 1$ *charged*	*neutral window*
5	$\mathcal{Q}_5$	$L = 2$ *example*	$L = 3$ *empty*
9	*real-sign square*	$L = 2$ *examples*	$L = 3$ *empty*
16	*real-sign square*	$L = 3$ *examples*	$L = 4$ *empty*
25	*real-sign square*	$L = 3$ *strict examples*	$L = 4$ *empty*
36	*reported real-sign square*	$L = 3$ *strict examples*	$L = 4$ *reported failure*
900	*reported CRT square*	$L = 4$ *strict examples*	$L = 5$ *reported failure*
44100	*reported CRT square*	$L = 4$ *strict example*	$L = 5$ *reported failure*
5336100	*reported CRT square*	$H_5 = 0$ *targeted*	$L = 4, L = 5$ *reported failure*

The rows through $N = 25$ are the theorem-level rows cited in Definition 9428.19, Definition 9431.8, Definition 9433.7, Definition 9434.10, and Definition 9436.9. The rows for $N = 36$, $N = 900$, $N = 44100$, and $N = 5336100$ are search-ledger rows: they motivate the cofinal prime-register formulation but do not carry theorem status in this chapter.

Principle 9437.4 (Four-prime CRT witness ledger)**.** *The reported four-prime primorial-square row uses*

$$N = (2 \cdot 3 \cdot 5 \cdot 7)^2 = 44100$$

and the CRT factorization

$$\mathbb{Z}/44100\mathbb{Z} \cong \mathbb{Z}/4\mathbb{Z} \times \mathbb{Z}/9\mathbb{Z} \times \mathbb{Z}/25\mathbb{Z} \times \mathbb{Z}/49\mathbb{Z}.$$

It is the product row

$$v(a) = v_4(a \bmod 4)v_9(a \bmod 9)v_{25}(a \bmod 25)v_{49}(a \bmod 49),$$

where the local negative positions are

$$\begin{gathered} I_4 = \{3\}, \\ I_9 = \{1, 5, 6\}, \\ I_{25} = \{0, 1, 2, 3, 4, 5, 6, 9, 19, 23\}, \\ I_{49} = \{1, 2, 5, 6, 9, 10, 16, 17, 20, 21, 24, 27, 30, 31, 34, 35, 37, 38, 39, 41, 43\}. \end{gathered}$$

The local sums are

$$\sum v_4 = 2, \qquad \sum v_9 = 3, \qquad \sum v_{25} = 5, \qquad \sum v_{49} = 7,$$

so the product row satisfies the Q3 sum rule

$$\sum_{a=0}^{44099} v_a = 2 \cdot 3 \cdot 5 \cdot 7 = 210 = \sqrt{44100}.$$

The reported anchored real neutral $L = 4$ matrix is symmetric and positive definite, with

$$\lambda_{\min}(M_4) \approx 7.63 \times 10^{-4}$$

and least diagonal certificate

$$M_{(2,3),(2,3)} = \frac{1}{1225} > 0.$$

The same row fails the anchored real neutral $L = 5$ matrix already at the symmetry layer:

$$M_{(1,3),(1,2,4,5)} = \frac{1}{441}, \qquad M_{(1,2,4,5),(1,3)} = -\frac{11}{2205},$$

with discrepancy

$$\frac{1}{441} - \left(-\frac{11}{2205}\right) = \frac{16}{2205}.$$

It also has the negative diagonal certificate

$$M_{(3,5),(3,5)} = -\frac{1}{441} < 0.$$

Thus the four-prime CRT row strengthens the horizon pattern: primorial structure improves finite-window survival, while a fixed finite register still exhibits a finite-window obstruction.

Principle 9437.5 (Primorial-square homomorphic delay)**.** *For the anchored real neutral $L = 5$ window, define the primitive Hermitian defect*

$$H_5 := M_{(1,3),(1,2,4,5)} - M_{(1,2,4,5),(1,3)}.$$

The reported CRT rows for

$$N_3 = (2 \cdot 3 \cdot 5)^2 = 900$$

and

$$N_4 = (2 \cdot 3 \cdot 5 \cdot 7)^2 = 44100$$

exhibit the same anchored real neutral $L = 5$ Hermitian defect shape. In both rows the first displayed asymmetry occurs between the support $(1, 3)$ and the support $(1, 2, 4, 5)$. For N_3 the reported values are

$$M_{(1,3),(1,2,4,5)} = \frac{1}{45}, \qquad M_{(1,2,4,5),(1,3)} = -\frac{11}{225},$$

so the defect is

$$H_5(N_3) = \frac{1}{45} - \left(-\frac{11}{225}\right) = \frac{16}{225}.$$

For N_4 the corresponding values are

$$M_{(1,3),(1,2,4,5)} = \frac{1}{441}, \qquad M_{(1,2,4,5),(1,3)} = -\frac{11}{2205},$$

so the defect is

$$H_5(N_4) = \frac{1}{441} - \left(-\frac{11}{2205}\right) = \frac{16}{2205}.$$

The defect ratio is therefore

$$\frac{H_5(N_4)}{H_5(N_3)} = \frac{16/2205}{16/225} = \frac{5}{49}.$$

Adding the prime-7 register does not change the visible obstruction type; it attenuates the obstruction. The positive-window horizon has therefore not crossed $L = 5$ in these two reported rows, but the obstruction has the form of a stable finite-window defect whose amplitude decreases under prime-register enlargement.

Principle 9437.6 (Five-prime cancellation tradeoff)**.** *At the five-prime level*

$$N_5 = (2 \cdot 3 \cdot 5 \cdot 7 \cdot 11)^2 = 5336100,$$

the CRT factorization is

$$\mathbb{Z}/N_5\mathbb{Z} \cong \mathbb{Z}/4\mathbb{Z} \times \mathbb{Z}/9\mathbb{Z} \times \mathbb{Z}/25\mathbb{Z} \times \mathbb{Z}/49\mathbb{Z} \times \mathbb{Z}/121\mathbb{Z}.$$

The reported product row uses a 121*-component real-sign factor with negative positions*

$$\begin{gathered} I_{121} = \{0, 1, 2, 4, 6, 7, 10, 14, 17, 22, 26, 27, 30, 32, 33, 36, \\ 37, 38, 39, 40, 45, 49, 51, 56, 58, 59, 62, 63, 66, 67, 68, 69, \\ 70, 71, 73, 74, 75, 77, 82, 83, 84, 87, 90, 95, 99, 100, \\ 103, 104, 106, 108, 109, 111, 112, 114, 115\}. \end{gathered}$$

Thus $\#(-) = 55$*,* $\#(+) = 66$*, and*

$$\sum v_{121} = 11.$$

Together with the local sums $2, 3, 5, 7$*, the product row has total sum*

$$2 \cdot 3 \cdot 5 \cdot 7 \cdot 11 = 2310 = \sqrt{5336100},$$

so it is Q3-compatible.

For this selected five-prime row, the inherited primitive Hermitian defect is cancelled:

$$H_5(N_5) = 0.$$

Equivalently, the two reflected correlation blocks agree:

$$\Gamma(0, 2, 3, 4, 6, 7) = \Gamma(0, 1, 3, 4, 5, 7) = -\frac{5326399}{25885425951}.$$

This shows that the H_5 *channel is not an immutable finite-level obstruction. It can be killed by a suitable prime-*11 *local factor.*

The same selected row does not pass the window tests. Its anchored real neutral $L = 5$ *matrix has a larger Hermitian defect at the support pair* $(1, 4)$ *and* $(1, 2, 3, 5)$*:*

$$M_{(1,4),(1,2,3,5)} = -\frac{5324243}{31637742829}, \qquad M_{(1,2,3,5),(1,4)} = \frac{69333739}{94913228487},$$

with difference

$$-\frac{85306468}{94913228487} \approx -8.9878 \times 10^{-4}.$$

The anchored real neutral $L = 4$ *test is also lost for this row:*

$$\max |M_4 - M_4^{\mathsf{T}}| \approx 1.7991 \times 10^{-4},$$

and

$$\lambda_{\min}\left(\frac{M_4 + M_4^{\mathsf{T}}}{2}\right) \approx -3.40 \times 10^{-4}.$$

Thus adjoining a prime channel can cancel a chosen high-window defect while creating lower-window incompatibility.

Principle 9437.7 (Local-factor compatibility problem)**.** *The primorial-square search is therefore not a one-defect optimization problem. It asks for a recursive choice of local real-sign factors*

$$v_4, v_9, v_{25}, v_{49}, v_{121}, \dots$$

such that adjoining a prime factor v_{p^2} preserves every previously secured anchored neutral window while reducing the next obstruction. In schematic form, if the S-register row has passed the windows $\ell \le L$, the extension to $S \cup \{p\}$ must keep

$$M_\ell^{(S\cup\{p\})} \succeq 0 \qquad \ell \le L$$

and only then use the extra prime channel to suppress a higher-window defect. Complete RP is a tower-compatibility problem, not an isolated finite-N search.

Principle 9437.8 (Diagonal obstruction persists beside symmetry failure)**.** *The same comparison also shows that the $L = 5$ failure is not merely a choice of non-Hermitian presentation. The reported N_3 row has a negative diagonal certificate*

$$M_{(1,2,3,5),(1,2,3,5)} = -\frac{5393}{202275} < 0,$$

while the reported N_4 row has

$$M_{(3,5),(3,5)} = -\frac{1}{441} < 0.$$

Thus positive semidefiniteness still fails after ignoring the Hermitian asymmetry. The $L = 5$ obstruction is therefore layered: the Hermitian defect blocks reflection symmetry, and negative diagonal entries block positive semidefiniteness even after discarding that asymmetry. The primorial-square evidence supports a two-part reading: finite prime registers can weaken high-window defects, but a fixed finite register still leaves a concrete finite-window obstruction.

9437.2 Finite Alphabet Finiteness

Conjecture 9437.9 (Finite-alphabet RP finiteness)**.** *For every finite alphabet size N, no Q3 self-substitution row over that alphabet passes all neutral finite-window RP tests:*

$$\forall N < \infty, \qquad \mathcal{R}_N^{\mathrm{neu}} = \varnothing.$$

Equivalently, for every fixed finite N and every $v \in \mathcal{Q}_N$, there is a finite neutral RP window $\mathcal{B}$ such that

$$M_{\mathcal{B}}(v) \not\succeq 0.$$

In the anchored-depth language of Definition 9437.1, this predicts

$$L_{\max}^{\mathrm{neu}}(N) < \infty$$

for every finite N.

Status: `open`

Principle 9437.10 (Finite alphabets delay rather than remove RP failure)**.** *Under Definition 9437.9, increasing N can raise the finite-window horizon, especially when the prime factor structure of N gives more independent carry channels. It cannot turn a single finite row into an all-window OS/RP source. The input Hamiltonian gate of Definition 9443.12 therefore treats every finite-window negative certificate as a genuine source-side exclusion, even when the same row has strong lower-window positivity.*

9437.3 Prime-Register Approximation

Definition 9437.11 (Cofinal square prime-register tower)**.** *Let p_k be the k-th prime and set*

$$P_k := \prod_{p \le p_k} p, \qquad N_k := P_k^2.$$

The associated prime sets

$$S_k := \{p : p \le p_k\}$$

increase cofinally to the set $\mathbb{P}$ of all primes. The stationary finite-register solenoid attached to level k is

$$\Sigma_k = \varprojlim \left(\mathbb{T} \xleftarrow{z \mapsto z^{P_k^2}} \mathbb{T} \right),$$

with charge group

$$\widehat{\Sigma_k} = \mathbb{Z}[S_k^{-1}]$$

at finite prime register S_k.

Conjecture 9437.12 (Prime-register RP approximation)**.** *For every finite neutral RP window $\mathcal{B}$, there is a prime level k and a Q3 row*

$$v^{(k)} \in \mathcal{Q}_{P_k^2}$$

such that

$$M_{\mathcal{B}}(v^{(k)}) \succeq 0.$$

Equivalently, for the anchored-depth audit,

$$\forall L \ \exists k \ \exists v^{(k)} \in \mathcal{Q}_{P_k^2}, \qquad v^{(k)} \in \bigcap_{\ell=1}^{L} \mathcal{R}^{\mathrm{neu}}_{P_k^2,\ell,1}.$$

Together with Definition 9437.9, this says that every fixed level remains finite-window vulnerable:

$$\forall k \ \forall v \in \mathcal{Q}_{P_k^2} \ \exists \mathcal{B}, \qquad M_{\mathcal{B}}(v) \not\succeq 0,$$

while every fixed finite window can be made positive at a sufficiently large prime-register level.

Status: `open`

Conjecture 9437.13 (Cofinal-tail RP approximation)**.** *There is a compatible primorial-square CRT family*

$$v^{(k)} \in \mathcal{Q}_{P_k^2}$$

such that every fixed anchored neutral window eventually becomes positive-semidefinite along the tail:

$$\forall L \ \exists k_0(L) \ \forall k \ge k_0(L), \qquad v^{(k)} \in \bigcap_{\ell=1}^{L} \mathcal{R}^{\mathrm{neu}}_{P_k^2,\ell,1}.$$

For every fixed finite k, however, some finite neutral window still obstructs the same row:

$$\forall k \ \exists \mathcal{B}, \qquad M_{\mathcal{B}}(v^{(k)}) \not\succeq 0.$$

This is the tail-strength form of the limit RP conjecture: complete RP is not assigned to any single finite alphabet, but to the cofinal prime-register limit.

Status: `open`

Principle 9437.14 (Solenoid-limit source reading)**.** *The conjectural source object is not a distinguished finite N. It is the cofinal prime-register limit*

$$S_k \nearrow \mathbb{P}, \qquad P_k^2 = \left(\prod_{p \le p_k} p\right)^2,$$

and the corresponding full solenoid

$$\Sigma_{\mathbb{P}} \cong \widehat{\mathbb{Q}}.$$

Its visible circle projection has hidden fibre

$$K_{\mathbb{P}} := \ker(\Sigma_{\mathbb{P}} \to \mathbb{T}) \cong \prod_{p \in \mathbb{P}} \mathbb{Z}_p.$$

This is the arithmetic form of the RP limit intuition: finite alphabets carry only finitely many branch registers, while the all-prime solenoid retains an infinite compatible fibre capable of absorbing arbitrarily deep carry, anchor, and boundary constraints.

9437.4 Limit Matrix Problem

Principle 9437.15 (Fixed-window limit problem)**.** *For each finite neutral window $\mathcal{B}$, the prime-register programme asks for a selected tower of rows*

$$v^{(k)} \in \mathcal{Q}_{P_k^2}$$

for which the entrywise limit

$$M_{\mathcal{B}}^{(\infty)} := \lim_{k \to \infty} M_{\mathcal{B}}(v^{(k)})$$

exists and satisfies

$$M_{\mathcal{B}}^{(\infty)} \succeq 0.$$

The stronger compatibility problem asks that these limits agree under restriction of windows, so that the family of positive finite-window forms defines one OS/RP source form on the solenoid input process.

Principle 9437.16 (Complete RP as a limit property)**.** *The finite-window evidence and the solenoid arithmetic row point to the same classification. Q3 compatibility is a finite refinement law; local RP is a finite-window positivity event; complete RP is a compatible all-window positivity structure. The first two can occur at finite alphabet size. The third is conjecturally a property of the cofinal prime-register limit. Even if the limit source form is obtained, the Hilbert–Polya upgrade remains a separate bridge obligation by Definition 9443.10.*

Chapter 9438

Innovation Input Pentary Golden Hermitian Obstruction

chapter 9432 turns the anchored $L = 3$ link diagonals into explicit pentary formulas. This chapter records a Q3 row that passes those scalar tests but fails the Hermitian symmetry required by the finite-window RP matrix.

9438.1 Golden Symmetric Word

Definition 9438.1 (Golden symmetric pentary word)**.** *Let*

$$c := \frac{\sqrt{5}-3}{2},$$

choose $\theta \in (0, \pi)$ *with* $\cos\theta = c$*, and set*

$$r := e^{i\theta}.$$

Define

$$v_\diamond := (1, \overline{r}, 1, r, 1).$$

Theorem 9438.2 (Golden symmetric row is Q3)**.** *The row* $v_\diamond$ *lies in* $\mathcal{Q}_5$*.*

Proof. Since $r + \overline{r} = 2c$,

$$1 + \overline{r} + 1 + r + 1 = 3 + 2c = 3 + 2\frac{\sqrt{5}-3}{2} = \sqrt{5}.$$

Thus the Q3 equation holds. □

Theorem 9438.3 (Golden symmetric row passes the link-diagonal filter)**.** *For* $v_\diamond$*,*

$$\mu = \frac{\sqrt{5}-3}{2}$$

and

$$\nu = D_{12} = D_{13} = D_{23} = 3 - \frac{6\sqrt{5}}{5}.$$

Numerically,

$$\mu \approx -0.381966$$

and

$$\nu = D_{12} = D_{13} = D_{23} \approx 0.316718.$$

Consequently,

$$D_{12} \geq |\mu|^2, \qquad D_{13} \geq |\nu|^2, \qquad D_{23} \geq |\mu|^2.$$

Proof. The edge ratios of $v_\diamond$ are

$$x_0 = r, \qquad x_1 = \overline{r}, \qquad x_2 = \overline{r}, \qquad x_3 = r, \qquad x_4 = 1.$$

Definition 9432.3 gives

$$\mu = \frac{r + \overline{r} + \overline{r} + r}{5 - 1} = \frac{r + \overline{r}}{2} = c.$$

Definition 9432.4 gives

$$\nu = \frac{1}{5}\left[2 + \overline{r}^2 + 2r\mu\right].$$

Because $2r\mu = r(r + \overline{r}) = r^2 + 1$,

$$\nu = \frac{1}{5}(3 + r^2 + \overline{r}^2) = \frac{1}{5}(3 + 2\cos 2\theta).$$

Using $\cos 2\theta = 2c^2 - 1$ and

$$c^2 = \left(\frac{\sqrt{5} - 3}{2}\right)^2 = \frac{7 - 3\sqrt{5}}{2},$$

one obtains

$$\nu = \frac{1}{5}(1 + 4c^2) = 3 - \frac{6\sqrt{5}}{5}.$$

Substituting the same edge ratios into Definition 9432.6, Definition 9432.7, and Definition 9432.8 gives $D_{12} = D_{13} = D_{23} = \nu$.

Finally,

$$|\mu|^2 = \left(\frac{\sqrt{5} - 3}{2}\right)^2 \approx 0.145898$$

and

$$|\nu|^2 \approx 0.100310.$$

Both are smaller than $3 - 6\sqrt{5}/5 \approx 0.316718$, giving the displayed link inequalities. □

9438.2 Hermitian Obstruction

Definition 9438.4 (Anchored $L = 3$ Hermitian defect)**.** *Let $M_3(v)$ be the anchored $L = 3$ neutral RP matrix associated to the neutral monomials generated by $1, F_{12}, F_{13}, F_{23}$. Define*

$$\mathcal{H}_3(v) := M_3(v) - M_3(v)^*.$$

An anchored $L = 3$ RP candidate must have

$$\mathcal{H}_3(v) = 0$$

before the positive-semidefinite condition can even be tested as a Hermitian matrix condition.

Theorem 9438.5 (Golden symmetric Hermitian obstruction)**.** *For $v_\diamond = (1, \overline{r}, 1, r, 1)$, the two crossed entries*

$$C_{12,13} := \langle \theta F_{12}, F_{13} \rangle$$

and

$$C_{13,12} := \langle \theta F_{13}, F_{12} \rangle$$

satisfy

$$C_{12,13} = C_{13,12} = \frac{3c + 2c^3}{5} + i\frac{2s^3}{5},$$

where $c = \cos\theta = (\sqrt{5} - 3)/2$ and $s = \sin\theta > 0$. Hence

$$C_{12,13} \neq \overline{C_{13,12}},$$

and the anchored $L = 3$ neutral RP matrix is not Hermitian.

Proof. After translation normalization,

$$C_{12,13} = \Gamma(\delta_0 - \delta_1 + \delta_2 - \delta_4)$$

and

$$C_{13,12} = \Gamma(\delta_0 - \delta_2 + \delta_3 - \delta_4).$$

For $v_\diamond$, the carry recursion for each of these two blocks closes on the zero block and the one-step block. The five residues give the same average:

$$C_{12,13} = C_{13,12} = \frac{1}{5}\left[2r + (2 + \overline{r}^2)\mu\right].$$

Since $\mu = c$ and $r = c + is$,

$$2r + (2 + \overline{r}^2)c = 2(c + is) + c\left(2 + c^2 - s^2 - 2ics\right).$$

Using $c^2 + s^2 = 1$, this becomes

$$3c + 2c^3 + i\,2s^3.$$

Therefore the crossed entry has imaginary part $2s^3/5$, which is nonzero. Since the reverse crossed entry is the same nonreal number, the Hermitian relation $M_{12,13} = \overline{M_{13,12}}$ fails. □

Corollary 9438.6 (Diagonal passage does not imply Hermitian passage)**.** *There exists a pentary Q3 row satisfying all three anchored $L = 3$ link-diagonal necessary inequalities while failing the Hermitian condition for the same window.*

Proof. Use $v_\diamond$. The link-diagonal inequalities are Definition 9438.3, while the Hermitian failure is Definition 9438.5. □

Principle 9438.7 (Pentary $L = 3$ RP gates)**.** *For pentary self-substitution rows, anchored $L = 3$ neutral RP has three distinct finite-window gates:*

link diagonals are real and nonnegative,

$$M_3(v) = M_3(v)^*,$$

and

$$M_3(v) \succeq 0.$$

The Pythagorean row $v_\star$ fails the first gate because $D_{23} = -1/5$. The golden symmetric row $v_\diamond$ passes the first gate but fails the Hermitian gate. Thus diagonal positivity is not the reflection-symmetry content of RP; it is only the first scalar shadow of the finite-window matrix condition.

Principle 9438.8 (Pentary search stratification)**.** *The finite-window stratification visible at $N = 5$ is:*

row	*Q3*	*two-point*	$L = 2$ *RP*	$L = 3$ *link*	$L = 3$ *Hermitian*
$v_\star = (a, b, -a, b, a)$	*yes*	*real*	*pass*	*fail*	*not tested*
$v_5^{(+)}$	*yes*	*real*	*fail*	*not tested*	*not tested*
$v_5^{(-)}$	*yes*	*real*	*fail*	*not tested*	*not tested*
$v_\diamond = (1, \overline{r}, 1, r, 1)$	*yes*	*real*	*diagonal pass*	*pass*	*fail*

The unresolved finite-window problem is therefore not only to maximize the link diagonals, but to solve the Hermitian equations and then test the least eigenvalue inside that Hermitian locus.

Chapter 9439

Innovation Input Pentary Palindromic Hermitian Reduction

chapter 9438 shows that link-diagonal positivity does not force the anchored $L = 3$ RP matrix to be Hermitian. This chapter identifies a structural sufficient condition for Hermitian symmetry: palindromic phase words make the balanced correlation function reflection-even. Inside the pentary Q3 palindromic locus, the finite-window problem is therefore reduced from a non-Hermitian matrix problem to a positive-semidefinite problem on a real one-dimensional curve.

9439.1 Reflection Evenness

Definition 9439.1 (Block reflection)**.** *Use the anchored reflection*

$$\theta(j) = 1 - j.$$

For a signed block

$$\alpha = \sum_j e_j \delta_j,$$

define

$$\theta\alpha := \sum_j e_j \delta_{1-j}.$$

Definition 9439.2 (Balanced neutral block)**.** *A signed block*

$$\alpha = \sum_j e_j \delta_j$$

is balanced in the sense of Definition 9427.2 when

$$Q(\alpha) := \sum_j e_j = 0.$$

Balanced blocks are the correlation blocks of neutral monomials, for example $u_{n+i}\overline{u_{n+j}}$ and their finite products.

Definition 9439.3 (Reflection-even balanced correlations)**.** *A self-substitution correlation function Γ is reflection-even on balanced blocks when*

$$\Gamma(\alpha) = \Gamma(\theta\alpha)$$

for every balanced block α.

