The substrate does not include `Classical.choice`, `Quot.sound`, `propext`, or any other Lean stdlib axiom as a dependency of BEDC.MetaCIC theorems. A strict purity audit asks each accepted theorem for its transitive axiom dependencies. For theorem content belonging to the BEDC.MetaCIC substrate, `#print axioms` returns no axioms, and `axiom-purity -strict` enforces the same boundary at project scale.

This is not a rhetorical preference for fewer assumptions. It is a typing discipline for the project. If a result needs choice, extensionality, quotient soundness, or propositional extensionality, the need must appear as a named external route, a displayed setup field, or an explicit boundary. It is not part of the substrate by default.

9454.2.5 Apophatic external boundary

Anything beyond the preceding commitments is treated as external supply. The supply is named apophatically: the project states what is not internally derivable from the current substrate and exposes a socket for that input. It does not convert the socket into a hidden axiom.

The apophatic discipline of chapter 9400 is thus part of the identity of BEDC.MetaCIC. A named hypothesis, setup field, or GAP socket is not a disguised internal theorem. It is a visible boundary marker where the substrate stops and an external route may begin.

9454.3 The defining conjunction

The five commitments are not independent slogans. Together they define the theory:

$$\begin{aligned}\text{BEDC.MetaCIC} = {} & \text{closed generators}\\ & + \text{literal AST equality}\\ & + \text{structural recursors}\\ & + \text{zero-axiom strict purity}\\ & + \text{apophatic external boundary.}\end{aligned}$$

This is a positive definition. The theory is not identified by taking a different calculus and removing a feature from it. It is identified by the commitments it actually makes.

Consequently, the first question to ask of a BEDC.MetaCIC theorem is not which classical theorem it resembles. The first question is which closed generators, recursors, literal equalities, and named boundaries its proof uses. Only after that internal reading is fixed does a comparison with classical CIC become meaningful.

9454.4 Why classical CIC is a different theory

Classical CIC has its own first-principles commitments. In familiar presentations, a conversion rule permits typing to move across computational equality:

$$T_1 \equiv_\beta T_2 \quad \Longrightarrow \quad (t : T_1) \Leftrightarrow (t : T_2).$$

This rule is a type-level identification principle. It changes how typing judgments behave and gives subject-reduction arguments access to a kind of equality that BEDC.MetaCIC does not install.

Many classical CIC environments also provide, or commonly sit beside, extensional and classical principles such as propositional extensionality, function extensionality, quotient soundness, and classical choice. Different systems choose different packages of this supply. The shared point is that the resulting environment is organized around a broader practical proof surface than BEDC.MetaCIC's closed audit substrate.

The design objectives also differ. Classical CIC is built to support a large mechanized mathematics environment. BEDC.MetaCIC is built to delimit the smallest audit-clean closed-observational substrate on which its meta-theory can run. These objectives produce neighbouring theories with different commitments. Neither one is the technical parent of the other.

9454.5 What comparison is good for

Comparison with classical CIC is useful when it isolates a specific design decision and its consequences. The axiom dependency map of chapter 9455 is one such comparison. It asks how a classical-looking universal claim meets the BEDC.MetaCIC substrate and records whether the result is an unconditional proof, a restricted proof, or an obstruction with named supply.

In that role, comparison is secondary and diagnostic. It helps readers see why conversion, extensionality, quotient soundness, or choice matter for particular proof routes. It does not define BEDC.MetaCIC's identity. The theory exists on its own footing, and its theorems are first read as theorems of that theory.

9454.6 What comparison is not good for

Subtractive slogans about BEDC.MetaCIC are structurally misleading. They imply that classical CIC is the reference and that BEDC.MetaCIC is valuable only as a depleted copy. That implication is false. Both theories have first-principles definitions, and neither is the other's reference point.

They also suggest that BEDC.MetaCIC is missing something required for its own identity. That is false as well. BEDC.MetaCIC has exactly the commitments that define it: closed generators, literal AST equality, structural recursors, strict purity, and visible external boundaries. A principle present in another calculus is not an absence inside BEDC.MetaCIC unless BEDC.MetaCIC itself claims that principle.

Finally, they misread obstruction theorems. The subject-reduction obstruction of chapter 9377 is not a failure relative to an external yardstick. It is a positive theorem about what happens when dependent codomains are read through literal AST equality on the BEDC.MetaCIC substrate. Classical CIC avoids that obstruction by making different type-theoretic commitments.