Theorem 9439.4 (Reflection evenness implies Hermitian RP matrices)**.** *Let*

$$\mathcal{B} = \{\alpha_0, \ldots, \alpha_m\}$$

be a finite set of balanced future blocks, and set

$$M_{ij} := \Gamma(\alpha_j - \theta\alpha_i).$$

If Γ *is reflection-even on balanced blocks, then*

$$M = M^*.$$

Proof. It is enough to prove $M_{ij} = \overline{M_{ji}}$. By definition,

$$M_{ij} = \Gamma(\alpha_j - \theta\alpha_i)$$

and

$$M_{ji} = \Gamma(\alpha_i - \theta\alpha_j).$$

Complex conjugation of a balanced correlation reverses the signed block, so

$$\overline{M_{ji}} = \Gamma(-\alpha_i + \theta\alpha_j).$$

But

$$\theta(\alpha_j - \theta\alpha_i) = \theta\alpha_j - \alpha_i = -\alpha_i + \theta\alpha_j.$$

Reflection evenness therefore gives

$$\overline{M_{ji}} = \Gamma(\theta(\alpha_j - \theta\alpha_i)) = \Gamma(\alpha_j - \theta\alpha_i) = M_{ij}.$$

□

Corollary 9439.5 (Hermitian audit reduction)**.** *For any self-substitution row whose balanced correlations are reflection-even, every neutral finite-window RP matrix is Hermitian. Within such a class, the finite-window RP audit is the single condition*

$$M \succeq 0.$$

9439.2 Palindromic Reflection

Definition 9439.6 (Palindromic phase word)**.** *A phase word* $v = (v_0, \ldots, v_{N-1}) \in \mathbb{T}^N$ *is palindromic when*

$$v_a = v_{N-1-a} \qquad 0 \le a < N.$$

In the pentary case this is the shape

$$v = (a, b, c, b, a).$$

Theorem 9439.7 (Palindromic rows are reflection-even)**.** *If* v *is palindromic, then its self-substitution correlation function satisfies*

$$\Gamma(\alpha) = \Gamma(\theta\alpha)$$

for every balanced block α*.*

Proof. At finite depth K, write

$$n = a_0 + a_1 N + \cdots + a_{K-1} N^{K-1}$$

and

$$u_n^{(K)} = \prod_{\ell=0}^{K-1} v_{a_\ell}.$$

Let

$$R_K(n) := N^K - 1 - n.$$

If n has N-ary digits $(a_0, \ldots, a_{K-1})$, then $R_K(n)$ has digits $(N-1-a_0, \ldots, N-1-a_{K-1})$. Since v is palindromic,

$$u_{R_K(n)}^{(K)} = u_n^{(K)}.$$

For a balanced block $\alpha = \sum_j e_j \delta_j$, take the finite-depth average over indices for which every shifted term remains in the depth K interval. The omitted boundary set has density tending to zero. In the surviving average, substitute $n' = R_K(n)$. The identity above gives

$$u_{n+j}^{(K)} = u_{R_K(n+j)}^{(K)} = u_{R_K(n)-j}^{(K)} = u_{n'-j}^{(K)}.$$

Passing to the correlation limit yields

$$\Gamma(\alpha) = \Gamma\left(\sum_j e_j \delta_{-j}\right).$$

Because α is balanced, translating the block by one unit does not change the neutral correlation, and hence

$$\Gamma\left(\sum_j e_j \delta_{-j}\right) = \Gamma\left(\sum_j e_j \delta_{1-j}\right) = \Gamma(\theta\alpha).$$

□

Corollary 9439.8 (Palindromic rows have Hermitian neutral RP matrices)**.** *Every palindromic self-substitution row has Hermitian neutral finite-window RP matrices.*

Proof. Combine Definition 9439.7 with Definition 9439.4. □

9439.3 Pentary Palindromic Q3 Curve

Definition 9439.9 (Pentary palindromic Q3 locus)**.** *Define*

$$\mathcal{P}_5 := \left\{(a, b, c, b, a) \in \mathbb{T}^5 : 2a + 2b + c = \sqrt{5}\right\}.$$

Definition 9439.10 (Palindromic edge variables)**.** *For $v = (a, b, c, b, a)$, set*

$$q := a\overline{b}, \qquad r := b\overline{c}.$$

Then $|q| = |r| = 1$, and

$$a = qb, \qquad c = \overline{r}\, b.$$

Theorem 9439.11 (Pentary palindromic Q3 equation)**.** *A palindromic phase word $v = (a, b, c, b, a)$ lies in $\mathcal{P}_5$ if and only if there are $q, r \in \mathbb{T}$ such that*

$$|2q + 2 + \overline{r}| = \sqrt{5},$$

and

$$b = \frac{\sqrt{5}}{2q + 2 + \overline{r}}, \qquad a = qb, \qquad c = \overline{r}\, b.$$

Equivalently, for $q = e^{i\alpha}$ and $r = e^{i\beta}$,

$$2\cos\alpha + \cos\beta + \cos(\alpha + \beta) = -1.$$

Proof. Using Definition 9439.10,

$$2a + 2b + c = b(2q + 2 + \overline{r}).$$

Since $|b| = 1$, the Q3 condition is equivalent to $|2q + 2 + \overline{r}| = \sqrt{5}$, with b then determined by the displayed formula.

Now square the modulus:

$$|2q + 2 + \overline{r}|^2 = 9 + 8\cos\alpha + 4\cos\beta + 4\cos(\alpha + \beta).$$

Setting this equal to 5 and dividing by 4 gives

$$2\cos\alpha + \cos\beta + \cos(\alpha + \beta) = -1.$$

□

Corollary 9439.12 (One-dimensional palindromic locus)**.** *Away from singular points of the displayed real constraint, the pentary palindromic Q3 locus $\mathcal{P}_5$ is a real one-dimensional curve.*

9439.4 Palindromic Link Formulas

Definition 9439.13 (Real palindromic edge coordinates)**.** *For $q = e^{i\alpha}$ and $r = e^{i\beta}$, write*

$$A := \operatorname{Re} q = \cos\alpha,$$

$$B := \operatorname{Re} r = \cos\beta,$$

$$C := \operatorname{Re}(qr) = \cos(\alpha + \beta),$$

and

$$E := \operatorname{Re}(q\overline{r}) = \cos(\alpha - \beta).$$

The Q3 equation on $\mathcal{P}_5$ is

$$2A + B + C = -1.$$

Theorem 9439.14 (Palindromic $L = 3$ link formulas)**.** *For every $v = (a, b, c, b, a) \in \mathcal{P}_5$,*

$$\mu = \frac{A + B}{2},$$

$$\nu = D_{23} = \frac{1 + 2C + A(A + B)}{5},$$

$$D_{12} = \frac{1 + 2E + B(A + B)}{5},$$

and

$$D_{13} = \frac{1 + 4\mu^2}{5}.$$

Proof. The pentary edge ratios from Definition 9432.1 are

$$x_0 = q, \qquad x_1 = r, \qquad x_2 = \overline{r}, \qquad x_3 = \overline{q}, \qquad x_4 = 1.$$

Substituting these values into Definition 9432.3 gives

$$\mu = \frac{q + r + \overline{r} + \overline{q}}{4} = \frac{A + B}{2}.$$

For ν, use Definition 9432.4:

$$\nu = \frac{1}{5}\left[qr + 1 + \overline{qr} + (\overline{q} + q)\mu\right] = \frac{1 + 2C + 2A\mu}{5}.$$

Since $2A\mu = A(A + B)$, the formula for $\nu = D_{23}$ follows from Definition 9432.8.

For D_{12}, use Definition 9432.6:

$$D_{12} = \frac{1}{5}\left[q\overline{r} + r\overline{q} + 1 + (\overline{r} + r)\mu\right] = \frac{1 + 2E + 2B\mu}{5}.$$

Since $2B\mu = B(A + B)$, this is the stated formula. Finally, Definition 9432.7 gives

$$D_{13} = \frac{1}{5}\left[1 + (\overline{q} + \overline{r} + r + q)\mu\right] = \frac{1 + 2(A + B)\mu}{5} = \frac{1 + 4\mu^2}{5}.$$

□

Corollary 9439.15 (Palindromic three-link necessary inequalities)**.** *If $v \in \mathcal{P}_5$ passes the anchored $L = 3$ neutral RP window, then*

$$\frac{1 + 2E + B(A + B)}{5} \geq \left(\frac{A + B}{2}\right)^2,$$

$$\frac{1 + 2C + A(A + B)}{5} \geq \left(\frac{A + B}{2}\right)^2,$$

and

$$\frac{1 + 4\mu^2}{5} \geq \nu^2.$$

Proof. These are the 2×2 principal minor inequalities from Definition 9432.9. For the palindromic locus, μ and ν are real, and the link formulas are those of Definition 9439.14. □

9439.5 Known Rows Inside the Reduction

Example 9439.16 (Pythagorean row)**.** *For $v_\star = (a, b, -a, b, a)$, one has*

$$q = a\overline{b} = i, \qquad r = b\overline{(-a)} = i.$$

Thus

$$A = 0, \qquad B = 0, \qquad C = -1, \qquad E = 1.$$

The formulas above give

$$\mu = 0$$

and

$$\nu = D_{23} = \frac{1 + 2(-1)}{5} = -\frac{1}{5}.$$

Thus the $L = 3$ failure of $v_\star$ is exactly the negative second-link diagonal.

Example 9439.17 (Golden palindrome endpoints)**.** *The two golden palindrome rows*

$$v_5^{(+)} = (\xi, \xi^{-1}, -1, \xi^{-1}, \xi), \qquad \xi = e^{\pi i/5},$$

and

$$v_5^{(-)} = (\zeta, \zeta^{-1}, 1, \zeta^{-1}, \zeta), \qquad \zeta = e^{2\pi i/5},$$

are palindromic Q3 rows. Hence their neutral RP matrices are Hermitian by Definition 9439.8. Their failure is already visible at the anchored $L = 2$ window by Definition 9430.14.

Theorem 9439.18 (Pentary palindromic search reduction)**.** *Within $\mathcal{P}_5$, all neutral finite-window RP matrices are Hermitian. The $L = 3$ link-diagonal layer is controlled by the four real coordinates*

$$A = \operatorname{Re} q, \qquad B = \operatorname{Re} r, \qquad C = \operatorname{Re}(qr), \qquad E = \operatorname{Re}(q\overline{r}),$$

subject to

$$2A + B + C = -1.$$

Therefore the pentary palindromic RP search is a positive-semidefinite matrix problem along the real curve

$$2\cos\alpha + \cos\beta + \cos(\alpha + \beta) = -1.$$

Proof. Hermitian symmetry is Definition 9439.8. The parameterization and curve equation are Definition 9439.11. The link-diagonal formulas are Definition 9439.14. □

Principle 9439.19 (Projection reading)**.** *Each tick of the self-substitution ledger chooses a local phase v_a. Finite windows see only the projected correlations $\Gamma(\alpha)$. Palindromic symmetry forces these projected balanced correlations to be reflection-even, so the observed finite-window matrix has no Hermitian twist:*

$$M = M^*.$$

This symmetry is still weaker than reflection positivity. The OS-compatible condition is the positive-semidefinite gate

$$M \succeq 0.$$

Chapter 9440

Innovation Input Pentary Palindromic RP Exclusion

chapter 9439 reduces the pentary palindromic Q3 search to a Hermitian positive-semidefinite problem on a real curve. This chapter sharpens that reduction: inside the palindromic Q3 locus, the anchored $L = 2$ neutral RP window is rigid. The only rows that pass it are the Pythagorean row and its conjugate, and those rows fail at anchored $L = 3$.

9440.1 Literature Positioning

Principle 9440.1 (Adjacent traditions)**.** *The finite-window Q3/RP search lies near three established bodies of work. Constant-length substitution systems and generalized Thue–Morse sequences provide the closest symbolic-dynamical context: Baake–Grimm type diffraction calculations and generalized Thue–Morse Riesz products explain why recursive correlation calculations are the natural language for self-substitution phase rows. Reflection positivity and Osterwalder–Schrader reconstruction provide the operator-theoretic context: Jaffe-style reflection-positive frameworks, Jorgensen-style spectral formulations, and lattice-spin RP methods all stress that the relevant object is not merely real two-point correlation, but a reflected quadratic form that must be positive. Hankel, Toeplitz, and moment-kernel positivity supply a nearby matrix-positivity toolkit for finite principal windows.*

The present object combines these themes in a more specific finite problem: constant-length complex phase self-substitution, the Q3 phase-sum constraint, anchored neutral windows, and explicit RP matrices. The calculations below treat that finite object directly rather than importing an ambient spectral theorem.

9440.2 Anchored $L = 2$ Matrix

Definition 9440.2 (Palindromic anchored $L = 2$ structure)**.** *For a pentary palindromic Q3 row $v = (a, b, c, b, a)$, take*

$$F := u_{n+1}\overline{u_{n+2}}$$

and

$$\alpha := \delta_1 - \delta_2.$$

The anchored neutral $L = 2$ window is

$$\mathcal{B}_2 = \{0, \alpha, -\alpha\}.$$

Write

$$\mu := \langle F \rangle = \Gamma(\delta_0 - \delta_1),$$
$$D := \langle \theta F, F \rangle = \Gamma(\delta_0 - \delta_1 + \delta_2 - \delta_3),$$

and

$$C := \langle \theta F, \overline{F} \rangle = \Gamma(\delta_0 - \delta_1 - \delta_2 + \delta_3).$$

By Definition 9439.8, the matrix is Hermitian, so it has the form

$$M_2(v) = \begin{pmatrix} 1 & \mu & \mu \\ \mu & D & C \\ \mu & \overline{C} & D \end{pmatrix}.$$

Theorem 9440.3 (Palindromic $L = 2$ semidefinite tests)**.** *If $M_2(v) \succeq 0$, then*

$$D \geq |C|$$

and

$$\det M_2(v) \geq 0.$$

Proof. The lower-right principal block is

$$\begin{pmatrix} D & C \\ \overline{C} & D \end{pmatrix},$$

whose eigenvalues are $D + |C|$ and $D - |C|$. Positivity of this principal block gives $D \geq |C|$. Positivity of the full Hermitian matrix gives $\det M_2(v) \geq 0$. □

9440.3 Half-Angle Curve

Definition 9440.4 (Half-angle variables)**.** *For the edge variables*

$$q = e^{i\alpha}, \qquad r = e^{i\beta},$$

set

$$u := \tan \frac{\alpha}{2}, \qquad w := \tan \frac{\beta}{2}.$$

Then

$$q = \frac{1 + iu}{1 - iu}, \qquad r = \frac{1 + iw}{1 - iw}.$$

Lemma 9440.5 (Half-angle Q3 equation)**.** *The pentary palindromic Q3 equation is equivalent to*

$$-u^2w^2 - u^2 - 4uw + w^2 + 5 = 0.$$

Equivalently,

$$(1 - u^2)w^2 - 4uw + (5 - u^2) = 0.$$

Proof. Use

$$\cos \alpha = \frac{1 - u^2}{1 + u^2}, \qquad \cos \beta = \frac{1 - w^2}{1 + w^2},$$

and

$$\cos(\alpha + \beta) = \frac{(1 - u^2)(1 - w^2) - 4uw}{(1 + u^2)(1 + w^2)}.$$

Substitution into the curve equation

$$2 \cos \alpha + \cos \beta + \cos(\alpha + \beta) = -1$$

from Definition 9439.11 gives the displayed polynomial equation after clearing denominators. □

9440.4 Determinant Factorization

Definition 9440.6 (Palindromic determinant numerator)**.** *Define*

$$\begin{aligned} P(u,w) := {} & u^4w^2 - 2u^3w^3 - 2u^3w + 5u^2w^4 + 12u^2w^2 + 5u^2 \\ & - 2uw^3 - 2uw + w^2. \end{aligned}$$

Theorem 9440.7 (Anchored $L = 2$ determinant factorization)**.** *On the pentary palindromic Q3 locus,*

$$\det M_2(v) = -\frac{16(u-w)^2(u+w)^2P(u,w)}{25(1+u^2)^4(1+w^2)^4}.$$

Moreover $P(u,w) > 0$ on the real Q3 curve. Hence

$$\det M_2(v) \le 0.$$

Proof. Substitute

$$q = \frac{1+iu}{1-iu}, \qquad r = \frac{1+iw}{1-iw}$$

into the anchored $L = 2$ quantities of Definition 9440.2. The determinant of the Hermitian matrix is

$$\det M_2(v) = D^2 - |C|^2 - 2\mu^2(D - \operatorname{Re} C).$$

Direct simplification gives the displayed factorization.

It remains to record why the last factor has no sign change on the real Q3 curve. Eliminating w between $P(u,w) = 0$ and Definition 9440.5 gives, with $z = u^2$,

$$z^6 + 6z^5 + 119z^4 + 84z^3 + 5615z^2 - 730z + 25.$$

Its Sturm chain has no nonnegative real root. Since $P(1,1) = 16 > 0$, the factor P is positive on the real Q3 curve. The denominator is positive, so the sign of the determinant is controlled by the leading minus sign and the two square factors. □

9440.5 Anchored $L = 2$ Rigidity

Theorem 9440.8 (Palindromic $L = 2$ rigidity)**.** *For $v \in \mathcal{P}_5$, the matrix $M_2(v)$ is positive semidefinite if and only if*

$$q = r = i$$

or

$$q = r = -i.$$

Equivalently, the only pentary palindromic Q3 rows passing anchored $L = 2$ neutral RP are the Pythagorean row

$$v_\star = (a, b, -a, b, a), \qquad a = \frac{1+2i}{\sqrt{5}}, \qquad b = \frac{2-i}{\sqrt{5}},$$

and its complex conjugate.

Proof. If $M_2(v) \succeq 0$, then Definition 9440.3 gives $\det M_2(v) \geq 0$. By Definition 9440.7, the determinant is nonpositive, and $P(u, w) > 0$ on the real Q3 curve. Therefore

$$(u - w)^2(u + w)^2 = 0,$$

so either $u = w$ or $u = -w$.

If $u = w$, the half-angle Q3 equation becomes

$$-u^4 - 4u^2 + 5 = 0.$$

With $z = u^2$, this is

$$z^2 + 4z - 5 = 0,$$

so the real solutions have $u^2 = 1$. Hence $u = w = 1$ or $u = w = -1$, giving $q = r = i$ or $q = r = -i$.

If $u = -w$, the half-angle Q3 equation becomes

$$-u^4 + 4u^2 + 5 = 0.$$

With $z = u^2$, this is

$$z^2 - 4z - 5 = 0,$$

so the real branch has $u^2 = 5$. On this branch, direct substitution gives

$$D = \frac{1}{3}, \qquad |C| = \frac{5}{9}.$$

Thus $D - |C| = -2/9 < 0$, contradicting the lower-right principal minor condition. The branch $u = -w$ is excluded.

For $q = r = i$, the Q3 reconstruction in Definition 9439.11 gives the displayed Pythagorean row. The case $q = r = -i$ is its complex conjugate. Conversely, Definition 9431.8 shows that the Pythagorean row passes anchored $L = 2$ neutral RP, and conjugation preserves the same real positive-semidefinite matrix. □

9440.6 Anchored $L = 3$ Exclusion

Theorem 9440.9 (No pentary palindromic anchored $L = 3$ candidate)**.** *There is no row*

$$v \in \mathcal{P}_5$$

that passes anchored $L = 3$ neutral RP.

Proof. If $v \in \mathcal{P}_5$ passed anchored $L = 3$ neutral RP, it would pass the anchored $L = 2$ subwindow. By Definition 9440.8, v would be the Pythagorean row or its complex conjugate. But Definition 9431.10 gives the negative anchored $L = 3$ diagonal value

$$D_{23} = -\frac{1}{5}.$$

The value is real, so the conjugate row gives the same obstruction. Hence no row in $\mathcal{P}_5$ passes anchored $L = 3$ neutral RP. □

Corollary 9440.10 (Palindromic exclusion)**.** *For the anchored neutral $L = 3$ finite-window class,*

$$\mathcal{P}_5 \cap \mathcal{R}^{\text{neu}}_{5,3,1} = \varnothing.$$

Proof. This is exactly Definition 9440.9. □

Principle 9440.11 (Symmetry window)**.** *Palindromic symmetry solves the Hermitian part of the finite-window RP problem, but it also makes the anchored $L = 2$ window rigid. The only surviving rows are the Pythagorean row and its conjugate, and both fail at anchored $L = 3$. Thus a pentary RP candidate, if one exists, cannot be found by imposing full palindromy alone; it must satisfy the Hermitian equations by a finer non-palindromic symmetry.*

Chapter 9441

Innovation Input Self-Similar RP Scaling

chapter 9440 excludes the palindromic pentary Q3 locus from anchored $L = 3$ neutral RP. This chapter records the scale principle behind such finite-window obstructions. The ledger machine is not primarily a state table; it is a self-similar refinement rule. A displayed state is a section of one layer, while the same local refinement rule is the invariant object repeated across all scales.

9441.1 Self-Substitution Rule

Definition 9441.1 (Constant-length phase self-substitution)**.** *Let $N \geq 2$ and let*

$$v = (v_0, \ldots, v_{N-1}) \in \mathbb{T}^N.$$

A constant-length phase self-substitution row is a phase sequence (u_n) satisfying

$$u_{Nn+a} = v_a u_n, \qquad a = 0, \ldots, N-1.$$

If additionally

$$\sum_{a=0}^{N-1} v_a = \sqrt{N},$$

then the row is Q3-compatible, equivalently $v \in \mathcal{Q}_N$.

Principle 9441.2 (Rule before section)**.** *The invariant object of a self-substitution ledger is the local refinement rule*

$$u_{Nn+a} = v_a u_n.$$

A finite state row is only a section through one refinement layer. The cross-layer datum is the repeated rule, not a completed external table of states.

9441.2 Scale Dilation

Definition 9441.3 (Block dilation)**.** *For an integer $M \geq 1$, define the dilation of basis blocks by*

$$D_M \delta_j := \delta_{Mj}.$$

For a signed block $\alpha = \sum_j e_j \delta_j$ in the sense of Definition 9427.1, set

$$D_M \alpha := \sum_j e_j \delta_{Mj}.$$

Theorem 9441.4 (Balanced correlation scale invariance)**.** *Let α be a balanced block in the sense of Definition 9427.2. For every $k \geq 0$,*

$$\Gamma(D_{N^k}\alpha) = \Gamma(\alpha).$$

In particular,

$$\Gamma(D_N \alpha) = \Gamma(\alpha).$$

Proof. It suffices to prove the case $k = 1$. Write

$$\alpha = \sum_j e_j \delta_{r_j}.$$

Then

$$\Gamma(D_N \alpha) = \left\langle \prod_j u_{n+Nr_j}^{e_j} \right\rangle_n .$$

Split $n = Nq + a$, where $a = 0, \ldots, N-1$. Then

$$n + Nr_j = N(q + r_j) + a,$$

and the self-substitution rule gives

$$u_{N(q+r_j)+a} = v_a u_{q+r_j}.$$

Hence

$$\prod_j u_{n+Nr_j}^{e_j} = \prod_j (v_a u_{q+r_j})^{e_j} = v_a^{\sum_j e_j} \prod_j u_{q+r_j}^{e_j}.$$

Since α is balanced, $\sum_j e_j = 0$, so the residue factor is $v_a^0 = 1$. Every residue class gives the same average as $\Gamma(\alpha)$, and averaging over a does not change the result. Iteration gives the formula for D_{N^k}. □

Corollary 9441.5 (Scale copying of finite correlation defects)**.** *If a balanced block α has*

$$\operatorname{Im} \Gamma(\alpha) \neq 0,$$

then every dilated block $D_{N^k}\alpha$ has the same nonzero imaginary part. If

$$\Gamma(\alpha) < 0,$$

then every $D_{N^k}\alpha$ has the same negative value.

Proof. This is immediate from Definition 9441.4. □

Principle 9441.6 (Smooth projection)**.** *Microscopic refinement repeatedly introduces local digit choices. A balanced finite observation does not see a single choice in isolation; it sees the fixed point of the repeated self-substitution rule:*

$$\Gamma(\alpha) = \Gamma(D_N \alpha) = \Gamma(D_{N^2}\alpha) = \cdots .$$

The apparent smoothness of a macroscopic correlation read is therefore a projection of infinitely repeated local choices onto a scale-invariant balanced observable.

9441.3 Reflection-Centered Dilation

Definition 9441.7 (Reflection-centered dilation)**.** *Assume N is odd. Define*

$$\mathcal{D}_N^\theta(\delta_j) := \delta_{\frac{1+N(2j-1)}{2}}.$$

Equivalently, in the half-integer coordinate $x = j - \frac{1}{2}$, the map is

$$x \mapsto Nx.$$

Because N is odd, $\frac{1+N(2j-1)}{2}$ is an integer.

Lemma 9441.8 (Reflection-centered dilation commutes with reflection)**.** *For odd N,*

$$\theta\mathcal{D}_N^\theta = \mathcal{D}_N^\theta\theta.$$

Proof. It is enough to compute on a basis index. First dilate and then reflect:

$$\theta\mathcal{D}_N^\theta(j) = 1 - \frac{1+N(2j-1)}{2} = \frac{1-N(2j-1)}{2}.$$

Reflect first and then dilate:

$$\mathcal{D}_N^\theta(1-j) = \frac{1+N(2(1-j)-1)}{2} = \frac{1-N(2j-1)}{2}.$$

The two expressions agree. □

Lemma 9441.9 (Reflection-centered dilation is ordinary dilation up to translation)**.** *For odd N,*

$$\mathcal{D}_N^\theta(\delta_j) = \delta_{Nj-\frac{N-1}{2}}.$$

Thus on balanced blocks, $\mathcal{D}_N^\theta$ has the same correlation read as D_N.

Proof. The displayed equality is the simplification

$$\frac{1+N(2j-1)}{2} = Nj - \frac{N-1}{2}.$$

The shift by $-(N-1)/2$ is common to every site in the block. Translation does not change balanced finite-block correlations by Definition 9427.4; hence the correlation read agrees with that of D_N. □

9441.4 RP Window Scaling

Definition 9441.10 (Finite neutral RP window)**.** *Let*

$$\mathcal{B} = \{\alpha_0, \ldots, \alpha_m\}$$

be a finite family of balanced future blocks. Its neutral RP matrix is

$$M_{\mathcal{B}}(v)_{ij} := \Gamma(\alpha_j - \theta\alpha_i).$$

Definition 9441.11 (Reflection-centered window dilation)**.** *For odd N, define*

$$\mathcal{D}_N^\theta \mathcal{B} := \{\mathcal{D}_N^\theta \alpha_0, \dots, \mathcal{D}_N^\theta \alpha_m\}.$$

Theorem 9441.12 (Odd-length RP window self-similarity)**.** *Assume N is odd. For every finite neutral RP window $\mathcal{B}$,*

$$M_{\mathcal{D}_N^\theta \mathcal{B}}(v) = M_{\mathcal{B}}(v).$$

More generally,

$$M_{(\mathcal{D}_N^\theta)^k \mathcal{B}}(v) = M_{\mathcal{B}}(v) \qquad k \geq 0.$$

Proof. The (i, j) entry of the dilated-window matrix is

$$\Gamma(\mathcal{D}_N^\theta \alpha_j - \theta \mathcal{D}_N^\theta \alpha_i).$$

By Definition 9441.8,

$$\theta \mathcal{D}_N^\theta \alpha_i = \mathcal{D}_N^\theta \theta \alpha_i.$$

Thus the entry is

$$\Gamma(\mathcal{D}_N^\theta (\alpha_j - \theta \alpha_i)).$$

The block $\alpha_j - \theta \alpha_i$ is balanced because both α_i and α_j are balanced. By Definition 9441.9 and Definition 9441.4,

$$\Gamma(\mathcal{D}_N^\theta (\alpha_j - \theta \alpha_i)) = \Gamma(\alpha_j - \theta \alpha_i).$$

This is exactly the (i, j) entry of $M_{\mathcal{B}}(v)$. Iteration gives the statement for $(\mathcal{D}_N^\theta)^k$. □

Corollary 9441.13 (Scale copying of RP failure)**.** *For odd N, if $M_{\mathcal{B}}(v)$ has a negative eigenvalue, then every dilated matrix*

$$M_{(\mathcal{D}_N^\theta)^k \mathcal{B}}(v)$$

has the same negative eigenvalue.

Proof. The matrices are equal by Definition 9441.12, so their spectra are equal. □

9441.5 Primitive RP Shapes

Definition 9441.14 (Neutral RP feasibility class)**.** *Let $\mathcal{R}_{N,L,R}^{\text{neu}}$ denote the set of Q3 rows $v \in \mathcal{Q}_N$ whose anchored neutral windows of size parameters (L, R) have positive-semidefinite RP matrices. Define the full neutral finite-window class by*

$$\mathcal{R}_N^{\text{neu}} := \bigcap_{L,R} \mathcal{R}_{N,L,R}^{\text{neu}}.$$

Definition 9441.15 (Reflection-centered primitive window)**.** *For odd N, a finite neutral RP window $\mathcal{B}$ is N-primitive when there is no finite neutral RP window $\mathcal{C}$ and no $k \geq 1$ such that*

$$\mathcal{B} = (\mathcal{D}_N^\theta)^k \mathcal{C}.$$

Corollary 9441.16 (Primitive-window reduction)**.** *For odd N, nonprimitive windows do not add new RP matrix constraints. Each such window has the same RP matrix as its primitive root.*

Proof. Apply Definition 9441.12 to the primitive root and iterate until the displayed nonprimitive window is reached. □

Principle 9441.17 (Pentary primitive search)**.** *For $N = 5$, reflection-centered dilation sends*

$$1 \mapsto 3, \qquad 2 \mapsto 8, \qquad 3 \mapsto 13.$$

Thus windows supported on $\{1, 2, 3\}$ and on $\{3, 8, 13\}$ belong to the same RP scale class. A negative finite-window value at one representative is not a small-scale accident; it is a fixed obstruction on the whole reflection-centered dilation tower. Subsequent pentary searches should therefore enumerate primitive RP shapes modulo $\mathcal{D}_5^\theta$ before testing Hermitian symmetry and positive semidefiniteness.

Chapter 9442

Innovation Input Primitive RP Roots

chapter 9441 shows that, for odd substitution length, reflection-centered dilations do not change the neutral RP matrix. This chapter turns that scale invariance into a finite pruning rule. Every finite block and every finite window has a unique primitive root under reflection-centered dilation. Nonprimitive windows therefore carry no additional RP condition.

9442.1 Scale Root

Definition 9442.1 (Single-site scale order)**.** *Let N be odd. For an integer site j, define*

$$\nu_N(j) := \max\left\{k \geq 0 : j - \frac{N^k+1}{2} \in N^k\mathbb{Z}\right\}.$$

Equivalently, $\nu_N(j)$ is the largest k for which j can be written as

$$j = (\mathcal{D}_N^\theta)^k(i)$$

with $i \in \mathbb{Z}$.

Definition 9442.2 (Block scale order and root)**.** *For a nonzero signed block*

$$\alpha = \sum_j e_j\delta_j,$$

define

$$\nu_N(\alpha) := \min_{j:e_j\neq 0} \nu_N(j).$$

The block is N-primitive when $\nu_N(\alpha) = 0$. If $\nu_N(\alpha) = k > 0$, define its scale root by

$$\mathrm{root}_N(\alpha) := (\mathcal{D}_N^\theta)^{-k}\alpha.$$

On sites this inverse is

$$(\mathcal{D}_N^\theta)^{-k}(j) = \frac{j + \frac{N^k-1}{2}}{N^k}.$$

Theorem 9442.3 (Unique primitive block root)**.** *Let N be odd. Every nonzero signed block α has a unique decomposition*

$$\alpha = (\mathcal{D}_N^\theta)^k\alpha_0,$$

where

$$k = \nu_N(\alpha)$$

and α_0 is N-primitive.

Proof. By the definition of $k = \nu_N(\alpha)$, every support point of α can be inverse-dilated k times through $(\mathcal{D}_N^\theta)^{-k}$. This produces a signed block

$$\alpha_0 := (\mathcal{D}_N^\theta)^{-k}\alpha$$

with integer support. Since k is the minimum of the site scale orders over the support, at least one support point has scale order exactly k. Its inverse image has scale order 0, so α_0 is primitive.

The value k is determined by $\nu_N(\alpha)$, and $(\mathcal{D}_N^\theta)^k$ is injective on the integer lattice. Hence the primitive root is unique. □

9442.2 Window Roots

Definition 9442.4 (Future neutral window root)**.** *Let*

$$\mathcal{B} = \{\alpha_0, \ldots, \alpha_m\}$$

be a finite future neutral RP window, with each nonzero α_i balanced. Define

$$\nu_N(\mathcal{B}) := \min_{\alpha_i \neq 0} \nu_N(\alpha_i).$$

The window is N-primitive when $\nu_N(\mathcal{B}) = 0$. If $\nu_N(\mathcal{B}) = k > 0$, define

$$\mathrm{root}_N(\mathcal{B}) := \{(\mathcal{D}_N^\theta)^{-k}\alpha_i\}_i.$$

Theorem 9442.5 (RP matrix depends only on the primitive root)**.** *Let N be odd and let $\mathcal{B}$ be a finite neutral RP window. Then*

$$M_{\mathcal{B}} = M_{\mathrm{root}_N(\mathcal{B})}.$$

Proof. By the definition of the window root, there is a finite neutral window $\mathcal{C} = \mathrm{root}_N(\mathcal{B})$ and an integer $k \geq 0$ with

$$\mathcal{B} = (\mathcal{D}_N^\theta)^k \mathcal{C}.$$

The equality of RP matrices is exactly Definition 9441.12. □

Corollary 9442.6 (Primitive-window pruning)**.** *For odd N, it is enough to test primitive neutral RP windows. If a nonprimitive window passes or fails, its primitive root has the identical RP matrix and the same spectrum.*

Proof. This follows from Definition 9442.5. □

9442.3 Pentary Scale Test

Definition 9442.7 (Pentary reflection-centered address)**.** *For a future site $j \geq 1$, define its pentary reflection-centered address by*

$$\rho_5(j) := 2j - 1.$$

The reflection-centered dilation $j \mapsto 5j - 2$ sends

$$\rho_5(j) \mapsto 5\rho_5(j).$$

Theorem 9442.8 (Pentary site scale order)**.** *For $j \geq 1$,*

$$\nu_5(j) = v_5(2j-1),$$

where v_5 is the ordinary 5-adic valuation.

Proof. The equality

$$j = (\mathcal{D}_5^\theta)^k(i)$$

is equivalent to

$$j - \frac{1}{2} = 5^k\left(i - \frac{1}{2}\right).$$

Multiplying by 2 gives

$$2j - 1 = 5^k(2i-1).$$

Since $2i-1$ is an odd integer, the largest possible k is exactly $v_5(2j-1)$. □

Corollary 9442.9 (Pentary block scale order)**.** *For a nonzero signed block $\alpha = \sum_j e_j\delta_j$,*

$$\nu_5(\alpha) = \min_{j:e_j\neq 0} v_5(2j-1).$$

The block is 5-primitive if and only if at least one support point satisfies

$$5 \nmid (2j-1).$$

Corollary 9442.10 (Pentary window root formula)**.** *Let*

$$k = \min_{j\in\operatorname{supp}\mathcal{B}} v_5(2j-1).$$

Then the root of the window is obtained sitewise by

$$j \mapsto \frac{1 + \frac{2j-1}{5^k}}{2}.$$

Proof. Apply the inverse formula in Definition 9442.2 and simplify using $2j-1$. □

9442.4 Small Pentary Windows

Proposition 9442.11 (Small pentary windows are primitive)**.** *For $N = 5$, every nonzero neutral future window whose support is contained in*

$$\{1, 2, 3, 4, 5, 6, 7\}$$

is 5-primitive.

Proof. A support point can be inverse-dilated once precisely when j is congruent to 3 modulo 5. Inside $\{1, 2, 3, 4, 5, 6, 7\}$, the only such site is 3. If a nonzero balanced block were supported only at 3, it would have the form $e\delta_3$, and balancedness would force $e = 0$. Hence every nonzero neutral block in such a window has at least one primitive support point, and the window is primitive. □

Corollary 9442.12 (Early pentary failures are primitive)**.** *The pentary anchored $L = 2$ and $L = 3$ windows studied in the preceding chapters are primitive windows. In particular, the Pythagorean obstruction*

$$D_{23} = -\frac{1}{5}$$

is a primitive obstruction, not a dilation copy of a smaller RP failure.

Proof. Their supports lie in $\{1, 2, 3\}$, so Definition 9442.11 applies. The value $D_{23} = -1/5$ is Definition 9431.10. □

9442.5 Pentary Link Roots

Definition 9442.13 (Link block)**.** *For $1 \le i < j$, define*

$$\alpha_{ij} := \delta_i - \delta_j.$$

It corresponds to the link observable

$$F_{ij} = u_{n+i}\overline{u_{n+j}}.$$

Proposition 9442.14 (Pentary link primitive criterion)**.** *The link block α_{ij} is nonprimitive if and only if i and j are both congruent to 3 modulo 5. When*

$$i = 5i' - 2, \qquad j = 5j' - 2,$$

one has

$$\alpha_{ij} = \mathcal{D}_5^\theta(\alpha_{i'j'}).$$

Proof. The support of α_{ij} is $\{i, j\}$. It can be inverse-dilated once exactly when both support points can be inverse-dilated once, which is the congruence condition that i and j are both congruent to 3 modulo 5. In that case

$$i' = \frac{i+2}{5}, \qquad j' = \frac{j+2}{5}$$

are integers, and the displayed identity follows from $\mathcal{D}_5^\theta(t) = 5t - 2$. □

Example 9442.15 (First nonprimitive pentary links)**.** *The first nonprimitive pentary links are*

$$\alpha_{3,8} = \mathcal{D}_5^\theta(\alpha_{1,2}),$$

$$\alpha_{3,13} = \mathcal{D}_5^\theta(\alpha_{1,3}),$$

and

$$\alpha_{8,13} = \mathcal{D}_5^\theta(\alpha_{2,3}).$$

Therefore the corresponding two-link neutral windows have exactly the same RP matrices as their roots.

Principle 9442.16 (Reflection-centered address rather than distance)**.** *Ordinary link distance does not determine an RP diagonal. The relevant scale datum is the reflection-centered address $2j - 1$ of every support point. Thus F_{12} and F_{23} are both distance-one links, but they occupy different positions relative to the reflection center. This is why the Pythagorean row can have*

$$D_{12} = \frac{3}{5}$$

and

$$D_{23} = -\frac{1}{5}.$$

9442.6 Odd-Length Address Formula

Definition 9442.17 (Reflection-centered N-address)**.** *For odd N and $j \geq 1$, set*

$$\rho_N(j) := 2j - 1.$$

Theorem 9442.18 (Odd-length scale order)**.** *For odd N,*

$$\nu_N(j) = \max\{k \geq 0 : N^k \mid (2j-1)\}.$$

If

$$N = \prod_{p \mid N} p^{e_p},$$

then

$$\nu_N(j) = \min_{p \mid N} \left\lfloor \frac{v_p(2j-1)}{e_p} \right\rfloor.$$

Proof. The equality $j = (\mathcal{D}_N^\theta)^k(i)$ is equivalent to

$$2j - 1 = N^k(2i - 1).$$

Thus N^k must divide $2j-1$, and the largest such k is the first displayed formula. The prime-factor expression follows because $N^k \mid m$ holds exactly when $ke_p \leq v_p(m)$ for every prime $p \mid N$. □

Principle 9442.19 (Solenoid address reading)**.** *The primitive RP shape test is an S-adic address test. For a refinement length N with prime set S, the visible site j carries the reflection-centered address $2j-1$; the number of times a window is a scale copy is the number of times those addresses are divisible by N. Thus finite RP constraints are indexed by primitive residues in the hidden S-adic fibre, while nonprimitive windows are repetitions along the same solenoidal scale direction.*

Chapter 9443

Innovation Input Self-Adjoint Hamiltonian Gate

chapter 9442 reduces odd-length neutral RP checks to primitive reflection-centered windows. The present chapter records what those checks are allowed to mean. They are input-side tests for the existence of an Osterwalder–Schrader Hamiltonian. They are not, by themselves, a construction of a Riemann-zero spectral operator.

9443.1 Three Operator Rows

Definition 9443.1 (Hilbert–Polya zero target)**.** *A Hilbert–Polya zero target for the completed Riemann function is a self-adjoint operator A_ξ^{HP} whose spectral row satisfies an identification of the form*

$$\mathrm{Spec}(A_\xi^{\mathrm{HP}}) = \{\gamma : \xi(1/2 + i\gamma) = 0\}.$$

Such a row is an RH-strength target: if the operator is genuinely self-adjoint and the displayed identification is complete, the spectral values on the right are real ordinates on the critical line.

Definition 9443.2 (Input-side OS/RP Hamiltonian)**.** *Let $v \in \mathcal{Q}_N$ be a Q3-compatible constant-length self-substitution row, and suppose its complete future reflection form is realized by a positive contraction transition row P_v on the OS Hilbert space of the input process. The associated input Hamiltonian is*

$$H_v := -\frac{1}{\ln N} \log P_v$$

on the nonzero spectral subspace of P_v.

Definition 9443.3 (Riemann scattering row)**.** *At the modular cusp, the Eisenstein constant term has scattering coefficient*

$$\varphi(s) = \frac{\Lambda(2s-1)}{\Lambda(2s)}.$$

Thus the completed zeta function enters the modular input interface as a scattering coefficient. Its zeros are reached there as scattering poles or resonances, as in Definition 9452.29, not as an already identified self-adjoint spectrum.

Principle 9443.4 (Operator rows are not interchangeable)**.** *The rows*

$$A_\xi^{\mathrm{HP}}, \qquad H_v = -\frac{1}{\ln N} \log P_v, \qquad \varphi(s) = \frac{\Lambda(2s-1)}{\Lambda(2s)}$$

have different meanings. The first is the desired zero-spectrum row. The second is the input Hamiltonian produced by reflection positivity. The third is the scattering entry through which Riemann zeta reaches the modular boundary. A proof route may compare these rows only after it exhibits explicit bridge data between the corresponding interfaces.

9443.2 RP as the Input Source of Self-Adjointness

Theorem 9443.5 (Positive transition row gives an input Hamiltonian)**.** *Assume $0 \preceq P_v \preceq I$ on the OS Hilbert space associated to a Q3-compatible self-substitution input. Then*

$$H_v := -\frac{1}{\ln N} \log P_v$$

is self-adjoint and nonnegative on the nonzero spectral subspace, and

$$e^{-(\ln N)H_v} = P_v.$$

Proof. The operator P_v is a positive contraction, hence its spectrum lies in $[0, 1]$. On the nonzero spectral subspace, the scalar function

$$x \mapsto -\frac{1}{\ln N} \log x$$

is real-valued and nonnegative. The spectral calculus therefore defines a self-adjoint nonnegative operator H_v, and the exponential identity is the same scalar identity applied through the functional calculus. □

Corollary 9443.6 (Finite-window failure blocks the Hamiltonian gate)**.** *If a finite future window has a vector F with*

$$\langle \theta F, F \rangle < 0,$$

then the corresponding self-substitution row cannot pass complete RP, and therefore cannot supply an input Hamiltonian through the OS/RP gate of Definition 9443.2.

Proof. Complete RP requires every finite-window reflection form to be nonnegative. A negative finite-window vector is already a contradiction to that requirement, so no positive contraction P_v representing the complete reflection form can be present. □

Principle 9443.7 (Hilbert–Polya prefilter)**.** *Finite-window RP is a prefilter for any Hilbert–Polya style route that starts from self-similar input. A row failing a finite RP window cannot generate the input Hamiltonian H_v; hence it cannot serve as the positive input layer of a later construction of A_ξ^{HP}. This is a necessary-condition statement only. A row passing all input RP tests would still need an independent spectral bridge from H_v to the completed zeta zero row.*

Principle 9443.8 (Known small Q3 obstructions)**.** *The small Q3 rows already isolated in Definition 9428.19, Definition 9431.15, and Definition 9440.10 are therefore input-Hamiltonian exclusions. The binary representative fails the charged one-site gate, the ternary and quartic representatives fail neutral finite-window RP, the Pythagorean pentary row passes the anchored $L = 2$ neutral gate but fails at anchored $L = 3$, and the pentary palindromic Q3 locus has empty intersection with the anchored $L = 3$ neutral RP class. These are not statements about the truth value of RH; they remove self-similar input rows from the OS/RP source side.*

9443.3 Zeta Upgrade Obligation

Definition 9443.9 (Zeta Hilbert–Polya upgrade)**.** *A Q3-compatible self-substitution row v admits a zeta Hilbert–Polya upgrade when it supplies an input Hamiltonian H_v and there is a natural self-adjoint operator $\mathcal{A}_v$ built from the same input, boundary, or scattering data such that its spectral row satisfies*

$$\gamma \in \mathrm{Spec}(\mathcal{A}_v) \quad \Longleftrightarrow \quad \xi(1/2 + i\gamma) = 0.$$

The construction of H_v is only the input-side part of this definition.

Principle 9443.10 (Two independent bridge obligations)**.** *Two bridge obligations are separated. The input bridge must pass from a self-similar RP row to a positive self-adjoint Hamiltonian H_v. The zeta bridge must identify a self-adjoint spectral row with the completed zeta zeros, or else convert the scattering pole row of Definition 9443.3 into a self-adjoint spectral row. Lax–Phillips, de Branges, and Hermite–Biehler style interfaces belong to the second obligation, not to the finite-window RP computation itself.*

Principle 9443.11 (Three-level zeta interface)**.** *The input programme has three distinct zeta-facing levels:*

level	*row*	*output*
self-substitution RP	$v \in \mathcal{Q}_N,\ M_{\mathcal{B}}(v) \succeq 0$	H_v
boundary transfer	*Gauss/Mayer transfer row*	$Z_{\mathrm{Selberg}}(s)$
modular scattering	$\varphi(s) = \Lambda(2s-1)/\Lambda(2s)$	*Riemann scattering poles*

The first level is where the finite-window Q3 search lives. The second is the boundary determinant interface of Definition 9453.7. The third is the cusp scattering interface of Definition 9452.29. Moving from one level to another is not automatic.

Theorem 9443.12 (Complete RP is necessary for OS-source upgrade)**.** *If a Q3-compatible self-substitution row is to yield a Hilbert–Polya upgrade through the OS/RP input source, then it must satisfy complete RP on all finite future windows used by that source.*

Proof. The OS/RP source requires a positive Hilbert quotient for future observables and a positive contraction transition row before Definition 9443.5 can define H_v. A negative finite-window reflection form prevents the positive quotient and hence prevents the positive transition row. Thus complete RP is a necessary condition for this source route. □

9443.4 Pentary Hermitian Locus

Definition 9443.13 (Anchored three-link neutral window)**.** *For the anchored $L = 3$ neutral audit, set*

$$e_{12} := \delta_1 - \delta_2, \qquad e_{13} := \delta_1 - \delta_3, \qquad e_{23} := \delta_2 - \delta_3,$$

and use the future block family

$$\mathcal{B}_3 := \{0, e_{12}, -e_{12}, e_{13}, -e_{13}, e_{23}, -e_{23}\}.$$

Its RP matrix is

$$M_3(v)_{\alpha,\beta} := \Gamma(\beta - \theta\alpha), \qquad \alpha, \beta \in \mathcal{B}_3.$$

Definition 9443.14 (Pentary Hermitian and RP loci)**.** *Inside $\mathcal{Q}_5$, define*

$$\mathcal{H}^{\mathrm{neu}}_{5,3,1} := \{v \in \mathcal{Q}_5 : M_3(v) = M_3(v)^*\}$$

and

$$\mathcal{R}^{\mathrm{neu}}_{5,3,1} := \{v \in \mathcal{H}^{\mathrm{neu}}_{5,3,1} : M_3(v) \succeq 0\}.$$

Theorem 9443.15 (Hermitian condition as reflected correlation equality)**.** *For $v \in \mathcal{Q}_5$, the anchored three-link matrix is Hermitian if and only if, for all $\alpha, \beta \in \mathcal{B}_3$,*

$$\Gamma(\beta - \theta\alpha) = \Gamma(\theta\beta - \alpha).$$

Proof. The matrix entry is

$$M_{\alpha,\beta} = \Gamma(\beta - \theta\alpha).$$

Hermitian symmetry asks for

$$M_{\alpha,\beta} = \overline{M_{\beta,\alpha}}.$$

Since complex conjugation reverses a balanced correlation block,

$$\overline{M_{\beta,\alpha}} = \overline{\Gamma(\alpha - \theta\beta)} = \Gamma(\theta\beta - \alpha).$$

This is exactly the displayed equality. □

Corollary 9443.16 (Reflection-even rows are Hermitian)**.** *If the balanced correlation function of v is reflection-even in the sense of Definition 9439.3, then $v \in \mathcal{H}^{\mathrm{neu}}_{5,3,1}$.*

Proof. Apply Definition 9439.4 to the finite window $\mathcal{B}_3$. □

Principle 9443.17 (Nonpalindromic feasibility surface)**.** *Palindromic rows lie in the Hermitian locus by Definition 9439.8, but Definition 9440.10 gives*

$$\mathcal{P}_5 \cap \mathcal{R}^{\mathrm{neu}}_{5,3,1} = \varnothing$$

for the anchored three-link class. Therefore the remaining pentary input-Hamiltonian surface is

$$(\mathcal{Q}_5 \setminus \mathcal{P}_5) \cap \mathcal{R}^{\mathrm{neu}}_{5,3,1}.$$

A point on this surface would still be only an OS/RP input candidate: it would provide the finite-window shadow of H_v, not the zeta Hilbert–Polya operator.

Principle 9443.18 (Hermitian before positivity)**.** *For the nonpalindromic pentary search, the finite-window gates occur in a fixed order:*

$$\textit{Q3 phase-sum compatibility}, \qquad M_3(v) = M_3(v)^*, \qquad M_3(v) \succeq 0.$$

The golden symmetric row of Definition 9438.5 passes the scalar link-diagonal filter but fails the Hermitian gate. Thus the Hermitian equations are not cosmetic symmetry conditions; they are the finite-window expression of self-adjointness before the PSD gate can be read as reflection positivity.

Chapter 9444

Innovation Input Pentary Mirror Decomposition Gate

chapter 9443 separates Q3 compatibility, Hermitian reflection symmetry, and positive RP. This chapter supplies the mirror decomposition behind the pentary Hermitian gate. Q3 fixes the symmetric total of the self-substitution word, while the nonpalindromic variables are mirror-antisymmetric phase twists. Hermitian defects are odd under this mirror action, so after the finite carry-closure denominator is cleared they lie in the palindromic ideal.

9444.1 Mirror Coordinates

Definition 9444.1 (Pentary mirror)**.** *For a pentary phase word $v = (v_0, \dots, v_4)$, define*

$$\sigma(v)_a := v_{4-a}.$$

Equivalently,

$$\sigma(v_0, v_1, v_2, v_3, v_4) = (v_4, v_3, v_2, v_1, v_0).$$

The fixed points of σ are exactly the palindromic words (a, b, c, b, a).

Proposition 9444.2 (Q3 is mirror invariant)**.** *If $v \in \mathcal{Q}_5$, then $\sigma(v) \in \mathcal{Q}_5$.*

Proof. The phase sum is unchanged by reversing the five entries:

$$\sum_{a=0}^{4} \sigma(v)_a = v_4 + v_3 + v_2 + v_1 + v_0 = \sum_{a=0}^{4} v_a.$$

Thus the equation $\sum_a v_a = \sqrt{5}$ is preserved. □

Definition 9444.3 (Symmetric and antisymmetric coordinates)**.** *Set*

$$s_0 := \frac{v_0 + v_4}{2}, \qquad d_0 := \frac{v_0 - v_4}{2},$$

$$s_1 := \frac{v_1 + v_3}{2}, \qquad d_1 := \frac{v_1 - v_3}{2},$$

and

$$c := v_2.$$

Then

$$v_0 = s_0 + d_0, \qquad v_4 = s_0 - d_0,$$

and

$$v_1 = s_1 + d_1, \qquad v_3 = s_1 - d_1.$$

The palindromic condition is $d_0 = d_1 = 0$.

Theorem 9444.4 (Q3 only sees the symmetric part)**.** *In the coordinates of Definition 9444.3, the Q3 equation is*

$$2s_0 + 2s_1 + c = \sqrt{5}.$$

It contains no d_0 *or* d_1 *term.*

Proof. Adding the five entries gives

$$v_0 + v_1 + v_2 + v_3 + v_4 = (v_0 + v_4) + (v_1 + v_3) + v_2 = 2s_0 + 2s_1 + c.$$

□

Corollary 9444.5 (Nonpalindromy is not a Q3 obstruction)**.** *The Q3 layer constrains the symmetric skeleton* (s_0, s_1, c) *but does not directly remove the antisymmetric coordinates* (d_0, d_1)*. Any exclusion of nonpalindromic pentary rows must therefore come from Hermitian reflection symmetry, RP positivity, or a stronger bridge row.*

Theorem 9444.6 (Unit-circle mirror coordinates)**.** *The conditions*

$$|v_0| = |v_4| = 1$$

are equivalent to

$$|s_0|^2 + |d_0|^2 = 1, \qquad \mathrm{Re}(s_0\overline{d_0}) = 0.$$

Similarly,

$$|v_1| = |v_3| = 1$$

is equivalent to

$$|s_1|^2 + |d_1|^2 = 1, \qquad \mathrm{Re}(s_1\overline{d_1}) = 0.$$

Proof. For the first pair,

$$|s_0 + d_0|^2 = |s_0|^2 + |d_0|^2 + 2\,\mathrm{Re}(s_0\overline{d_0}),$$

and

$$|s_0 - d_0|^2 = |s_0|^2 + |d_0|^2 - 2\,\mathrm{Re}(s_0\overline{d_0}).$$

If both are 1, their sum and difference give the two displayed conditions. Conversely, those two conditions make both squared moduli equal to 1. The second pair is identical with indices shifted from $0, 4$ to $1, 3$. □

Principle 9444.7 (Antisymmetric phase twist)**.** *When* $s_0 \neq 0$*, the unit-circle equations force* d_0 *to be orthogonal to* s_0 *in the real plane underlying* $\mathbb{C}$*; equivalently*

$$d_0 = it_0 s_0$$

for some real t_0*, with*

$$|s_0|^2(1 + t_0^2) = 1.$$

The same statement holds for d_1 *relative to* s_1*. Thus nonpalindromy is a pair of mirror-antisymmetric phase twists over the Q3 symmetric skeleton.*

9444.2 Mirror Transport of Correlations

Theorem 9444.8 (Mirror word reflects balanced correlations)**.** *For every pentary self-substitution row v and every balanced block α,*

$$\Gamma_{\sigma v}(\alpha) = \Gamma_v(\theta\alpha).$$

Proof. At finite depth K, write

$$n = a_0 + a_1 5 + \cdots + a_{K-1} 5^{K-1}.$$

The phase read for v is

$$u_v^{(K)}(n) = \prod_{\ell=0}^{K-1} v_{a_\ell},$$

whereas the phase read for σv is

$$u_{\sigma v}^{(K)}(n) = \prod_{\ell=0}^{K-1} v_{4-a_\ell}.$$

Let

$$R_K(n) := 5^K - 1 - n.$$

The base-5 digits of $R_K(n)$ are $(4 - a_0, \ldots, 4 - a_{K-1})$, so

$$u_{\sigma v}^{(K)}(n) = u_v^{(K)}(R_K(n)).$$

For a balanced block $\alpha = \sum_j e_j \delta_j$, form the finite-depth average over indices for which all shifted entries lie inside the depth K interval. Boundary omissions have density tending to zero. Since

$$R_K(n + j) = R_K(n) - j,$$

the substitution $m = R_K(n)$ gives, in the limit,

$$\Gamma_{\sigma v}(\alpha) = \Gamma_v\left(\sum_j e_j \delta_{-j}\right).$$

Balanced correlations are invariant under common translation of the block, hence

$$\Gamma_v\left(\sum_j e_j \delta_{-j}\right) = \Gamma_v\left(\sum_j e_j \delta_{1-j}\right) = \Gamma_v(\theta\alpha).$$

□

Corollary 9444.9 (Palindromy gives reflection evenness)**.** *If $\sigma v = v$, then*

$$\Gamma_v(\alpha) = \Gamma_v(\theta\alpha)$$

for every balanced block α.

Proof. Apply Definition 9444.8 and use $\sigma v = v$. □

9444.3 Mirror-Odd Hermitian Defects

Definition 9444.10 (Pairwise Hermitian defect)**.** *For future balanced blocks α and β, define*

$$H_{\alpha,\beta}(v) := \Gamma_v(\beta - \theta\alpha) - \Gamma_v(\theta\beta - \alpha).$$

The anchored three-link Hermitian condition is the vanishing of these defects for the block pairs in $\mathcal{B}_3$ of Definition 9443.13.

Theorem 9444.11 (Hermitian defects are mirror-odd)**.** *For future balanced blocks α and β,*

$$H_{\alpha,\beta}(\sigma v) = -H_{\alpha,\beta}(v).$$

Proof. By Definition 9444.8,

$$H_{\alpha,\beta}(\sigma v) = \Gamma_v(\theta(\beta - \theta\alpha)) - \Gamma_v(\theta(\theta\beta - \alpha)).$$

The reflected blocks are

$$\theta(\beta - \theta\alpha) = \theta\beta - \alpha$$

and

$$\theta(\theta\beta - \alpha) = \beta - \theta\alpha.$$

Therefore

$$H_{\alpha,\beta}(\sigma v) = \Gamma_v(\theta\beta - \alpha) - \Gamma_v(\beta - \theta\alpha) = -H_{\alpha,\beta}(v).$$

□

Corollary 9444.12 (Hermitian defects vanish on the palindromic locus)**.** *If $v \in \mathcal{P}_5$, then*

$$H_{\alpha,\beta}(v) = 0$$

for all future balanced α, β.

Proof. For a palindromic word, $\sigma v = v$. Hence

$$H_{\alpha,\beta}(v) = H_{\alpha,\beta}(\sigma v) = -H_{\alpha,\beta}(v),$$

so $H_{\alpha,\beta}(v) = 0$. □

9444.4 Palindromic Ideal

Definition 9444.13 (Palindromic Laurent ideal)**.** *Let*

$$\mathcal{L}_5 := \mathbb{C}[v_0^{\pm 1}, v_1^{\pm 1}, v_2^{\pm 1}, v_3^{\pm 1}, v_4^{\pm 1}]$$

and define

$$I_{\text{pal}} := (v_0 - v_4,\ v_1 - v_3) \subset \mathcal{L}_5.$$

Proposition 9444.14 (The palindromic ideal is prime)**.** *The ideal I_{pal} is prime.*

Proof. The quotient is

$$\mathcal{L}_5/I_{\text{pal}} \cong \mathbb{C}[v_0^{\pm 1}, v_1^{\pm 1}, v_2^{\pm 1}],$$

where v_4 is identified with v_0 and v_3 with v_1. This quotient is a Laurent polynomial domain, so I_{pal} is prime. □

Theorem 9444.15 (Cleared Hermitian defects lie in the palindromic ideal)**.** *Let $H_{\alpha,\beta}(v)$ be a pairwise Hermitian defect whose correlations are computed by a finite carry-closure linear system, and let*

$$\Delta_{\alpha,\beta}(v)$$

be a common determinant denominator for that system. Then

$$\Delta_{\alpha,\beta}(v)H_{\alpha,\beta}(v) \in I_{\mathrm{pal}}.$$

Equivalently, there are Laurent polynomials $A_{\alpha,\beta}(v)$ and $B_{\alpha,\beta}(v)$ such that

$$\Delta_{\alpha,\beta}(v)H_{\alpha,\beta}(v) = A_{\alpha,\beta}(v)(v_0 - v_4) + B_{\alpha,\beta}(v)(v_1 - v_3).$$

Proof. By the finite carry-closure evaluator of Definition 9429.19, the correlations in $H_{\alpha,\beta}$ are rational Laurent functions of $v_0, \ldots, v_4$. Multiplying by a common determinant denominator gives a Laurent polynomial

$$F_{\alpha,\beta}(v) := \Delta_{\alpha,\beta}(v)H_{\alpha,\beta}(v).$$

By Definition 9444.12, this polynomial vanishes after the substitutions $v_4 = v_0$ and $v_3 = v_1$. In the Laurent polynomial quotient by I_{pal}, that means the class of $F_{\alpha,\beta}$ is zero. Hence $F_{\alpha,\beta} \in I_{\mathrm{pal}}$, which is the displayed decomposition. □

Corollary 9444.16 (Basic three-link defects have nonpalindromic factors)**.** *The defects*

$$H_{12,13}, \qquad H_{12,23}, \qquad H_{13,23}$$

of Definition 9446.5 admit decompositions of the form

$$H_i(v) = A_i(v)(v_0 - v_4) + B_i(v)(v_1 - v_3)$$

on every chart where the corresponding carry-closure determinant denominator is nonzero.

Proof. Apply Definition 9444.15 to the three defects and divide by the nonzero determinant denominator on the chart under consideration. □

9444.5 Rank Form of the Remaining Problem

Definition 9444.17 (Hermitian coefficient matrix)**.** *Choose finite Hermitian defects $H_1, \ldots, H_m$ and write, on a common nonzero-denominator chart,*

$$H_\ell(v) = A_\ell(v)(v_0 - v_4) + B_\ell(v)(v_1 - v_3).$$

Define

$$K(v) := \begin{pmatrix} A_1(v) & B_1(v) \\ \vdots & \vdots \\ A_m(v) & B_m(v) \end{pmatrix}$$

and

$$R(v) := \begin{pmatrix} v_0 - v_4 \\ v_1 - v_3 \end{pmatrix}.$$

Theorem 9444.18 (Nonpalindromic Hermitian points force rank drop)**.** *If a point on the chosen chart satisfies the selected Hermitian equations and is nonpalindromic, then*

$$\operatorname{rank} K(v) \leq 1.$$

Proof. The selected Hermitian equations are

$$K(v)R(v) = 0.$$

If the point is nonpalindromic, then $R(v) \neq 0$. Hence $K(v)$ has a nonzero kernel vector. Since it has two columns, its rank is at most 1. □

Corollary 9444.19 (Minor test for Hermitian rigidity)**.** *If two selected Hermitian defects give a* 2×2 *minor*

$$J_{ij}(v) := A_i(v)B_j(v) - A_j(v)B_i(v)$$

that is nonzero on $\mathcal{Q}_5$ *in the relevant nonzero-denominator chart, then no nonpalindromic point of that chart satisfies the selected Hermitian equations.*

Proof. If such a point existed, the rank-drop theorem would force every 2×2 minor of $K(v)$ to vanish. This contradicts $J_{ij}(v) \neq 0$. □

Principle 9444.20 (Mirror decomposition of the main line)**.** *The pentary main line has a two-stage algebraic form. Q3 permits mirror-antisymmetric phase twists because it sees only the symmetric phase sum. Hermitian reflection symmetry makes the defect functions odd under the mirror, forcing their cleared carry-closure forms into* I_{pal}*. Thus a nonpalindromic Hermitian row can exist only at a rank-drop point of the Hermitian coefficient matrix.*

Chapter 9445

Innovation Input Pythagorean Local Hermitian Rigidity

chapter 9444 shows that Q3 compatibility leaves two mirror-antisymmetric phase-twist directions, while Hermitian three-link symmetry can only hold at rank-drop points of the resulting defect matrix. The Pythagorean row from Definition 9431.4 is the unique palindromic row surviving the anchored $L = 2$ positive semidefinite gate, up to complex conjugation, and it fails anchored $L = 3$ positivity by Definition 9431.10. This chapter records the local Hermitian fact at that boundary point: the surviving palindromic row is not the endpoint of a first-order nonpalindromic Hermitian branch.

9445.1 Antisymmetric Tangent Directions

Definition 9445.1 (Pythagorean antisymmetric phase perturbation)**.** *Let*

$$a := \frac{1+2i}{\sqrt{5}}, \qquad b := \frac{2-i}{\sqrt{5}}.$$

For $x, y \in \mathbb{R}$, define

$$v(\varepsilon; x, y) := \left(ae^{i\varepsilon x}, be^{i\varepsilon y}, -a, be^{-i\varepsilon y}, ae^{-i\varepsilon x}\right).$$

At $\varepsilon = 0$ this is the Pythagorean row $v_\star = (a, b, -a, b, a)$. The pair (x, y) is the mirror-antisymmetric tangent coordinate over the two edge pairs (v_0, v_4) and (v_1, v_3).

Proposition 9445.2 (Antisymmetric perturbations are Q3-tangent)**.** *For every $x, y \in \mathbb{R}$,*

$$\frac{d}{d\varepsilon} \sum_{j=0}^{4} v_j(\varepsilon; x, y)\bigg|_{\varepsilon=0} = 0.$$

Thus (x, y) is tangent to $\mathcal{Q}_5$ at $v_\star$.

Proof. The derivatives of the mirror-paired entries are

$$\frac{d}{d\varepsilon} v_0(\varepsilon; x, y)\bigg|_{\varepsilon=0} = iax, \qquad \frac{d}{d\varepsilon} v_4(\varepsilon; x, y)\bigg|_{\varepsilon=0} = -iax,$$

and

$$\frac{d}{d\varepsilon} v_1(\varepsilon; x, y)\bigg|_{\varepsilon=0} = iby, \qquad \frac{d}{d\varepsilon} v_3(\varepsilon; x, y)\bigg|_{\varepsilon=0} = -iby.$$

The middle entry is constant. The sum of the five derivatives is therefore zero. □

Definition 9445.3 (Linearized three-link Hermitian defect)**.** *For $\alpha, \beta \in \mathcal{B}_3$, set*

$$\dot{H}_{\alpha,\beta}(x,y) := \frac{d}{d\varepsilon}\left(M_3(v(\varepsilon;x,y))_{\alpha,\beta} - \overline{M_3(v(\varepsilon;x,y))_{\beta,\alpha}}\right)\Big|_{\varepsilon=0}.$$

If the anchored three-link Hermitian condition is preserved to first order along the perturbation, then every $\dot{H}_{\alpha,\beta}(x,y)$ vanishes.

9445.2 Defect Linearization

Lemma 9445.4 (Pythagorean three-link defect slopes)**.** *At $v_\star$, the antisymmetric perturbation of Definition 9445.1 has the following nonzero basic first-order Hermitian defects:*

$$\dot{H}_{0,e_{13}}(x,y) = -\frac{4i}{5}(x-y),$$

$$\dot{H}_{0,-e_{13}}(x,y) = \frac{4i}{5}(x-y),$$

$$\dot{H}_{e_{12},e_{23}}(x,y) = \frac{4i}{5}(2x-y),$$

$$\dot{H}_{-e_{12},-e_{23}}(x,y) = -\frac{4i}{5}(2x-y),$$

$$\dot{H}_{e_{13},-e_{23}}(x,y) = -\frac{4}{5}(x-2y),$$

and

$$\dot{H}_{-e_{13},e_{23}}(x,y) = -\frac{4}{5}(x-2y).$$

All other first-order defects in the anchored three-link window either vanish or are obtained from these by the forced sign and conjugation relations.

Proof. Apply the finite carry-closure recursion of Definition 9429.19 to the balanced blocks that occur in the entries of $M_3(v)$. For each such block α, the correlation satisfies a finite system of the form

$$\Gamma_v(\alpha) = \frac{1}{5}\sum_{r=0}^{4} C_r(v,\alpha)\Gamma_v(\alpha_r),$$

where the branch coefficients $C_r(v,\alpha)$ are Laurent monomials in the five phase entries. Differentiating this finite system at $v_\star$ gives

$$\dot{\Gamma}(\alpha) = \frac{1}{5}\sum_{r=0}^{4}\left[\dot{C}_r(\alpha)\Gamma_{v_\star}(\alpha_r) + C_r(v_\star,\alpha)\dot{\Gamma}(\alpha_r)\right].$$

The derivative of the phase row is

$$\dot{v}_0 = iax, \qquad \dot{v}_4 = -iax, \qquad \dot{v}_1 = iby, \qquad \dot{v}_3 = -iby, \qquad \dot{v}_2 = 0.$$

Substituting these five derivatives, solving the finite linearized carry-closure system, and then forming the Hermitian differences of Definition 9445.3 gives exactly the displayed six slopes. The remaining entries of the Hermitian defect matrix are fixed by skew-Hermitian symmetry of $M_3 - M_3^*$ and by the sign symmetry between opposite neutral links. □

9445.3 Local Rigidity

Theorem 9445.5 (Pythagorean first-order Hermitian rigidity)**.** *If the antisymmetric perturbation $v(\varepsilon; x, y)$ preserves the anchored three-link Hermitian condition to first order at $\varepsilon = 0$, then*

$$x = 0, \qquad y = 0.$$

Equivalently, $v_\star$ has no nonzero mirror-antisymmetric tangent direction inside the anchored $L = 3$ Hermitian locus.

Proof. First-order Hermitian preservation forces every defect slope in Definition 9445.4 to vanish. From

$$\dot{H}_{0,e_{13}}(x, y) = -\frac{4i}{5}(x - y)$$

one gets $x - y = 0$. From

$$\dot{H}_{e_{12},e_{23}}(x, y) = \frac{4i}{5}(2x - y)$$

one gets $2x - y = 0$. Hence $x = y$ and $2x = y$, so $x = y = 0$. The remaining linear factor $x - 2y$ then vanishes automatically. □

Corollary 9445.6 (No first-order nonpalindromic branch at the Pythagorean row)**.** *The Pythagorean row is not the endpoint of a smooth nonpalindromic anchored three-link Hermitian branch whose tangent has nonzero mirror-antisymmetric part. In particular, a nonpalindromic point of $\mathcal{H}^{\mathrm{neu}}_{5,3,1}$, if one exists, cannot be obtained by leaving $v_\star$ through a nonzero first-order antisymmetric phase twist.*

Proof. A smooth curve through $v_\star$ whose first-order displacement changes the mirror-paired phases in opposite directions has an antisymmetric tangent coordinate (x, y). If the curve remains in $\mathcal{H}^{\mathrm{neu}}_{5,3,1}$ to first order, the tangent must satisfy Definition 9445.5; therefore it is zero. This excludes a nonzero first-order nonpalindromic departure at that point. □

Corollary 9445.7 (Conjugate Pythagorean first-order rigidity)**.** *The complex conjugate row $\overline{v_\star}$ has the same first-order Hermitian rigidity: every mirror-antisymmetric tangent direction that preserves the anchored three-link Hermitian condition to first order is zero.*

Proof. Complex conjugation carries the anchored three-link matrix to its conjugate matrix and carries Hermitian defects to their conjugates. The linear factors in Definition 9445.4, namely

$$x - y, \qquad 2x - y, \qquad x - 2y,$$

are unchanged as real equations. The proof of Definition 9445.5 therefore applies verbatim. □

Principle 9445.8 (Local role of the Pythagorean boundary)**.** *Q3 compatibility sees only the symmetric phase sum, so it allows the antisymmetric phase twists (x, y) at first order. The anchored three-link Hermitian equations see three incompatible linear reads,*

$$x - y, \qquad 2x - y, \qquad x - 2y,$$

and their common zero is the palindromic tangent. Thus the Pythagorean row and its conjugate are not local sources of a nonpalindromic Hermitian branch. The unresolved pentary problem is therefore pushed to rank-drop points away from these palindromic $L = 2$ boundary points, in the sense of Definition 9444.18.

Chapter 9446

Innovation Input Pentary Hermitian Rigidity Gate

chapter 9444 shows that cleared Hermitian defects lie in the palindromic ideal and that nonpalindromic Hermitian points must occur at rank-drop points of a coefficient matrix. This chapter isolates the stronger certificate that would close the pentary three-link gate outright: enough coefficient rows must be nondegenerate on $\mathcal{Q}_5$ to force palindromy before the PSD condition is reached.

9446.1 Hermitian Defect Row

Definition 9446.1 (Three-link Hermitian defect)**.** *For $v \in \mathcal{Q}_5$, let $M_3(v)$ be the anchored three-link matrix of Definition 9443.13. Define the Hermitian defect row by*

$$\mathcal{D}_3(v) := M_3(v) - M_3(v)^*.$$

Thus

$$v \in \mathcal{H}^{\mathrm{neu}}_{5,3,1} \quad \Longleftrightarrow \quad \mathcal{D}_3(v) = 0.$$

Definition 9446.2 (Nonpalindromic defect coordinates)**.** *For a pentary phase word $v = (v_0, \dots, v_4)$, define*

$$R_0(v) := v_0 - v_4, \qquad R_1(v) := v_1 - v_3.$$

The equalities

$$R_0(v) = 0, \qquad R_1(v) = 0$$

are exactly the condition that v has the palindromic shape (a, b, c, b, a).

Principle 9446.3 (Pentary Hermitian rigidity target)**.** *The active algebraic target is the implication*

$$v \in \mathcal{H}^{\mathrm{neu}}_{5,3,1} \quad \Longrightarrow \quad R_0(v) = R_1(v) = 0.$$

Equivalently, the anchored $L = 3$ Hermitian locus inside $\mathcal{Q}_5$ is the palindromic locus, up to the evident conjugation and reflection symmetries that preserve the finite-window RP spectrum.

Theorem 9446.4 (Hermitian rigidity empties the pentary RP locus)**.** *Assume the implication of Definition 9446.3. Then*

$$\mathcal{R}^{\mathrm{neu}}_{5,3,1} = \varnothing.$$

Proof. If $v \in \mathcal{R}^{\mathrm{neu}}_{5,3,1}$, then by definition $v \in \mathcal{H}^{\mathrm{neu}}_{5,3,1}$. The rigidity implication gives $v \in \mathcal{P}_5$. But Definition 9440.10 gives

$$\mathcal{P}_5 \cap \mathcal{R}^{\mathrm{neu}}_{5,3,1} = \varnothing.$$

Hence no such v exists. □

9446.2 Cross-Entry Equations

Definition 9446.5 (Basic cross-entry defects)**.** *With*

$$e_{12} := \delta_1 - \delta_2, \qquad e_{13} := \delta_1 - \delta_3, \qquad e_{23} := \delta_2 - \delta_3,$$

define

$$H_{12,13}(v) := \Gamma(e_{13} - \theta e_{12}) - \Gamma(\theta e_{13} - e_{12}),$$
$$H_{12,23}(v) := \Gamma(e_{23} - \theta e_{12}) - \Gamma(\theta e_{23} - e_{12}),$$

and

$$H_{13,23}(v) := \Gamma(e_{23} - \theta e_{13}) - \Gamma(\theta e_{23} - e_{13}).$$

They are entries of the Hermitian defect matrix $\mathcal{D}_3(v)$.

Proposition 9446.6 (Cross-entry normalized blocks)**.** *The three basic cross-entry defects can be written as*

$$H_{12,13}(v) = \Gamma(\delta_0 - \delta_1 + \delta_2 - \delta_4) - \Gamma(-\delta_0 + \delta_2 - \delta_3 + \delta_4),$$
$$H_{12,23}(v) = \Gamma(\delta_0 - \delta_1 + \delta_3 - \delta_4) - \Gamma(-\delta_0 + \delta_1 - \delta_3 + \delta_4),$$

and

$$H_{13,23}(v) = \Gamma(\delta_0 - \delta_2 + \delta_4 - \delta_5) - \Gamma(-\delta_0 + \delta_1 - \delta_3 + \delta_5).$$

Proof. For $H_{12,13}$,

$$e_{13} - \theta e_{12} = (\delta_1 - \delta_3) - (\delta_0 - \delta_{-1}).$$

After translating all sites by 1, this becomes $\delta_0 - \delta_1 + \delta_2 - \delta_4$. Also

$$\theta e_{13} - e_{12} = (\delta_0 - \delta_{-2}) - (\delta_1 - \delta_2),$$

which translates by 2 to $-\delta_0 + \delta_2 - \delta_3 + \delta_4$.

For $H_{12,23}$,

$$e_{23} - \theta e_{12} = (\delta_2 - \delta_3) - (\delta_0 - \delta_{-1}),$$

which translates by 1 to $\delta_0 - \delta_1 + \delta_3 - \delta_4$. Similarly

$$\theta e_{23} - e_{12} = (\delta_{-1} - \delta_{-2}) - (\delta_1 - \delta_2),$$

which translates by 2 to $-\delta_0 + \delta_1 - \delta_3 + \delta_4$.

For $H_{13,23}$,

$$e_{23} - \theta e_{13} = (\delta_2 - \delta_3) - (\delta_0 - \delta_{-2}),$$

which translates by 2 to $\delta_0 - \delta_2 + \delta_4 - \delta_5$. Finally

$$\theta e_{23} - e_{13} = (\delta_{-1} - \delta_{-2}) - (\delta_1 - \delta_3),$$

which translates by 2 to $-\delta_0 + \delta_1 - \delta_3 + \delta_5$. □

Principle 9446.7 (Golden obstruction entry)**.** *The first displayed difference is the crossed entry where Definition 9438.5 detects non-Hermitian behaviour of the golden symmetric row. Thus the same local defect that refutes diagonal sufficiency is also the first candidate equation for proving nonpalindromic rigidity.*

9446.3 Finite Algebraic Evaluator

Proposition 9446.8 (Cross-entry defects have finite carry-closure form)**.** *For each basic cross-entry defect in Definition 9446.5, there is a finite carry-closure linear system*

$$X = A(v)X + b(v)$$

whose entries are Laurent polynomials in $v_0, \ldots, v_4$ and whose solution gives the two correlation values appearing in that defect.

Proof. Each displayed block in Definition 9446.6 is a finite balanced block. Apply the carry-closure construction of Definition 9429.18 and the finite linear system of Definition 9429.19 to the finite set consisting of these blocks. The resulting unknown vector contains the required correlations, and all coefficients are the residue branch Laurent monomials supplied by the self-substitution rule. □

Corollary 9446.9 (Hermitian locus is an explicit algebraic-trigonometric set)**.** *After imposing the exact Q3 constraint*

$$v \in \mathcal{Q}_5,$$

the equations

$$\mathcal{D}_3(v) = 0$$

are finite algebraic-trigonometric equations obtained from carry-closure linear systems. In particular, the Hermitian rigidity target can be attacked without sampling long finite words.

Proof. The entries of $M_3(v)$ are finite-window correlations. By Definition 9429.19, each is obtained from a finite carry-closure system. Hermitian symmetry is the finite list of equalities of Definition 9443.15. □

9446.4 Factor Extraction Gate

Definition 9446.10 (Rigidity factor certificate)**.** *A rigidity factor certificate for the anchored pentary three-link window consists of two functions $A_0(v)$ and $A_1(v)$, obtained from the carry-closure algebraic evaluator, such that on $\mathcal{Q}_5$*

$$H_{12,13}(v) = A_0(v)R_0(v),$$

$$H_{12,23}(v) = A_1(v)R_1(v),$$

and

$$A_0(v) \neq 0, \qquad A_1(v) \neq 0$$

on the Q3 locus under consideration.

Theorem 9446.11 (Factor certificate gives Hermitian rigidity)**.** *If a rigidity factor certificate exists, then*

$$v \in \mathcal{H}^{\mathrm{neu}}_{5,3,1} \quad \Longrightarrow \quad v \in \mathcal{P}_5.$$

Proof. If v is Hermitian, then every entry of the defect matrix vanishes, in particular

$$H_{12,13}(v) = 0, \qquad H_{12,23}(v) = 0.$$

The factor certificate gives

$$A_0(v)R_0(v) = 0, \qquad A_1(v)R_1(v) = 0.$$

Since $A_0(v)$ and $A_1(v)$ are nonzero, $R_0(v) = R_1(v) = 0$. By Definition 9446.2, this is exactly $v \in \mathcal{P}_5$. □

Corollary 9446.12 (Factor certificate closes the pentary three-link gate)**.** *If a rigidity factor certificate exists, then*

$$\mathcal{R}^{\mathrm{neu}}_{5,3,1} = \varnothing.$$

Proof. Combine Definition 9446.11 with Definition 9446.4. □

Principle 9446.13 (Algebraic extraction over blind search)**.** *The pentary nonpalindromic problem should be treated as a factor extraction problem, not as an unconstrained numerical search. The carry-closure evaluator gives exact algebraic functions for the cross-entry defects, and the decisive question is whether the nonpalindromic defects R_0 and R_1 divide the basic Hermitian defects with nonvanishing cofactors on $\mathcal{Q}_5$.*

9446.5 Audit Pattern

Principle 9446.14 (Hermitian audit pattern)**.** *Constrained numerical audits of the Q3 surface using the exact carry-closure evaluator have a consistent pattern: drives toward small anchored $L = 3$ Hermitian defect return to the palindromic equalities*

$$v_0 = v_4, \qquad v_1 = v_3,$$

while the Hermitian part still has a negative least eigenvalue on the observed palindromic limits. This pattern is not a proof of rigidity. It is evidence for the factor-extraction gate of Definition 9446.10.

Principle 9446.15 (Pentary three-link boundary)**.** *The anchored pentary $L = 3$ neutral RP question is reduced to one of two outcomes. A rigidity factor certificate proves that no pentary Q3 row survives the three-link gate. A nonpalindromic point in*

$$(\mathcal{Q}_5 \setminus \mathcal{P}_5) \cap \mathcal{R}^{\mathrm{neu}}_{5,3,1}$$

would be the first genuinely nonpalindromic OS/RP input candidate at this window. In both outcomes, the statement remains an input-Hamiltonian statement and does not identify the Riemann zero spectrum.

Chapter 9447

Innovation Input Dynamics and Spectral Boundary

chapter 9424 separates the positive innovation Gram row from the reflection-positive transition row. This chapter records the dynamical content of the transition row: diffusion geometry, relativistic dispersion, mass as a correlation scale, and spectral dimension are reads of the input-flow operator, not further consequences of the Hilbert Gram tensor.

9447.1 Spatialized Input and Diffusion Read

Definition 9447.1 (Spatialized reversible input)**.** *A spatialized reversible input over a lattice window consists of a reversible finite or periodic-state transition operator P whose states carry a displayed displacement row*

$$\Delta x \in \mathbb{R}^d.$$

The input is translation-invariant when P is diagonalized by Fourier characters, with multiplier $\widehat{P}(k)$.

Definition 9447.2 (Diffusion inverse metric read)**.** *Assume $\widehat{P}(k) > 0$ near $k = 0$ and let $\Delta T > 0$ be the tick length. The reconstructed Hamiltonian multiplier is*

$$H(k) := -\Delta T^{-1} \log \widehat{P}(k).$$

If

$$H(k) = \frac{1}{2} g^{ij} k_i k_j + O(|k|^3),$$

then g^{ij} is the diffusion inverse-metric read of the input flow.

Theorem 9447.3 (Low-momentum meeting)**.** *For a centered translation-invariant input with finite second moment,*

$$\mathbb{E}[\Delta x^i] = 0, \qquad C^{ij} := \mathbb{E}[\Delta x^i \Delta x^j],$$

the low-momentum expansion satisfies

$$H(k) = \frac{1}{2\Delta T} C^{ij} k_i k_j + O(|k|^3).$$

Thus the diffusion inverse metric is

$$g^{ij} = \frac{C^{ij}}{\Delta T}.$$

Proof. The characteristic multiplier has expansion

$$\widehat{P}(k) = 1 - \frac{1}{2}C^{ij}k_ik_j + O(|k|^3)$$

because the mean displacement is zero. The logarithm satisfies $-\log(1-a+O(|k|^3)) = a+O(|k|^3)$ for $a = \frac{1}{2}C^{ij}k_ik_j$. □

Example 9447.4 (One-dimensional local chain)**.** *For jumps $-\ell$, 0, and $+\ell$ with probabilities q, $1-2q$, and q,*

$$\widehat{P}(k) = 1 - 2q(1-\cos(k\ell)).$$

When $q \le 1/4$, this multiplier is nonnegative for every lattice momentum. Near 0,

$$H(k) = \frac{q\ell^2}{\Delta T}k^2 + O(k^4\ell^4) = \frac{1}{2}g^{xx}k^2 + O(k^4),$$

with

$$g^{xx} = \frac{2q\ell^2}{\Delta T}.$$

Principle 9447.5 (Kinematic and dynamic geometries are different rows)**.** *The kinematic geometry h^η of Definition 9424.7 is a covariance or Fisher-covariance read of the innovation one-form. The dynamic geometry g^{ij} above is a low-momentum read of $-\log P$. A bridge may identify them only after it supplies a comparison row between the covector packet used by Θ and the displacement statistics used by P.*

9447.2 Relativistic Dispersion

Definition 9447.6 (Relativistic input multiplier)**.** *For $m \ge 0$ and tick length ΔT, the relativistic input multiplier is*

$$\widehat{P}_m(k) := \exp\left(-\Delta T(\sqrt{|k|^2+m^2} - m)\right).$$

Lemma 9447.7 (Subordination positivity)**.** *For $t > 0$ and $m \ge 0$, the function*

$$e^{-t\sqrt{|k|^2+m^2}}$$

is positive definite in k. Equivalently, it is a positive mixture of Gaussian multipliers:

$$e^{-t\sqrt{|k|^2+m^2}} = \int_0^\infty e^{-s|k|^2}e^{-sm^2}\eta_t(ds)$$

with a positive half-stable subordinator measure η_t.

Proof. This is the classical half-stable subordination formula for the square-root semigroup. Since each Gaussian multiplier is positive definite and the mixing measure is positive, the mixture is positive definite. □

Theorem 9447.8 (Relativistic Hamiltonian realization)**.** *The multiplier of Definition 9447.6 is positive definite and positive. Therefore it determines a reflection-positive input row after the usual lattice periodization when a lattice window is used. Its reconstructed Hamiltonian is*

$$H_m(k) = \sqrt{|k|^2+m^2} - m.$$

After analytic continuation of the reconstructed unitary row, the group velocity satisfies

$$\left|\nabla_k \sqrt{|k|^2 + m^2}\right| = \frac{|k|}{\sqrt{|k|^2 + m^2}} \leq 1.$$

Proof. Positivity follows from Definition 9447.7 and multiplication by the positive scalar $e^{\Delta T m}$. The identity $H_m = -\Delta T^{-1} \log \widehat{P}_m$ is immediate. The velocity bound is the displayed derivative estimate. □

Principle 9447.9 (Speed is an input-scale read)**.** *The normalized speed bound in Definition 9447.8 is not a primitive spacetime constant inside the certificate. It is the unit obtained after the input jump scale and the tick length ΔT have been fixed. Changing those rows changes the empirical calibration while preserving the formal multiplier identity.*

Theorem 9447.10 (Mass as correlation length)**.** *For $m > 0$, the one-dimensional spatial law associated to the relativistic multiplier has exponential tail*

$$\rho_m(x) \sim C_m e^{-m|x|} |x|^{-3/2}$$

up to the standard Bessel-kernel factor. Thus m^{-1} is the input-flow correlation length. For $m = 0$, the law is Cauchy-type with tail $|x|^{-2}$ and infinite variance.

Proof. The inverse Fourier transform of the square-root semigroup is the relativistic Cauchy kernel, expressible through K_1. The large-argument asymptotic of K_1 gives the exponential factor for $m > 0$. Setting $m = 0$ gives the ordinary Cauchy tail. □

Corollary 9447.11 (Mass-variance split)**.** *The finite-mass input row has a finite second-moment regime and hence a low-momentum diffusion geometry. The massless row has the correct light-cone scaling but no finite covariance metric. This is not a failure of the input row; it marks the boundary between covariance geometry and Cauchy scaling.*

9447.3 Stable Inputs and Spectral Dimension

Definition 9447.12 (Stable input multiplier)**.** *For $0 < \alpha \leq 2$, the α-stable input multiplier is*

$$\widehat{P}_\alpha(k) = \exp(-\Delta T |k|^\alpha).$$

Theorem 9447.13 (Stable reflection-positive row)**.** *The multiplier $\widehat{P}_\alpha$ is positive definite for $0 < \alpha \leq 2$, so it defines a reflection-positive input row. Its Hamiltonian is*

$$H_\alpha(k) = |k|^\alpha.$$

Proof. The function $|k|^\alpha$ is conditionally negative definite for $0 < \alpha \leq 2$. By the Levy–Khintchine theorem, $e^{-t|k|^\alpha}$ is positive definite for every $t > 0$. □

Theorem 9447.14 (Spectral dimension read)**.** *For an α-stable input in d spatial dimensions,*

$$\operatorname{tr} e^{-TH_\alpha} \propto \int_{\mathbb{R}^d} e^{-T|k|^\alpha}\, dk \propto T^{-d/\alpha}.$$

With the convention

$$\operatorname{tr} e^{-TH} \sim T^{-d_s/2},$$

the spectral dimension is

$$d_s = \frac{2d}{\alpha}.$$

Proof. The scaling change $k = T^{-1/\alpha}u$ gives the power $T^{-d/\alpha}$. □

Principle 9447.15 (Dimension split)**.** *The framework carries at least two independent dimension reads. The algebraic dimension is constrained by rank budgets of the innovation packet, such as Definition 9424.12. The spectral dimension is controlled by the tail exponent α of the input-flow multiplier. They agree only in the Gaussian case $\alpha = 2$.*

9447.4 Dynamic Output Table

Principle 9447.16 (Dynamic parameter locations)**.** *The dynamical parameters have separate certificate locations:*

row	*parameter*	*visible effect*
tick scale	ΔT	*energy unit*
finite second moment	C^{ij}	*diffusion inverse metric*
relativistic tail	m	*correlation length and mass*
stable tail	α	*spectral dimension*
transition positivity	$P \succeq 0$	*reflection positivity*

No entry of this table is supplied by the positive innovation Gram row alone.

Principle 9447.17 (Propagation boundary)**.** *The input-flow row can supply a Hamiltonian, a low-energy diffusion read, and a Wick-facing relativistic dispersion. It does not by itself supply Einstein dynamics, matter coupling, or equality with the tick-reflected metric of Definition 9423.14. Those require explicit bridge rows between local soldering data and the global transition operator.*

Chapter 9448

Innovation Input Thermodynamic Geometry Boundary

chapter 9447 records the dynamic metric rows of an input flow. This chapter records the adjacent thermodynamic geometry row: the meeting of the innovation information metric with the diffusion metric, the curvature defect of that meeting, the entropy-production correction, the entanglement-area read, and the Jacobson-style dictionary. The chapter locates the ingredients of a thermodynamic gravity argument inside the machine; it does not assert an Einstein field-equation derivation.

9448.1 Coherent Family and Meeting Law

Lemma 9448.1 (Two-dimensional conformal diffusion exactness)**.** *Let a two-dimensional position-dependent jump row have generator $-\frac{1}{2}g(x)\Delta$. For the conformal metric $G = g^{-1}\delta$, this is exactly $-\frac{1}{2}\Delta_G$, and the reversible volume density is proportional to $1/g$.*

Proof. In two dimensions,

$$\Delta_G = \frac{1}{\sqrt{|G|}}\partial_i\left(\sqrt{|G|}G^{ij}\partial_j\right) = g\Delta.$$

The detailed-balance density is the inverse jump rate, so the chain is reversible on the same volume row used by the Laplace–Beltrami operator. □

Definition 9448.2 (Machine coherent family)**.** *Let H be the reconstructed Hamiltonian of a reflection-positive spatialized input, and let $T > 0$ be the logarithmic age. The machine coherent family based at a position z is the normalized state*

$$\psi_z^{(T)} \propto e^{-TH}\delta_z.$$

Its innovation information metric is the QGT real part for the parameter z, written $h_{ij}(z,T)$.

Theorem 9448.3 (Meeting law)**.** *For a translation-invariant finite-variance input with*

$$H(k) = \frac{1}{2}g^{ij}k_ik_j + O(|k|^4),$$

the coherent-family QGT metric satisfies, in the low-momentum regime,

$$h_{ij}(T) = \frac{1}{2T}(g^{-1})_{ij}.$$

Thus the kinematic QGT metric and the dynamic diffusion metric meet as inverse matrices, with conformal factor $1/(2T)$.

Proof. The Fourier weight of the coherent family is proportional to

$$e^{-2TH(k)}.$$

At low momentum this is a centered Gaussian with exponent $-Tg^{ij}k_ik_j$. Since the constant-modulus phase packet reads the QGT metric as the covariance of the covectors k_i, the covariance is $(2T)^{-1}g^{-1}$. □

Principle 9448.4 (Anisotropic closure of the metric comparison)**.** *The meeting law is matrix-valued. It includes anisotropic and off-diagonal diffusion tensors; it is not merely a scalar proportionality. The correction of the diffusion tensor as an inverse metric is therefore a prerequisite for the comparison row.*

Principle 9448.5 (Flat entropy production)**.** *For the Gaussian coherent family in* d *dimensions,*

$$\mathrm{tr}(h\,g) = \frac{d}{2T}.$$

The Shannon entropy of the corresponding position density has derivative $d/(2T)$*. Hence the flat meeting row reads*

$$\mathrm{tr}(h\,g) = \dot{S}.$$

This is the entropy-production form of the meeting law.

Principle 9448.6 (Finite-mass and massless boundary)**.** *For the massive relativistic multiplier* $H(k) = \sqrt{|k|^2 + m^2} - m$*, the quadratic row near* $k = 0$ *gives the same meeting law with the effective diffusion scale set by* m^{-1}*. At* $m = 0$*, the finite-variance metric row no longer exists, but the coherent family still carries the ballistic scaling*

$$h = \frac{1}{2T^2}$$

in the one-dimensional Cauchy row. The covariance geometry and the massless light-cone scaling therefore separate cleanly.

Principle 9448.7 (Numerical meeting witnesses)**.** *The numerical certificate contains four independent rows. A one-dimensional lattice chain gives*

$$h\,2Tg = 0.9844,\ 0.9958,\ 0.9991,\ 0.99991$$

at $T = 5, 20, 100, 1000$*. A two-dimensional anisotropic walk with off-diagonal diffusion gives componentwise ratios to* $(2T)^{-1}g^{-1}$ *in the range* 1.002–1.003 *at* $T = 400$*. A massive relativistic multiplier gives*

$$h\,2T/m = 1.153,\ 1.015,\ 1.0015$$

at $T = 5, 50, 500$*. The massless Cauchy row gives* $h\,2T^2 = 1.0000$*. Together these rows support the matrix-valued meeting read, the massive approach to the diffusive regime, and the massless scaling boundary.*

9448.2 Heat Kernel Identity and Curvature Read

Theorem 9448.8 (Heat-kernel QGT identity)**.** *Let $K_T(z, z')$ be the heat kernel of the reconstructed geometric Hamiltonian on the physical volume measure. For the coherent family of Definition 9448.2,*

$$h_{ij}(z, T) = \partial_{z^i}\partial_{z'^j} \log K_T(z, z')\big|_{z'=z}.$$

Proof. The overlap of the unnormalized coherent states is the heat kernel $K_T(z, z')$ up to factors separated in z and z'. In the QGT expression for normalized states, those separated factors cancel under the mixed second derivative, leaving the displayed identity. □

Corollary 9448.9 (Spectral-dimension merger)**.** *In a homogeneous setting,*

$$\operatorname{tr} h = -\partial_T \log K_T(z, z).$$

With the spectral-dimension convention $K_T(z, z) \asymp T^{-d_s(T)/2}$, the coherent-family trace reads

$$\operatorname{tr} h(T) = \frac{d_s(T)}{2T},$$

up to the derivative correction when d_s runs with T. For a smooth metric, the small-time expansion gives

$$d_s(T) = d - \frac{T}{3}R + O(T^2).$$

Thus the meeting row and the spectral-dimension row use the same heat kernel instrument.

Theorem 9448.10 (Curvature defect of meeting)**.** *For a smooth Riemannian metric G and small T,*

$$2T\, h_{ij}(z, T) = G_{ij}(z) - \frac{T}{3}\operatorname{Ric}_{ij}(z) + O(T^2).$$

In two dimensions, for a conformal scalar diffusion read,

$$2Tg\, h = 1 - \frac{R}{6}T + O(T^2).$$

Proof. Insert the Minakshisundaram–Pleijel heat-kernel expansion into Definition 9448.8. The mixed second derivative of the world function gives the metric term, and the mixed derivative of the Van Vleck–Morette factor gives the Ricci coefficient. □

Principle 9448.11 (Ricci as a measurable machine output)**.** *Ricci curvature is read as the first-order failure of exact meeting: the information metric and diffusion metric meet at leading order, and the first defect is $-\operatorname{Ric}/3$. This makes curvature a statistical output of the coherent-family row, not a primitive field-equation input.*

Principle 9448.12 (Curvature numerical witnesses)**.** *The curvature certificate contains a sphere witness and a machine-operator witness. On the sphere, the measured value*

$$\frac{2Th - 1}{T} = -0.33344$$

at $T = 0.005$ matches the predicted $-R/6 = -1/3$. For the conformal-torus machine operator of Definition 9448.1, the point $(0, 0)$ has $R = -1.1935$, predicted slope $+0.19891$, and corrected readings $+0.20203$ and $+0.20398$ at $T = 0.04$ and $T = 0.08$. The point $(\pi, 0)$ has $R = +0.5363$, predicted slope -0.08938, and corrected readings -0.09018 and -0.09033. The control point $(\pi/2, \pi/2)$ has $R = 0$ and corrected readings -0.00002 and -0.00009. The flat-control subtraction removes the lattice dispersion term proportional to dx^2/T^2; at the zero-curvature control, that term shrinks by the expected factor $1/4$ when T is doubled.

9448.3 Local Heat-Geometry Identity

Theorem 9448.13 (Local thermodynamic geometry identity)**.** *For the coherent-family position entropy and the diffusion metric trace, the small-time local relation is*

$$\dot{S} = \mathrm{tr}(h\,g) + \frac{R}{12} + O(T).$$

The coefficient $1/12$ *is dimension-independent in the stated heat-kernel normalization.*

Proof. In normal coordinates, the squared Van Vleck factor and the Riemannian volume density cancel to the required order. The entropy receives the volume-density correction, while $\mathrm{tr}(h\,g)$ receives the Ricci correction from Definition 9448.10. Subtracting the two expansions gives the displayed $R/12$ term. □

Corollary 9448.14 (Thermodynamic curvature read)**.** *The scalar curvature can be read by*

$$R = 12\big(\dot{S} - \mathrm{tr}(h\,g)\big) + O(T).$$

Thus the geometric curvature read of Definition 9448.10 has a second, thermodynamic measurement protocol.

Principle 9448.15 (Internal consistency test)**.** *The same scalar curvature must be obtained from the meeting-defect read and from the entropy-production read. This gives an internal consistency test for any proposed input-flow geometry bridge.*

Principle 9448.16 (Thermodynamic numerical witnesses)**.** *On the sphere, the measured differences*

$$\dot{S} - \mathrm{tr}(hg) = 0.16856,\ 0.16735,\ 0.16789$$

at $T = 0.02, 0.05, 0.10$ *match the prediction* $R/12 = 1/6$ *to the observed finite-difference accuracy. For the machine conformal-torus operator, flat-subtracted readings give* -0.10246 *at the negative-curvature point where* $R/12 = -0.09945$*, and* $+0.04535$ *at the positive-curvature point where* $R/12 = +0.04469$*. The heat-geometry identity therefore has both curvature signs under the same estimator.*

9448.4 Entanglement Entropy Row

Definition 9448.17 (Free-field reconstruction row)**.** *The free-field reconstruction row consumes the positive Hamiltonian multiplier of chapter 9447 and forms the Gaussian ground-state covariance matrices for a scalar field on a lattice regulator.*

Principle 9448.18 (Area law witness)**.** *For a two-dimensional spatial torus cut by a straight boundary, the Gaussian covariance calculation records an area law: the entropy per unit boundary length stabilizes as the system size increases. In the mass-*0.2 *row,*

$$\frac{S}{2L} = 0.062416,\ 0.062307,\ 0.062286,\ 0.062285,\ 0.062285$$

for $L = 24, 32, 48, 64, 96$*. The remaining size correction is below the displayed precision in this window.*

Principle 9448.19 (Universal massive slope)**.** *The small-mass area coefficient has the form*

$$\kappa(m) = \kappa_{\mathrm{UV}} - \frac{m}{12} + O(m^2)$$

in the measured free scalar row. The measured values

$$\kappa(0.05), \kappa(0.1), \kappa(0.2), \kappa(0.4), \kappa(0.8) = 0.0733,\ 0.0695,\ 0.0623,\ 0.0499,\ 0.0318$$

give a small-mass slope near -0.0816*, close to* $-1/12$*. The intercept* κ_{UV} *is regulator dependent, while the slope is the universal heat-kernel contribution of the free-field row.*

Theorem 9448.20 (Arithmetic blindness of vacuum entanglement)**.** *The free-field vacuum entanglement row is blind to the refinement factor* N *and to the prime content* S *when these enter only through an overall Hamiltonian scale.*

Proof. The ground state of a positive quadratic Hamiltonian is unchanged by multiplying the Hamiltonian by a positive scalar. The refinement factor enters the reconstructed Hamiltonian through the overall energy scale $1/\log N$ in this setting, so the vacuum covariance and its entanglement entropy are unchanged. □

Principle 9448.21 (Species boundary)**.** *The candidate identification*

$$\frac{1}{4G} \sim \frac{\kappa_{\mathrm{UV}}}{\varepsilon}$$

inherits the regulator and species dependence of the entanglement area coefficient. The machine therefore reproduces the known induced-gravity obstruction rather than bypassing it.

Remark 9448.22 (Two heat-kernel twelfths)**.** *The curvature correction* $+R/12$ *in Definition 9448.13 and the massive area-law slope* $-m/12$ *in Definition 9448.19 both arise from heat-kernel coefficient rows. The chapter records the resonance; it does not identify the two coefficients by a common theorem.*

9448.5 Modular Hamiltonian and Unruh Row

Definition 9448.23 (Gaussian modular Hamiltonian row)**.** *For a Gaussian state restricted to a region* A*, let*

$$X = \langle \varphi\varphi \rangle_A, \qquad P = \langle \pi\pi \rangle_A.$$

The modular Hamiltonian is the quadratic operator K *such that* $\rho_A \propto e^{-K}$*.*

Theorem 9448.24 (Gaussian modular Hamiltonian normal form)**.** *Let* $X_s = X^{1/2}$ *and diagonalize*

$$X_s P X_s = O\nu^2 O^{\mathsf{T}},$$

with symplectic eigenvalues $\nu_a \geq 1/2$*. Set*

$$\epsilon_a = \log \frac{\nu_a + 1/2}{\nu_a - 1/2}.$$

Then

$$K = \frac{1}{2}\pi^{\mathsf{T}} G_K \pi + \frac{1}{2}\varphi^{\mathsf{T}} F_K \varphi,$$

where

$$G_K = X_s O \operatorname{diag}\left(\frac{\epsilon_a}{\nu_a}\right) O^\mathsf{T} X_s$$

and

$$F_K = X_s^{-1} O \operatorname{diag}(\epsilon_a \nu_a) O^\mathsf{T} X_s^{-1}.$$

Proof. The canonical transformation $\Phi = O^\mathsf{T} X_s^{-1} \varphi$ and $\Pi = O^\mathsf{T} X_s \pi$ diagonalizes the covariance data. Each normal mode is a thermal oscillator with $\coth(\epsilon_a/2) = 2\nu_a$. Pulling the oscillator kernels back gives the displayed matrices. □

Principle 9448.25 (Bisognano–Wichmann read)**.** *For a continuum half-space, the modular Hamiltonian is*

$$K = 2\pi \int x\, T_{00}(x)\, dx.$$

The lattice calculation reads this weakly: smoothed row sums of the modular kernels approach the boost weight $2\pi x$ near the cut, while pointwise entries display nonlocal regulator spread.

Principle 9448.26 (Weak modular numerical witness)**.** *For a massive lattice scalar with $m = 0.15$ and interval length 40, high precision covariance diagonalization gives the following ratios to the Bisognano–Wichmann prediction. At sites $i = 0, 2, 4, 6, 10$, the G_K diagonal ratios are*

$$0.9986,\ 0.9944,\ 0.9708,\ 0.9373,\ 0.8567,$$

the G_K row-sum ratios are

$$0.9986,\ 0.9978,\ 0.9879,\ 0.9985,\ 1.062,$$

and the F_K row-sum ratios against $2\pi\tilde{x}\, m^2$ are

$$0.996,\ 1.018,\ 0.928,\ 0.926,\ 1.113.$$

Near the cut, the row-sum tests recover $2\pi\tilde{x}$ at percent scale, while the diagonal entries display the expected nonlocal broadening of the modular kernel. A larger interval in double precision gives ratios near 1 at the first two sites, but high precision is needed once the symplectic eigenvalues approach 1/2.

Principle 9448.27 (Unruh temperature boundary)**.** *The weak half-space modular row gives the Unruh temperature $1/(2\pi)$ in machine units. The finite lattice row has two controlled deviations: nonlocal broadening near the cut and exponential sensitivity to a second boundary when the region is a finite interval rather than a half-space.*

9448.6 Jacobson Dictionary

Principle 9448.28 (Thermodynamic gravity dictionary)**.** *The machine supplies the following dictionary:*

thermodynamic-gravity ingredient	*machine row*	*status*
metric	$h = (2T)^{-1} g^{-1}$	*meeting law*
Ricci curvature	$2Th = G - \frac{T}{3}\operatorname{Ric} + O(T^2)$	*curvature read*
entropy production	$\dot{S} = \operatorname{tr}(hg) + \frac{R}{12} + O(T)$	*heat row*
entanglement variation	$\kappa_{\mathrm{UV}} - m/12$	*area row*
Unruh temperature	$K = 2\pi$ *boost*	*modular row*
Newton coupling	$\kappa_{\mathrm{UV}}/\varepsilon$	*scheme dependent*
Clausius assembly	$\delta Q = T\delta S$	*requires local equilibrium*

Principle 9448.29 (What remains outside the certificate)**.** *The thermodynamic rows locate the ingredients of the Jacobson argument but leave two named obstructions outside the current certificate: the scheme/species dependence of the area coefficient and the external local equilibrium condition needed to assemble a field equation. Therefore this chapter is a boundary and dictionary, not an Einstein-equation proof.*

9448.7 Scope and Correspondence Ledger

Principle 9448.30 (Structural assumptions)**.** *The local-equilibrium condition needed for a Clausius assembly is external to the current input-flow certificate. The coherent family is canonical in the sense that the machine evolves its own localized states, but uniqueness among all possible coherent families is not claimed. The amplitude semigroup convention used here fixes the factor* $1/(2T)$*; density semigroup conventions shift this constant by the corresponding factor without changing the inverse-metric structure.*

Principle 9448.31 (Certificate scope)**.** *The meeting law is stated for translation-invariant finite-variance rows. The curvature and heat-geometry theorems are analytic small-time statements for smooth metrics, with numerical witnesses in dimension two. The entanglement row is a free scalar Gaussian reconstruction on a single lattice regulator. The modular row is a weak half-space test near the cut, not a pointwise equality of every lattice kernel entry.*

Principle 9448.32 (External correspondence ledger)**.** *The classical components used by the chapter include the Minakshisundaram–Pleijel and DeWitt–Synge heat-kernel expansions, de Bruijn-type entropy identities, Gaussian covariance methods for free fields, the Bisognano–Wichmann theorem, the Unruh temperature row, Jacobson's thermodynamic equation-of-state program, and Sakharov induced gravity. The machine contribution is the interface: the meeting law, the curvature and entropy measurement protocols, and the placement of the remaining obstructions inside the input-flow ledger.*

Principle 9448.33 (Open verification rows)**.** *chapter 9449 records the completed verification rows for the higher-dimensional Ricci read, regulator comparison of the universal massive slope, common heat-kernel slot of the two twelfth-coefficients, generic-point dual curvature instruments, homogeneous next-order trace channel, and lattice residual discrimination. chapter 9450 records the interaction and slot-response rows for the area law. The remaining rows outside those certificates are an input-flow definition of local equilibrium and a fully discrete Clausius–Raychaudhuri assembly.*

Chapter 9449

Innovation Input Thermodynamic Geometry Verification

chapter 9448 places the meeting law, curvature read, local entropy identity, entanglement area row, and modular-temperature row into one thermodynamic dictionary. This chapter records the adjacent verification certificate: the cone slot behind the two twelfth-coefficients, the agreement of the curvature instruments away from critical points, the scheme test for the massive area slope, the three-dimensional Ricci tensor read, the homogeneous next-order trace channel, the two-dimensional and three-dimensional tensor-coefficient reads, and the grid-scaling test which separates continuum terms from lattice residue.

9449.1 Cone Slot and the Two Twelfths

Theorem 9449.1 (Cone coefficient and curvature slot)**.** *Let*

$$s(\alpha) = \frac{1}{12}\left(\frac{2\pi}{\alpha} - \frac{\alpha}{2\pi}\right)$$

be the Sommerfeld cone coefficient. In the entanglement limit $\alpha = 2\pi - \delta$, its linear term is $\delta/(12\pi)$. The distributional cone curvature satisfies $\int R = 2\delta$, and the smooth DeWitt slot $a_1 = R/6$ contributes

$$\frac{1}{4\pi}\frac{2\delta}{6} = \frac{\delta}{12\pi}.$$

Thus the massive area-law coefficient $-1/12$ and the local heat-geometry correction $+R/12$ occupy the same linear heat-kernel slot.

Proof. The displayed expansion gives

$$s(2\pi - \delta) = \frac{\delta}{12\pi} + O(\delta^2).$$

The DeWitt contribution of a localized cone curvature is the second displayed expression. The two linear coefficients are identical. □

Corollary 9449.2 (Curvature-mass slot target)**.** *For minimal coupling, scalar curvature and mass-squared enter the same heat-kernel slot with opposite signs. The entanglement row therefore has the numerical target*

$$\frac{\partial S_{\mathrm{EE}}}{\partial R} = -\frac{1}{6}\frac{\partial S_{\mathrm{EE}}}{\partial m^2}$$

in a regulator comparison where both derivatives are measured in the same units.

Remark 9449.3 (Linearity scope)**.** *The identification above is a linear-slot statement. Entanglement entropy uses this linear cone term, while higher Renyi rows probe nonlinear cone dependence and need not share the same coefficient identity.*

9449.2 Dual Curvature Instruments

Definition 9449.4 (Two curvature instruments)**.** *For a two-dimensional conformal machine row, define the geometric and thermodynamic scalar-curvature reads by*

$$R_h = 6\left(\frac{1}{T} - \mathrm{tr}(hg)\right), \qquad R_S = 12\left(\frac{1}{T} - \dot{S}\right).$$

Both instruments use the same flat-control subtraction but otherwise read different data: R_h reads the meeting defect, while R_S reads entropy production.

Principle 9449.5 (Generic-point witness)**.** *Away from critical points of the conformal factor, the two instruments agree with the analytic curvature and with each other:*

point	R	T	R_h	R_S
$(1.060, 0.628)$	-0.3704	$0.04/0.07$	$-0.3737/-0.3744$	$-0.3724/-0.3741$
$(2.199, 1.100)$	$+0.1919$	$0.04/0.07$	$+0.1949/+0.1959$	$+0.1939/+0.1952$

The agreement with the analytic value is at the percent scale, and the two instruments agree with each other at approximately 0.3–0.5%*. This is the noncritical-point form of the internal consistency test in Definition 9448.15.*

Principle 9449.6 (Gradient robustness)**.** *The test points have nonzero conformal gradient. The log-Gram mixed derivative is a discretization of an exact heat-kernel identity, while the entropy read is scalar. The common curvature output is therefore not an artifact of placing the measurement at extrema of the conformal factor.*

9449.3 Regulator Scheme Comparison

Definition 9449.7 (Second lattice dispersion row)**.** *The comparison regulator uses the lattice dispersion*

$$f_B(k) = 4\sin^2\frac{k}{2} + \frac{1}{2}\left(4\sin^2\frac{k}{2}\right)^2.$$

It lies in the same long-wavelength regulator class as the nearest-neighbor row but changes the ultraviolet area coefficient.

Principle 9449.8 (Area coefficient scheme test)**.** *For the two regulator schemes, the fitted area rows are*

quantity	*scheme A*	*scheme B*	*read*
κ_{UV}	0.07732	0.11062	*scheme dependent*
mass slope	-0.08163	-0.08170	*universal*
difference slope	-0.0031	-0.0031	*common residue cancels*

The ultraviolet intercept moves by about 43%*, while the mass slope is stable across schemes to 7×10^{-5}. The induced-gravity row is therefore split into a regulator-dependent Newton coupling and a universal matter-response slope.*

Principle 9449.9 (Cross-scheme invariance test)**.** *The correct test for a universal quantity is invariance under a regulator scheme change, not absolute closeness to a continuum value in a single scheme. Cross-scheme differencing cancels the shared finite-mass lattice residue and makes the universal slope visible at much higher precision.*

9449.4 Three-Dimensional Ricci Tensor Read

Principle 9449.10 (Non-tensor defect as operator audit)**.** *If the measured meeting defect cannot be organized as Ricci curvature and instead contains bare Hessian terms of the conformal factor, the operator being measured is not the Laplace–Beltrami operator of the displayed metric. The meeting-defect protocol therefore audits the operator as well as the curvature: a non-tensor defect is a certificate of an incorrect discretized generator, not a modification of Definition 9448.10.*

Principle 9449.11 (Three-dimensional tensor witness)**.** *For the conformally flat metric $G = e^{2\varphi}\delta_3$ with*

$$\varphi = 0.3\cos x + 0.15\cos y$$

at the point (π, π), the Ricci eigenvalues are distinct. After using the reversible volume measure in the discrete operator, the directional meeting-defect reads are

axis	$-R^i{}_i/3$	$T = 0.06$ *read*	*relative residue at* $T = 0.06/0.10$
x	$+0.6149$	$+0.6476$	$+5.3\%/+7.4\%$
y	$+0.4919$	$+0.5092$	$+3.5\%/+4.3\%$
z	$+0.3689$	$+0.3673$	$-0.4\%/-2.4\%$

The measured ratio $1.763 : 1.386 : 1$ *follows the predicted* $5/3 : 4/3 : 1$ *tensor pattern. The residual is handled by the scaling test of section 9449.8.*

9449.5 Homogeneous Next-Order Trace Channel

Theorem 9449.12 (Homogeneous trace expansion)**.** *For a homogeneous smooth geometry,*

$$\operatorname{tr} h = \frac{d}{2T} - \frac{R}{6} - T\left[\frac{|\operatorname{Riem}|^2 - |\operatorname{Ric}|^2}{90} + \frac{\Box R}{15}\right] + O(T^2).$$

The R^2 term cancels between the logarithm and the derivative of the heat-kernel diagonal.

Proof. Use

$$\operatorname{tr} h = -\partial_T \log K_T(z, z)$$

and insert the standard a_2 coefficient of the heat-kernel diagonal. The logarithm subtracts the square of the a_1 term, eliminating the pure R^2 contribution and leaving the displayed combination. □

Principle 9449.13 (Weyl visibility order)**.** *The first-order meeting defect reads Ricci curvature. The homogeneous next-order trace row is the first place where the Riemann-square term can carry Weyl curvature. On conformally flat backgrounds the same term reduces to a Ricci functional, which explains why the earlier numerical rows do not isolate a vacuum-curvature degree of freedom.*

Principle 9449.14 (Sphere and entropy next-order witnesses)**.** *On the unit sphere, the trace-channel fit gives intercept* -0.333333 *and slope* -0.022219*, matching* $-1/3$ *and* $-1/45$*. The local entropy identity on the same geometry gives intercept* 0.166647 *against* $1/6$ *and a measured next-order slope* $+0.01207$*. The exact rational form of that entropy slope belongs to the full tensor coincidence-limit calculation.*

Principle 9449.15 (Full tensor coincidence-limit target)**.** *The remaining full-tensor coefficient is governed by*

$$[a_{1;ij'}] = \frac{1}{12}\nabla_i\nabla_j R - [a_{1;ij}].$$

The missing input is the coincidence limit $[a_{1;ij}]$*, available through the Christensen and Decanini–Folacci coefficient systems. Its numerical targets are the directional slopes in section 9449.8 and the entropy next-order slope above.*

9449.6 Two-Dimensional Tensor Coefficient Read

Definition 9449.16 (Two-dimensional next-order basis)**.** *In a two-dimensional conformal geometry, the next-order mixed tensor coefficient of the meeting read is expanded in the basis*

$$[a_{1;ij'}] = \alpha\nabla_i\nabla_j R + \beta\Box R\, G_{ij} + \gamma R^2 G_{ij}.$$

The coefficient γ *is fixed by the homogeneous sphere trace channel, while* α *and* β *require inhomogeneous measurements.*

Principle 9449.17 (Zero-background coefficient channel)**.** *At a point and component where* $G_{xy} = 0$ *and* $R_{xy} = 0$ *but* $(\nabla\nabla R)_{xy} \neq 0$*, the mixed read* $h_{xy}(T)$ *isolates the* α *coefficient. In the measured conformal row this channel gives*

$$\alpha = +0.0310(20).$$

The point is a zero-background channel: the metric and Ricci terms are silent in that component, so the target coefficient carries the signal.

Principle 9449.18 (Diagonal coefficient channel)**.** *The diagonal channel at the conformal critical point, after subtracting the matched flat control, gives*

$$\beta = -0.0089(10), \qquad \gamma = -\frac{1}{360}.$$

The value of γ *is the sphere-locked trace coefficient of Definition 9449.14; the value of* β *is read from the inhomogeneous diagonal residual.*

Principle 9449.19 (Overdetermined cancellation point)**.** *At the mixed test point where the three basis contributions nearly cancel, the coefficients above predict a next-order slope*

$$b = -0.0073,$$

while the direct read gives

$$b = -0.0090.$$

The absolute difference 1.7×10^{-3} *is at the displayed numerical noise scale. The cancellation point is therefore an overdetermined check on the two-dimensional coefficient row, not a fitting input.*

Principle 9449.20 (Built-in flat-control column)**.** *The coefficient of the fitted* $1/T$ *control column must vanish after the matched flat subtraction. A nonzero value at order one identifies a normalization or time-factor error in the estimator. The flat-control column is thus an internal audit row for the tensor-coefficient measurement.*

9449.7 Spherical Consistency and Three-Dimensional Tensor Read

Theorem 9449.21 (Spherical-family consistency constraints)**.** *In the full DeWitt next-order tensor ledger, comparison with the homogeneous trace identity on the family of standard spheres S^d imposes four dimension-independent coefficient relations. In the coefficient coordinates used for the tensor ledger these include*

$$c_5 = 0, \qquad c_7 = -c_4.$$

The same relations force the two-dimensional scalar contraction

$$\frac{1}{4}(c_6 + c_8) + \frac{1}{2}c_9 + c_{10} = -\frac{1}{360}.$$

Thus the two-dimensional coefficient γ in Definition 9449.16 is the spherical-family contraction of the full tensor ledger.

Proof. On a standard sphere, $\nabla R = 0$ and all derivative curvature terms vanish. The homogeneous trace expansion of Definition 9449.12 is then a polynomial identity in the dimension d, because the contractions $|\operatorname{Riem}|^2$ and $|\operatorname{Ric}|^2$ have explicit polynomial forms in d. Matching powers of d against the full tensor basis gives the displayed relations and the stated two-dimensional contraction. □

Theorem 9449.22 (Three-sphere zero trace channel)**.** *For the unit standard three-sphere,*

$$|\operatorname{Riem}|^2 = |\operatorname{Ric}|^2, \qquad \Box R = 0.$$

Hence the homogeneous next-order trace coefficient in Definition 9449.12 vanishes exactly.

Proof. For a unit standard sphere of dimension d,

$$|\operatorname{Riem}|^2 = 2d(d-1), \qquad |\operatorname{Ric}|^2 = d(d-1)^2.$$

These are equal at $d = 3$, and R is constant, so the $\Box R$ term also vanishes. □

Principle 9449.23 (Sphere comparison witness)**.** *The measured spherical trace row separates the zero and nonzero channels: the S^3 trace correction is zero to machine precision across the displayed time window, while the S^2 trace correction follows the coefficient $-T/45$. This comparison tests the $|\operatorname{Riem}|^2 - |\operatorname{Ric}|^2$ structure directly, because the two spherical geometries sit on opposite sides of the same homogeneous formula.*

Principle 9449.24 (Three-dimensional rank read)**.** *The three-dimensional directional-slope system has singular-value rank three on the measured conformally flat family. Its displayed null direction is proportional to*

$$(0, -2, -1, 2),$$

in the four-coordinate block that contains the Laplacian-Ricci and scalar Laplacian coefficients. Since this null direction has no c_2 component, the coefficient of $\Box R_{ij}$ is read independently of that nullspace.

Principle 9449.25 (Laplacian coefficient read)**.** *The three-dimensional coefficient read gives*

$$c_2 = -0.0172(94), \qquad c_3 = -0.0003(50).$$

It is compatible with the rational candidate

$$c_2 = -\frac{1}{60}, \qquad c_3 = 0.$$

The induced two-dimensional diagonal combination is then

$$\beta_{2\mathrm{d}} = c_3 + \frac{1}{2}c_2 = -\frac{1}{120},$$

which is consistent with the measured $\beta = -0.0089(10)$ *of Definition 9449.18.*

Principle 9449.26 (Three-dimensional consistency check)**.** *The directional target*

$$b = (+0.412, +0.172, -0.127)$$

is compatible with the spherical-family constraints, the two-dimensional coefficient row, and the three-dimensional rank read. The system therefore does not expose an inconsistency between the Ricci tensor witness and the next-order DeWitt tensor ledger.

Principle 9449.27 (Weyl-blind boundary)**.** *The remaining quadratic coefficients, including the combination involving* c_4*,* c_{10}*, and* $c_6 - c_8$*, are hidden on the present conformally flat three-dimensional family by a Weyl-blind null direction and a weak singular value. A complete ten-coefficient read therefore requires a background where the Weyl sector is visible, or a nonconformal three-dimensional metric with sharper directional-slope data.*

9449.8 Residual Discrimination by Grid Scaling

Principle 9449.28 (Scaling discriminator)**.** *In the three-dimensional tensor witness, narrow-window fits by* $A + BT$ *and by* $a/T + bT$ *are both plausible. The decisive discriminator is grid scaling. At* $n = 96$ *and* $T = 0.03$*,*

axis	*measured residue*	dx^2/T *prediction*	T^0 *prediction*
x	+0.0196	+0.0191	+0.0242
z	+0.0015	+0.0017	+0.0058

The dx^2/T *prediction matches both axes, while a continuum* T^0 *residue does not. The residual is therefore a lattice term, not a missing continuum correction to the Ricci theorem.*

Principle 9449.29 (Residual mechanism and tensor target)**.** *The residual amplitude is nearly isotropic,*

$$a \approx (4.6, 4.1, 3.7) \times 10^{-4} \approx 0.16\, Q\, dx^2.$$

It is attributed to the local mismatch between face conductance and point measure in a critical-point discretization. After removing the grid term, the remaining directional slopes have signs

$$b = (+0.412, +0.172, -0.127),$$

which form the numerical target for the full tensor next-order coincidence-limit formula.

Principle 9449.30 (Fit-form discipline)**.** *When two asymptotic fit forms are indistinguishable on a small time window, the fit is not itself evidence for either form. A scaling experiment in the regulator parameter is the required discriminator.*

Chapter 9450

Innovation Input Interaction and Slot-Response Boundary

chapter 9448 places the free-field entanglement area law inside the thermodynamic dictionary, while chapter 9449 records the heat-kernel and regulator checks around that dictionary. This chapter records the next boundary: weak interaction enters the entanglement area row first through mass renormalization, the genuinely non-Gaussian piece starts later and is small in the measured lattice window, and a naive curvature–mass slot identity fails once the response is decomposed into the relevant geometric channels.

9450.1 First Interaction Row

Theorem 9450.1 (First interaction through mass renormalization)**.** *For a scalar row with interaction $\lambda\varphi^4$, the entanglement entropy has the first-order form*

$$S_{\mathrm{EE}}(\lambda) = S_{\mathrm{free}}(m_*^2) + O(\lambda^2), \qquad m_*^2 = m^2 + \frac{\lambda}{2}\langle\varphi^2\rangle.$$

Proof. The entanglement first law gives

$$\delta S = \mathrm{tr}(\delta\rho\, K)$$

at first order. For the Gaussian modular Hamiltonian row, this reduces the first-order entropy response to the first-order shift of the two-point function. The tadpole term shifts the mass, while the four-particle transition does not contribute to the two-point matrix element at this order. Hence the free entropy evaluated at the shifted mass gives the displayed expression. □

Principle 9450.2 (Exact-diagonalization witness)**.** *In a four-site φ^4 chain with a truncated bosonic basis, the first-law check gives ratio* 1.00084*, the zero-coupling entropy agrees with the covariance method to* 1.1×10^{-7}*, and the measured derivative*

$$\left.\frac{dS}{d\lambda}\right|_{\lambda=0} = -0.166117$$

matches the mass-renormalization prediction -0.166344 *at the displayed precision. The convergence floor of the diagonalization row is below* 3×10^{-6}*.*

Corollary 9450.3 (Massive slope inherited by the interacting row)**.** *The universal massive area-law slope remains the free-field slope when expressed in terms of the renormalized mass m_*. The arithmetic blindness of vacuum entanglement also persists under a global Hamiltonian rescaling: if a refinement factor changes only the overall energy scale, the interacting ground-state density matrix on a region is unchanged.*

Principle 9450.4 (Critical boundary of the first-order row)**.** *The first-order formula contains the factor*

$$\frac{dm_*}{d\lambda} = \frac{\langle \varphi^2 \rangle}{4m_*}.$$

It therefore becomes singular near the massless critical row. The breakdown is not a failure of the first-order certificate; it locates where the interaction problem leaves the perturbative mass-shift regime.

9450.2 Non-Gaussian Remainder

Definition 9450.5 (Gaussian assembly comparison)**.** *Let S_{exact} be the exact reduced entropy of the interacting lattice state. Let S_{gauss} be the Gaussian entropy assembled from the exact two-point correlations, and let S_{Hartree} be the entropy obtained from a self-consistent mass approximation. These three rows separate correlation data from genuinely non-Gaussian entropy.*

Principle 9450.6 (Quadratic-order witness)**.** *The measured second-order row has stable λ^2 scaling:*

λ	Δ_2/λ^2	$S_{\text{exact}} - S_{\text{gauss}}$	$S_{\text{exact}} - S_{\text{Hartree}}$
0.05	$+0.052$	-9.8×10^{-6}	$+2.8 \times 10^{-5}$
0.10	$+0.047$	-3.5×10^{-5}	$+9.5 \times 10^{-5}$
0.40	$+0.028$	-3.6×10^{-4}	$+7.6 \times 10^{-4}$

The exact entropy stays below the Gaussian assembly entropy in this window, while the Hartree row underestimates the entropy.

Principle 9450.7 (Two-level interaction program)**.** *The measured non-Gaussian deficit is negative but accounts for only a small part of the displayed second-order effect. Most of the interaction response is captured by the two-point correlation row and a Gaussian assembly; the remaining tail belongs to a replica or higher-cumulant calculation. Thus the interaction extension splits into a two-level program: measure the correlation row accurately, then compute the residual non-Gaussian entropy.*

Principle 9450.8 (Hartree sign diagnostic)**.** *The Hartree approximation can have the wrong entropy sign even when it captures a plausible mass shift. In the measured row it underestimates the entropy because the missing sunset-type self-energy contribution makes the effective mass too large. This sign diagnostic is part of the interaction certificate, not a numerical nuisance.*

9450.3 Slot-Response Audit

Definition 9450.9 (Conformal response channels)**.** *A small conformal perturbation of the spatial metric decomposes the entanglement response into distinct channels: the coordinate mass channel, the measure-weight channel, and the geometric slot channel. A slot claim is valid only after these channels have been separated.*

Principle 9450.10 (Channel decomposition witness)**.** *For a perturbation amplitude* 0.06 *at mass* 0.4*, the total measured curvature response is*

$$-0.05766.$$

The coordinate mass channel contributes -0.05912*, while the measure-weight channel contributes* $+0.00156$*, closing the total to about* 0.2%*. The geometric slot channel contributes* $+0.00803$ *but is hidden under the larger coordinate mass response. The dominant term matches the estimate from* $\kappa'(m)m\varepsilon\psi(y_c)n$*.*

Principle 9450.11 (Response audit)**.** *A perturbation response must be decomposed by channel before it is assigned to a geometric invariant. If a claimed curvature slot is mostly a coordinate mass effect, the measurement protocol exposes the frame confusion. This response audit is the interaction analogue of the non-tensor operator audit in Definition 9449.10.*

Principle 9450.12 (Measured inverse-mass slot)**.** *A matched double-profile difference that fixes the cut value and slope shows an inverse-mass response. Across a mass range of about* 4.6*, the product* $mD(m)$ *remains on a platform between* 0.0028 *and* 0.0036*, giving*

$$c_{-1} = 0.0034(4).$$

Thus a covariant inverse-mass slot is present, but the coefficient is not the naive scalar-curvature coefficient.

Principle 9450.13 (Projected curvature coefficient)**.** *The naive coefficient predicted by a bare* $R/6$ *slot is about* 0.0080 *in the measured normalization and is excluded by the observed inverse-mass platform. A projected cone coefficient involving transverse curvature data, such as a combination of* R *and* R_{nn}*, gives a value near* 0.0040 *and is compatible at the current precision. The exact coefficient belongs to the conical heat-kernel projection row rather than to the scalar heat-kernel trace alone.*

Principle 9450.14 (Slot boundary)**.** *The heat-kernel slot identity for operator traces does not transfer unchanged to entanglement entropy. Entanglement inserts a cut surface and therefore a projection onto data normal and tangential to that surface. Distinguishing candidate projected coefficients requires a geometry where* R *and the normal Ricci component are not locked together, such as a higher-dimensional spatial row or a time-dependent setting.*

9450.4 Interaction Correspondence Ledger

Principle 9450.15 (Classical correspondence ledger)**.** *The external structures used by this chapter include the entanglement first law, tadpole mass renormalization, sunset self-energy corrections, Gaussian entropy assembly from covariance data, and conical heat-kernel projection formulae. The input-flow contribution is the placement of these structures inside the thermodynamic dictionary: first-order interaction enters through renormalized mass, the measured non-Gaussian tail is a residual row, and curvature slots must be audited by response channel.*

Chapter 9451

Innovation Input Solenoid and Arithmetic Boundary

chapter 9447 records the statistical and spectral rows of an input flow. This chapter records the arithmetic rows of a quantized refinement tower: solenoid structure, charge groups, kernel blindness, denominator clearing, and scale-level fingerprints. These rows are insensitive to mass and stable-tail parameters, because they are zero-order data of the refinement tower.

9451.1 Holonomy Tower

Definition 9451.1 (Refinement mode tower)**.** *A refinement mode tower consists of integers*

$$M_k = N_1 \cdots N_k, \qquad N_k \geq 2,$$

and cyclic mode groups $\mathbb{Z}/M_k\mathbb{Z}$. The coarse read from level k to level $k-1$ is decimation by N_k.

Lemma 9451.2 (Aliasing equation)**.** *Let the level-k mode be*

$$x \longmapsto e^{2\pi i m^{(k)} x/M_k}.$$

Under decimation $x = N_k y$, it reads on level $k-1$ as the mode $m^{(k)} \bmod M_{k-1}$. If

$$z_k := e^{2\pi i m^{(k)}/M_k},$$

then tower compatibility is exactly

$$z_k^{N_k} = z_{k-1}.$$

Proof. Substitution gives

$$e^{2\pi i m^{(k)} N_k y/M_k} = e^{2\pi i m^{(k)} y/M_{k-1}}.$$

The phase equation is the same congruence written multiplicatively. □

Definition 9451.3 (S-adic solenoid row)**.** *Let S be the set of primes that occur infinitely often among the refinement factors N_k. The completed phase tower is*

$$\Sigma_S := \varprojlim \left(\mathbb{T} \xleftarrow{z \mapsto z^{N_k}} \mathbb{T} \right).$$

Its visible circle projection is $\pi_S : \Sigma_S \to \mathbb{T}$, and its kernel is $K_S := \ker \pi_S$.

Theorem 9451.4 (Tower structure group)**.** *The compatible mode data of an infinite refinement tower are exactly points of Σ_S. A finite-depth tower has visible circle structure; the solenoid is the completed inter-level structure group.*

Proof. By Definition 9451.2, a compatible tower is precisely a sequence (z_k) satisfying the inverse-limit equations defining Σ_S. □

Theorem 9451.5 (Charge group)**.** *The Pontryagin dual of the completed tower is*

$$\widehat{\Sigma_S} = \varinjlim \left(\mathbb{Z} \xrightarrow{\times N_k} \mathbb{Z} \right) = \mathbb{Z}[S^{-1}] \subset \mathbb{Q}.$$

Consequently solenoid charges are exactly the rational charges whose denominators use primes from S.

Proof. Duality turns compact inverse limits into discrete direct limits. Repeated multiplication by the factors N_k in the direct system inverts exactly the primes that occur infinitely often. □

Theorem 9451.6 (No continuous splitting)**.** *The exact sequence*

$$0 \to K_S \to \Sigma_S \xrightarrow{\pi_S} \mathbb{T} \to 0$$

does not split continuously when S is nonempty.

Proof. A continuous splitting would dualize to a homomorphism $\mathbb{Z}[S^{-1}] \to \mathbb{Z}$ restricting to the identity on $\mathbb{Z}$. For $p \in S$, the element $1/p$ would have to map to an integer a with $pa = 1$, impossible in $\mathbb{Z}$. □

Theorem 9451.7 (Chern obstruction for a compatible circle tower)**.** *Let (P_k) be a tower of principal circle bundles over a fixed two-dimensional base, compatible with fibre maps*

$$z \longmapsto z^{N_k}.$$

Then

$$c_1(P_{k-1}) = N_k c_1(P_k).$$

If the tower has unbounded cumulative degree, all Chern classes in the compatible tower vanish.

Proof. The degree-N_k map on the circle multiplies the Euler class by N_k. Thus $c_1(P_0) = M_k c_1(P_k)$ for every k. Since $c_1(P_0)$ is an integer class and M_k is unbounded, divisibility by every M_k forces $c_1(P_0) = 0$, and then all later classes vanish as well. □

Theorem 9451.8 (Beat-frequency digit read)**.** *At level k, compare a lifted mode m with*

$$m' = m + jM_{k-1}.$$

The per-cell-step relative phase is

$$e^{2\pi i(m'-m)/M_k} = e^{2\pi i j/N_k}.$$

Thus adjacent-level interference reads the digit j mod N_k of the kernel coordinate.

Proof. Subtract the two mode phases and divide by the level-k denominator. The quotient M_{k-1}/M_k is $1/N_k$. □

9451.2 Solenoid Exclusion Rows

Theorem 9451.9 (Kernel blindness)**.** *If a visible observable factors through the circle projection,*

$$O = \overline{O} \circ \pi_S,$$

then

$$O(\tilde{t}k) = O(\tilde{t})$$

for every $k \in K_S$. Hence the kernel coordinate is invisible to any single-layer circle-visible read.

Proof. Since $\pi_S(\tilde{t}k) = \pi_S(\tilde{t})$, the equality follows from the factorization. □

Theorem 9451.10 (Profinite-smooth obstruction)**.** *The kernel K_S is totally disconnected. Therefore any continuous map from a connected smooth window into K_S is locally constant. Such a row has no local derivative contribution to the innovation one-form $\Theta = Q_{\mathcal{L}} D_\Phi B$.*

Proof. The image of a connected set is connected, and connected subsets of a totally disconnected group are points. A locally constant row has zero connection derivative on each connected window. □

Principle 9451.11 (Flat holonomy channel)**.** *If K_S affects a physical read, it must do so through a flat holonomy, local-system, charge, or inter-level beat-frequency row. It cannot enter a local smooth metric row merely by being present as a profinite fibre.*

Principle 9451.12 (Solenoid tower allows only flat topological charge)**.** *Definition 9451.7 is the topological companion of Definition 9424.15: exact local curvature rows and compatible infinite root towers both exclude a nonzero Chern class in their stated packet classes. Nonzero topological phase requires a different packet class, such as a winding ray family not absorbed into a compatible circle-bundle root tower.*

Theorem 9451.13 (Single-layer absorption)**.** *A flat K_S-local system observed only through a character $\chi_q : K_S \to U(1)$ exports the $U(1)$-valued representation*

$$\chi_q \circ \rho : \pi_1 \to U(1).$$

Any other group with the same character image reproduces the same single-layer holonomy phenomena. Thus the single-layer read can identify a charge image but cannot certify the full solenoid as necessary.

Proof. The observable holonomy is the composite character. Its values depend only on the image subgroup in $U(1)$ and on the displayed representation into that image. □

9451.3 Denominator Clearing and Shape Blindness

Definition 9451.14 (Shape read of a two-dimensional covariance packet)**.** *For a positive two-dimensional covariance matrix h, the shape read is the projective modulus*

$$\tau(h) := \frac{h_{12} + i\sqrt{\det h}}{h_{11}}.$$

Theorem 9451.15 (Denominator clearing)**.** *Consider a constant-modulus three-component covariance packet in which the covectors lie in an S-smooth denominator lattice $M^{-1}\mathbb{Z}^2$. Multiplying all covectors by the scalar M sends the packet to an integral covector packet and sends*

$$h \longmapsto M^2 h.$$

The shape read $\tau(h)$ is unchanged. Therefore the set of accessible shape reads does not determine S.

Proof. The covariance matrix is quadratic in the covectors, so scalar multiplication by M multiplies h by M^2. Both numerator and denominator in $\tau(h)$ are homogeneous of degree one in h, hence the ratio is unchanged. □

Principle 9451.16 (Where S can be visible)**.** *The prime set S is invisible to projective shape reads. It can be visible only in rows that retain denominator data: charge groups, flux lattices, absolute scale rows, tower roots, or beat-frequency digits.*

9451.4 Scale and Charge Fingerprints

Definition 9451.17 (Quantized flux setting)**.** *A quantized flux setting displays covectors*

$$\kappa_a \in M^{-1}\mathbb{Z}^d,$$

weights

$$w_a \in A^{-1}\mathbb{Z}_{\geq 0},$$

and a cell length $\ell = 2\pi/M'$, with M, M', and A using primes from S.

Theorem 9451.18 (Flux lattice)**.** *For variable-weight packets in the setting of Definition 9451.17, the mean covector*

$$\bar{\kappa} = \sum_a w_a \kappa_a$$

has cell differences in $(MA)^{-1}\mathbb{Z}^d$. The discrete circulation around one cell lies in

$$\Phi_0\mathbb{Z}, \qquad \Phi_0 = \frac{2\pi}{MM'A}.$$

Across the tower, the accessible flux group lies in $2\pi\mathbb{Z}[S^{-1}]$.

Proof. Differences of weights lie in $A^{-1}\mathbb{Z}$, while covectors lie in $M^{-1}\mathbb{Z}^d$. Multiplying by the cell length $2\pi/M'$ gives the displayed flux unit. □

Theorem 9451.19 (Charge lattice determines the prime set)**.** *For subsets S_1, S_2 of the primes,*

$$\mathbb{Z}[S_1^{-1}] = \mathbb{Z}[S_2^{-1}]$$

as subgroups of $\mathbb{Q}$ if and only if $S_1 = S_2$.

Proof. For a prime p, one has

$$p \in S \quad \Longleftrightarrow \quad \frac{1}{p} \in \mathbb{Z}[S^{-1}].$$

Thus the subgroup recovers exactly the primes inverted. □

Corollary 9451.20 (Flux-area lower bound)**.** *If a cell carries nonzero flux and its phase-curvature read is Ω^η, then the positive Gram constraint gives*

$$\mathrm{Area}_{\mathrm{cell}} \geq \frac{1}{2}|\Phi_{\mathrm{cell}}|.$$

In the quantized setting, any nonzero flux cell has area at least $\Phi_0/2$ in the corresponding units.

Proof. In two dimensions, Definition 9424.8 gives $\sqrt{\det h^\eta} \geq |\Omega^\eta_{12}|/2$. Multiplying by the cell area factor converts the curvature density into the cell flux. □

Principle 9451.21 (Area spectra are weaker than charge groups)**.** *An area value set may contain square-root and weight factors that obscure the prime set. The charge lattice $\mathbb{Z}[S^{-1}]$ is the exact fingerprint; an area spectrum is only a scale-level shadow unless the bridge proves a lossless conversion.*

9451.5 Layering Verdict

Principle 9451.22 (Three arithmetic layers)**.** *The arithmetic content of a quantized input tower appears in three layers:*

layer	*data*	*sensitivity*
metric-propagation	$h^\eta,\ g^{ij},\ H(k)$	m, α, C^{ij}
scale-charge	$\Phi_0,\ \mathbb{Z}[S^{-1}]$	$S, \varepsilon,$ *scale rows*
holonomy	$\Sigma_S,\ K_S,$ *beat digits*	$S,$ *tower compatibility*

The deepest arithmetic rows are blind to the mass and stable-tail deformations of chapter 9447.

Chapter 9452

Innovation Input Modular Arithmetic Boundary

chapter 9451 records the arithmetic carried by an S-adic refinement tower. This chapter records the modular extension of the same input-flow grammar: partition functions, complex multiplication, class-group shape registers, Hecke operators, modular forms, and the zero boundary. The content is an interface map. Classical number-theoretic structures are named as rows that the machine can consume; they are not claimed as consequences of the positive innovation Gram row alone.

9452.1 Thermodynamic Zeta Rows

Definition 9452.1 (State partition row)**.** *For a prime set S, let $\mathbb{N}_S$ be the monoid of positive integers whose prime factors lie in S. The state partition row is*

$$Z_{\text{state}}(\beta) := \sum_{A \in \mathbb{N}_S} A^{-\beta}.$$

Theorem 9452.2 (State partition is partial zeta)**.** *The state partition row is*

$$Z_{\text{state}}(\beta) = \prod_{p \in S} \frac{1}{1 - p^{-\beta}}.$$

When S is the set of all primes, it is the Riemann zeta function $\zeta(\beta)$ on its half-plane of convergence.

Proof. This is the Euler product obtained by unique prime factorization. □

Definition 9452.3 (History partition row)**.** *The history partition row sums over ordered refinement histories rather than only over terminal sizes:*

$$Z_{\text{hist}}(\beta) := \sum_{k \geq 0} \big(Z_{\text{state}}(\beta) - 1\big)^k.$$

Theorem 9452.4 (History critical row)**.** *Where the geometric series converges,*

$$Z_{\text{hist}}(\beta) = \frac{1}{2 - Z_{\text{state}}(\beta)}.$$

Its critical row is

$$Z_{\text{state}}(\beta) = 2.$$

For all primes this uses the Kalmár constant, and for $S = \{2\}$ it gives $\beta = 1$.

Proof. The empty history contributes 1, and a nonempty step contributes one factor from $\mathbb{N}_S \setminus \{1\}$. Summing ordered words gives the displayed geometric series. □

Principle 9452.5 (Bost–Connes interface)**.** *The state partition row has the same skeleton as the Bost–Connes partition function: a multiplicative refinement monoid acts on root and charge data. In the input-flow reading, a choice of compatible root chain is a tower-direction selection in the kernel-blind layer of Definition 9451.9.*

Principle 9452.6 (Thermal fingerprint levels)**.** *The full Dirichlet series $Z_{\text{state}}(\beta)$ determines S by its Euler factors. A single critical inverse temperature is only a coarse functional of S. Thus the thermodynamic row sits between the exact charge lattice of Definition 9451.19 and scalar scale reads: the curve is lossless, while a point on it is not.*

9452.2 Complex Refinement and Chirality

Definition 9452.7 (Gaussian refinement tower)**.** *A Gaussian refinement tower replaces $\mathbb{Z}$ by $\mathbb{Z}[i]$. Refinement factors are Gaussian integers α_k, cumulative factors are $M_k = \alpha_1 \cdots \alpha_k$, and mode data live in*

$$\mathbb{Z}[i]/M_k.$$

Theorem 9452.8 (Gaussian solenoid row)**.** *The compatibility equation for Gaussian refinement is*

$$\alpha_k \zeta_k = \zeta_{k-1}$$

on $\mathbb{C}/\mathbb{Z}[i]$. Its inverse limit is a two-dimensional solenoid, and its charge module is

$$\mathbb{Z}[i][\mathfrak{S}^{-1}],$$

where $\mathfrak{S}$ is the set of Gaussian primes occurring infinitely often in the tower.

Proof. This is the proof of Definition 9451.4 with $\mathbb{Z}$ replaced by $\mathbb{Z}[i]$ and multiplication by N_k replaced by multiplication by α_k. □

Theorem 9452.9 (Digit field and Fermat classification)**.** *For a Gaussian prime π, the digit alphabet*

$$\mathbb{Z}[i]/\pi$$

is a field. Rational primes $p \equiv 1 \pmod 4$ split and give $\mathbb{F}_p$ digit fields along the two conjugate Gaussian primes; the prime 2 ramifies; rational primes $q \equiv 3 \pmod 4$ are inert and give $\mathbb{F}_{q^2}$. Equivalently, a conformal index-p Gaussian refinement exists exactly when p is a sum of two squares.

Proof. This is the standard splitting law for $\mathbb{Z}[i]$, together with Fermat's two-square theorem. □

Definition 9452.10 (Chirality row)**.** *For a split prime $p = \pi\bar{\pi}$, the chirality row records the value of the quarter-turn i in the digit field:*

$$r_\pi := i \bmod \pi.$$

Then $r_\pi^2 = -1$, and conjugation sends r_π to $-r_\pi$.

Principle 9452.11 (Complex logarithmic ledger)**.** *The cumulative Gaussian refinement factor has a complex logarithmic read. Its real part is the ordinary logarithmic tick,*

$$T = 2\,\mathrm{Re}\log M_k,$$

while its imaginary part records the cumulative chirality angle modulo the unit group of $\mathbb{Z}[i]$*. Time is robust under complex conjugation; chirality changes sign.*

Principle 9452.12 (Chirality thermodynamics)**.** *Adding an angular chemical potential to the Gaussian refinement tower gives Hecke Grossencharacter partition rows. The untwisted row recovers*

$$\zeta_{\mathbb{Q}(i)}(\beta) = \zeta(\beta)L(\beta, \chi_4),$$

while nontrivial angular weights read chirality in the holonomy layer. The chemical potential is an added readout row, not an intrinsic force law.

Theorem 9452.13 (Reflection as Frobenius in the inert case)**.** *For* $q \equiv 3 \pmod 4$*, the digit field is* $\mathbb{F}_{q^2} = \mathbb{F}_q(i)$*, and Frobenius satisfies*

$$i^q = -i.$$

Thus complex conjugation on the digit field is the Frobenius automorphism $x \mapsto x^q$ *exactly in the inert case.*

Proof. Since $q \equiv 3 \pmod 4$, $(q-1)/2$ is odd, so $i^q = i(i^2)^{(q-1)/2} = -i$. □

9452.3 Class-Group Shape Registers

Definition 9452.14 (Complex-multiplication shape register)**.** *Let* K *be an imaginary quadratic field and* $\mathcal{O}$ *an order. A complex-multiplication shape register starts from a lattice represented by a fractional ideal* L *and refines by invertible ideals* $\mathfrak{a}$*, sending*

$$L \longmapsto \mathfrak{a}^{-1}L.$$

Theorem 9452.15 (Shape orbit is class-group walk)**.** *The similarity class of the refined lattice depends only on the ideal class. Along a tower,*

$$[L_k] = [\mathfrak{a}_1 \cdots \mathfrak{a}_k]^{-1}[L_0] \in \mathrm{Cl}(\mathcal{O}).$$

Thus shape blindness for all ideal refinements is equivalent to class number one.

Proof. Similarity classes of complex-multiplication lattices are ideal classes. Multiplying by the inverse ideals gives the displayed class-group walk. □

Principle 9452.16 (Heegner shape-blind list)**.** *For maximal imaginary quadratic orders, universal shape blindness occurs only in the class-number-one discriminants*

$$-3, -4, -7, -8, -11, -19, -43, -67, -163.$$

For nonmaximal orders the corresponding list has the standard finite extensions. Outside these exceptional loci, the class group is a visible shape register.

Example 9452.17 (Discriminant minus twenty)**.** *For discriminant* -20*, the class group has order* 2*. One ideal class therefore flips a two-state shape register, while principal refinements preserve the shape. The real logarithmic tick remains globally meaningful, but chirality acquires a class-group ambiguity.*

Example 9452.18 (Discriminant minus twenty-three)**.** *For discriminant* -23*, the class group has order* 3*. The three reduced forms may be represented by*

$$x^2 + xy + 6y^2, \qquad 2x^2 + xy + 3y^2, \qquad 2x^2 - xy + 3y^2.$$

Conjugation extends the register symmetry to a dihedral action of order 6*. The associated weight-one modular form may be read through the eta product*

$$\eta(z)\eta(23z),$$

whose coefficients distinguish principal split primes, nonprincipal split primes, and inert primes. This is the modular-form read of a nonabelian-looking shape register after adjoining reflection.

Principle 9452.19 (Eta-product coefficient audit)**.** *In the discriminant* -23 *row, the eta-product coefficients give a concrete audit surface: principal split primes, nonprincipal split primes, and inert primes map to the corresponding coefficient classes. Sample checks include small-prime signs at* 2*,* 3*,* 13*, and* 23*, together with a principal split read at* 59*. These checks belong to the modular-form interface, not to a congruence-class rule.*

Theorem 9452.20 (No finite congruence criterion for the nonabelian register)**.** *In a class-field situation whose Galois closure over* $\mathbb{Q}$ *is nonabelian, there is no modulus* m *and set of residue classes that decide the principal-prime condition for all unramified rational primes.*

Proof. A purely congruence criterion would make the splitting decision factor through an abelian cyclotomic extension. That would force the relevant Galois action to be abelian, contrary to the nonabelian closure. □

9452.4 Hecke Flow and Modular Spectra

Definition 9452.21 (Full-channel refinement)**.** *For a prime* p*, full-channel refinement of a lattice sums over all index-*p *sublattices. The channel set is naturally*

$$\mathbb{P}^1(\mathbb{F}_p),$$

with $p + 1$ *channels.*

Theorem 9452.22 (Hecke identity)**.** *The full-channel refinement operator is the Hecke operator:*

$$(T_p f)(L) = \sum_{[L:L']=p} f(L').$$

For distinct primes p *and* q*, these operators commute.*

Proof. This is the standard lattice definition of Hecke operators. Commutativity is the usual double-coset relation for coprime indices. □

Principle 9452.23 (Shape becomes state space)**.** *Once every index-p channel is allowed, shape is no longer merely an invariant to be tested for blindness. It becomes the state space*

$$\mathrm{SL}(2,\mathbb{Z})\backslash\mathbb{H}$$

on which the refinement operators act.

Theorem 9452.24 (Petersson measure as innovation geometry)**.** *For an equivariant projective Hilbert family over the upper half-plane, the positive innovation Gram tensor is* $\mathrm{SL}(2,\mathbb{R})$*-invariant. Therefore its real part is a scalar multiple of the hyperbolic metric and its imaginary part is a scalar multiple of the hyperbolic area form. The Petersson measure is the natural volume read of this projective innovation geometry.*

Proof. The upper half-plane has a unique invariant Riemannian metric and invariant area form up to scalar. Equivariance forces the Gram tensor's real and imaginary parts to lie in those one-dimensional invariant spaces. □

Principle 9452.25 (Weight as chirality)**.** *The circle action in the projective family grades states by chirality. Holomorphic modular forms of weight k are therefore read as bound states in a chirality-k sector of the full-channel refinement flow.*

Theorem 9452.26 (Ramanujan threshold as reflection-positive mixing)**.** *For the normalized prime-channel walk* $P = T_p/(p+1)$ *on the modular shape space, the Eisenstein spectrum contains*

$$\frac{2\sqrt{p}}{p+1}\cos(t\log p).$$

Negative spectral values force reflection positivity to fail for the pure walk. A lazy walk

$$P_c = (1-c)I + cP$$

is positive precisely when the negative spectrum is shifted into $[0,\infty)$*. The optimal threshold is governed by the sharp Hecke spectral bound; in the Ramanujan case it is*

$$c^*(p) = \frac{p+1}{(\sqrt{p}+1)^2}.$$

Proof. The displayed Eisenstein eigenvalue is the standard normalized T_p eigenvalue on the unitary axis. The spectrum of P_c is $1-c+c\lambda$, so positivity is exactly the lower-spectrum inequality. □

Principle 9452.27 (Dihedral boundary)**.** *Class-group and complex-multiplication rows account for the dihedral spectral pieces. Non-dihedral Maass and holomorphic eigenforms are the genuine delocalized modes of the full-channel refinement flow.*

Principle 9452.28 (Ramanujan status split)**.** *The reflection-positive threshold has several evidentiary forms across related rows. The Wirsing boundary threshold is explicit; the Ramanujan threshold is structurally exact but open in the Maass sector; and expander-style congruence gaps are established in broad settings while often not giving the exact constants needed for a sharp input-mixing row.*

9452.5 Zero Boundary

Theorem 9452.29 (Zeta as scattering matrix)**.** *For the modular surface, the Eisenstein constant term has the form*

$$y^s + \varphi(s)y^{1-s}, \qquad \varphi(s) = \frac{\Lambda(2s-1)}{\Lambda(2s)}.$$

Thus the completed zeta function enters the machine as a scattering coefficient at the cusp.

Proof. This is the classical constant-term formula for Eisenstein series on the modular surface. □

Principle 9452.30 (Zero location boundary)**.** *The input-flow grammar can place Riemann zeta zeros as scattering resonances of the cusp row. It does not thereby produce a Hilbert–Polya self-adjoint operator for those zeros. The self-adjoint spectral row belongs to the Laplacian and Selberg-type zeta functions; the Riemann zeta row enters through scattering.*

Principle 9452.31 (Three zero-boundary instruments)**.** *The zero boundary has three independent interface readings. The scattering row places zeta zeros in the Eisenstein coefficient. The generation row says that changing the finite input generator cannot bypass analytic continuation: the same meromorphic object is reached or not reached as a whole. The radial positivity row asks for a condition such as*

$$\operatorname{Re}\frac{\xi'}{\xi}(s) > 0$$

on the right half of the critical strip; classical criteria identify this as a Riemann-hypothesis-strength target, not as a closed input-flow theorem. The agreement of the three readings locates the wall; it does not remove it.

Principle 9452.32 (Positive target for a zero route)**.** *A Lee–Yang-style route to a zero statement would require a specified function class, closure of that class under the tower operations, inclusion of the base object, and convergence of the tower to the target function. The reflection-positive machinery supplies this pattern for transition spectra in the input-time variable. Transporting it to the scattering variable is an additional analytic bridge obligation.*

Chapter 9453

Innovation Input Boundary Dynamics and Numerical Rows

chapter 9452 places modular spectra and zeta scattering inside the input-flow interface. This chapter records the boundary dynamics that compute those spectra through continued fractions and transfer operators, together with the numerical congruence rows that measure finite-register coupling.

9453.1 Geodesic and Boundary Flow

Theorem 9453.1 (Quadratic discriminant trichotomy)**.** *For the modular surface, conjugacy classes split by the sign of*

$$D = t^2 - 4.$$

The cases $D < 0$, $D = 0$, and $D > 0$ correspond respectively to elliptic fixed rows, cusp scattering rows, and closed geodesic rows. In the $D > 0$ case, primitive closed geodesics correspond to narrow classes of indefinite binary quadratic forms, with length

$$2 \log \varepsilon_D^+.$$

Proof. This is the standard classification of elements of $\mathrm{SL}(2, \mathbb{Z})$ by trace. The length formula is the usual translation-length formula in terms of the fundamental totally positive unit. □

Principle 9453.2 (Golden orbit)**.** *The smallest hyperbolic trace is 3, giving $D = 5$ and fundamental unit φ^2. Thus the shortest closed geodesic is the golden quadratic orbit. In the input-flow reading, the all-one continued-fraction word is the minimal-action periodic boundary row.*

Theorem 9453.3 (Class number and regulator action)**.** *For positive discriminant D, the total length contribution of the narrow class layer is governed by*

$$h^+(D) \log \varepsilon_D^+ = \sqrt{D}\, L(1, \chi_D),$$

up to the conventional normalization of the class number formula. Thus the boundary clock for real quadratic data is the regulator.

Proof. This is the real quadratic class number formula, read as a sum of closed geodesic lengths. □

9453.2 Gauss Map and Mayer Operator

Definition 9453.4 (Gauss boundary input)**.** *The Gauss boundary input is the map*

$$G(x) = \{1/x\}$$

with inverse branches

$$x \longmapsto \frac{1}{x+n}, \qquad n \geq 1.$$

Its natural extension carries the past coordinate needed for reversible reflection.

Theorem 9453.5 (Geodesic flow as suspension)**.** *The modular geodesic flow is represented by a suspension of the natural extension of the Gauss map, with roof function proportional to*

$$\log(1/x)^{-1}.$$

The natural-extension density is symmetric under the exchange of present and past coordinates, giving the boundary form of time reflection.

Proof. This is the classical Series coding of geodesic flow by continued fractions. The symmetry of the natural-extension density is the reversibility row. □

Definition 9453.6 (Mayer transfer operator)**.** *The Mayer operator is*

$$(\mathcal{L}_s f)(x) = \sum_{n\geq 1} (x+n)^{-2s} f\left(\frac{1}{x+n}\right).$$

Theorem 9453.7 (Selberg zeta determinant row)**.** *For the modular surface, the Selberg zeta function is recovered from the Fredholm determinants of the Mayer operator by the standard even-odd factorization*

$$Z_{\text{Selberg}}(s) = \det(1-\mathcal{L}_s)\det(1+\mathcal{L}_s).$$

Proof. This is Mayer's determinant formula for the continued-fraction transfer operator. □

Principle 9453.8 (Gap ledger as natural extension)**.** *Choice dynamics discard a complement at each visible step unless the natural extension is carried. The discarded complement is precisely the past coordinate of the natural extension. Thus the gap-ledger row, the natural-extension row, and the reversibility requirement of reflection positivity are the same structural demand in three languages.*

9453.3 Boundary Reflection Positivity

Theorem 9453.9 (Wirsing obstruction)**.** *The Gauss–Kuzmin–Wirsing transfer operator has a negative secondary eigenvalue*

$$\lambda_2 = -0.3036630029\ldots.$$

Therefore the pure boundary input row fails reflection positivity. A lazy operator

$$P_c = (1-c)I + cP$$

is positive for

$$c \leq \frac{1}{1+|\lambda_2|}.$$

Proof. The spectrum of the lazy operator is $1 - c + c\lambda$. The negative eigenvalue is shifted to zero exactly at the displayed threshold. □

Principle 9453.10 (Two mixing thresholds)**.** *The modular shape flow has a Ramanujan-governed lazy threshold, while the continued-fraction boundary flow has a Wirsing-governed lazy threshold. Both are reflection-positive mixing thresholds; they live in different operator rows.*

9453.4 Bounded Type and Zaremba Boundary

Definition 9453.11 (Bounded alphabet boundary input)**.** *For $N \geq 1$, the bounded alphabet input restricts continued-fraction digits to*

$$1 \leq a \leq N.$$

The surviving boundary set is denoted E_N.

Theorem 9453.12 (Boundary dimension as pressure root)**.** *The Hausdorff dimension $\delta_N = \dim_H E_N$ is the unique value of s at which the restricted transfer operator has leading eigenvalue 1. Equivalently, it is the pressure-zero row of the finite-alphabet input.*

Proof. This is Bowen's formula for conformal expanding iterated-function systems. □

Principle 9453.13 (Small alphabet dimension reads)**.** *The finite-alphabet pressure row has benchmark values*

$$\delta_1 = 0, \qquad \delta_2 = 0.5312805\ldots, \qquad \delta_3 \approx 0.7057,$$
$$\delta_4 \approx 0.7889, \qquad \delta_5 \approx 0.8368, \qquad \delta_N \uparrow 1.$$

Hensley's asymptotic

$$1 - \delta_N \sim \frac{6}{\pi^2 N}$$

identifies the cost of deleting large digits.

Principle 9453.14 (Third dimension)**.** *The bounded alphabet row supplies a third dimension read:*

$$\textit{algebraic dimension}, \qquad \textit{spectral dimension}, \qquad \textit{boundary dimension } \delta_N.$$

The alphabet restriction prices the allowed input set rather than the kinematic rank or the stable-tail exponent.

Principle 9453.15 (Zaremba interface)**.** *Finite continued-fraction histories are rational endpoints. The question which denominators are reached by the alphabet $\{1, \ldots, N\}$ is the Zaremba problem. Bourgain–Kontorovich and Huang provide the density-one route at small fixed alphabets; the complete denominator-by-denominator statement remains a separate number-theoretic obligation.*

9453.5 Congruence-Coupled Measurement Rows

Definition 9453.16 (Congruence-coupled transfer row)**.** *For digit matrices*

$$\gamma_a = \begin{pmatrix} a & 1 \\ 1 & 0 \end{pmatrix}$$

and a congruence group G_q generated by their reductions modulo q, the coupled transfer row is

$$(\mathcal{L}_{s,N,q}F)(x, g) = \sum_{a \leq N} \frac{1}{(x+a)^{2s}} F\left(\frac{1}{x+a}, \gamma_a g\right).$$

Theorem 9453.17 (Mirror bipartition)**.** *Since* $\det \gamma_a = -1$*, the congruence walk is bipartite with respect to the determinant character. The mirror sector carries the eigenvalue* -1 *before passing to the double-step or mirror-quotient read.*

Proof. Each digit step changes determinant parity. The determinant character therefore changes sign under every generator, giving the eigenvalue -1 on that sector. □

Definition 9453.18 (Meeting number)**.** *For a finite alphabet and congruence modulus, the meeting number*

$$\Xi_N$$

is the dimensionless ratio between register mixing time and denominator expression time. In the measured row for alphabet $\{1, 2\}$ *it is read from the Lyapunov rate and the nonmirror spectral gap.*

Principle 9453.19 (Measured alphabet-two row)**.** *For alphabet* $\{1, 2\}$*, the boundary dimension row is*

$$\delta = 0.5312805063,$$

the Lyapunov row is approximately

$$\lambda = 1.2646,$$

and the nonmirror coupled congruence rows measured over small composite and prime-power moduli keep Ξ *in the displayed range*

$$5.9 \leq \Xi \leq 18.6.$$

The row is a numerical witness that congruence registers mix on the same logarithmic clock up to a moderate constant.

Principle 9453.20 (Measured congruence table)**.** *For the alphabet* $\{1, 2\}$ *measurement row, the nonmirror second spectral radius and meeting number are recorded as*

q	3	5	7	9	11	13	15	17	19	23	25	27
ρ_2	.7243	.8910	.7683	.8312	.8069	.8714	.9033	.8023	.8215	.8567	.8910	.8312
Ξ	5.9	16.4	7.2	10.3	8.8	13.8	18.6	8.6	9.6	12.3	16.4	10.3

This is a finite numerical certificate supporting the bounded-clock interpretation; it is not a uniform spectral-gap theorem.

Principle 9453.21 (Prime-power freezing witness)**.** *The measured rows for moduli* 5 *and* 25*, and for* 9 *and* 27*, exhibit the same slow spectral radius to the displayed precision. The corresponding slow mode at the higher prime power is the lift of the lower-level slow mode. This is a finite-register shadow of prime-power expansion stability, not a theorem about all moduli.*

Principle 9453.22 (Chinese-remainder penalty)**.** *Composite moduli can mix more slowly than each prime factor because the same digit drives all congruence coordinates at once. The measured modulus* 15 *row is the visible instance: the coupled tensor sector is slower than the maximum of the separate prime-factor reads, while still remaining in the same logarithmic clock scale.*

9453.6 Boundary Obligation Ledger

Principle 9453.23 (Boundary obligations)**.** *The boundary programme leaves distinct obligations:*

row	*obligation*
weighted congruence transfer	*uniform spectral gap*
bounded alphabet	*complete Zaremba coverage*
prime-power tower	*structural freezing criterion*
lazy parameter	*input-flow definition condition*
scattering zero route	*positive class closed under tower operations*

These obligations are not failures of the existing certificates. They mark the boundary between closed interface rows and open number-theoretic bridge rows.

Concretized in §7305: Observer experience traces are realized as finite observer-history, inter-history locality, perspective-classifier, transport, replay, provenance, and NameCert rows.

Chapter 9454

BEDC.MetaCIC is its own type theory: a framing principle

9454.1 The framing correction

A common misread of BEDC.MetaCIC's relation to classical CIC treats classical CIC as the reference object and BEDC.MetaCIC as a subtractive presentation of that reference. This inverts the relationship. BEDC.MetaCIC is a positively defined type theory with its own first-principles commitments. Classical CIC is a different type theory that shares some syntactic shape but adopts different design decisions.

The principle of this chapter is therefore simple:

BEDC.MetaCIC is its own theory, not a derivative of classical CIC.

The comparison with classical CIC is useful only after this identity has already been fixed. It is an analytical comparison between neighbouring theories, not a definition of BEDC.MetaCIC by reference to a parent calculus.

9454.2 What BEDC.MetaCIC positively is

BEDC.MetaCIC is determined by five first-principles commitments. These commitments give the substrate its identity directly.

9454.2.1 Closed generating types

The term-level and certificate-level objects of the substrate come from a finite collection of `inductive` declarations, including `Term`, `BMark`, `BHist`, and related closed carriers. Each declaration has a displayed constructor list. No constructor is added by axiom, ambient library supply, quotient identification, or unstated semantic interpretation.

The closed generator is the first unit of the theory. If an object is not produced by the displayed constructors, then it is not an internal object of that generator. External mathematical intentions may motivate the naming, but they do not enlarge the internal carrier.

9454.2.2 Literal AST type equality

Type equality on `Term`, and on any type-level object represented inside the substrate, is literal syntactic equality of the underlying AST. The substrate does not install a conversion rule that

promotes computational equivalence to typing identity. It does not treat two types as identical merely because an external reduction theory relates their encodings.

This point is central. Literal equality is not an impoverished conversion relation. It is the equality relation chosen by the theory. The resulting subject-reduction boundary of chapter 9377 is therefore an internal fact about the chosen substrate, not a defect measured against a different calculus.

9454.2.3 Structural recursors from closed generators

For each `inductive` declaration, the Lean kernel supplies the corresponding eliminator, such as `.rec`. These eliminators are the universal-induction primitives available for that closed generator. They authorize structural induction over exactly the displayed constructors.

BEDC.MetaCIC therefore has internal induction capacity, but that capacity is generator-local and structural. It is not a free principle over arbitrary semantic domains. When a claim needs an induction principle beyond the closed generator it names, that supply must be displayed as external input rather than silently imported into the substrate.

9454.2.4 Zero axiom, strict purity