9454.7 The label classical CIC

The label "classical CIC" is itself coarse-grained. Coq libraries, Lean libraries, Agda libraries, and other mechanized settings make different decisions about axioms, quotients, extensionality, universe features, and library conventions. BEDC.MetaCIC does not target any one of these environments as its origin.

The target is instead a specific positive substrate. Classical CIC can serve as a comparison family, but not as a unitary reference object from which BEDC.MetaCIC receives its meaning. Treating that family label as the definition of BEDC.MetaCIC is a category error.

9454.8 Implications for related chapters

The audit map family of chapter 9406, the obstruction analysis of chapter 9377, the discharge routes of chapter 9374, the axiom dependency map of chapter 9455, and the closed-normal consistency result of chapter 9376 are all to be read as internal-to-BEDC statements first.

They describe what BEDC.MetaCIC does on its own substrate. References to classical CIC in those chapters are analytical comparisons. They are not definitional references, and they do not turn BEDC.MetaCIC into a subtheory relation with classical CIC.

9454.9 Apophatic framing of this principle

The apophatic framing is internally consistent with this principle. BEDC.MetaCIC names what is not derivable from its own substrate. It does not name what another calculus possesses and then define itself by lack.

This distinction matters for the reading of every named boundary. A GAP socket, setup field, or discharge obligation is a statement about the current BEDC.MetaCIC substrate. It says where the internal proof route stops. It is not a confession that the theory ought to have been a different theory.

9454.10 Boundary

This chapter is a framing principle, not a new proof and not a new Lean target. It declares how to read BEDC.MetaCIC: as its own type theory, defined from first principles. Other chapters may cite this principle when their comparison language needs to keep BEDC.MetaCIC's identity separate from the identity of classical CIC.

Concretized in §855: BEDC theory identity is realized as a finite NameCert packet for closed generators, literal AST equality, structural recursors, strict purity, and apophatic boundary rows.

Concretized in §865: The five positive BEDC.MetaCIC commitments are packaged as a finite InternalTheoryBoundaryUp certificate.

Concretized in §856: The MetaCIC theory-identity packet records the five positive commitments as finite NameCert rows.

Concretized in §869: The five positive commitments are packaged as a finite BEDC self-substrate certificate.

Concretized in §867: The positive identity of BEDC.MetaCIC is realized as a finite NameCert packet over closed generators, literal AST equality, structural recursors, strict purity, and visible external-boundary rows.

Concretized in §871: The self-theory vision is realized as a finite classifier packet for closed generators, literal equality, recursors, purity, and apophatic boundary rows.

Concretized in §872: Finite loop packet for self-theory identity, audit replay, and boundary non-escape.

Concretized in §873: The literal AST equality commitment is packaged as a finite boundary certificate.

Chapter 9455

BEDC as an axiom dependency map of classical CIC

9455.1 The reframing

The relationship between BEDC formalisation and classical CIC formalisation is often misread as a strength comparison: BEDC uses fewer axioms, proves fewer universal theorems, and is therefore a weaker calculus. That framing misses the positive deliverable. BEDC is not a weakened copy of classical CIC. BEDC is a mechanical dependency map from classical CIC universal claims to the axiom supply on which those claims rely.

Classical CIC presents its universal claims after conversion, extensionality, quotient soundness, and classical selection have already been made available as part of the ambient proof environment. BEDC.MetaCIC starts from the opposite end. It keeps the substrate closed, first-principles, and axiom-free, then asks each classical-looking claim what happens when the hidden supply is removed.

The result is not merely a shorter theorem list. It is a different artifact:

$$\phi \mapsto (\text{Mode}, \text{Witness}, \text{Required-Axiom-Set}).$$

Here ϕ is a universal claim one would expect from a classical CIC development. The output records whether the claim is internally provable, internally provable only on a restricted surface, or blocked by a mechanical witness that names the missing axiom-supplied content.

This map is the positive contribution. BEDC does not claim that every classical theorem can be replaced by a BEDC theorem. It claims that every contact between a classical universal claim and the BEDC substrate can expose the exact axiom budget required for that claim to pass.

9455.2 Three modes of engagement

For a classical CIC universal claim ϕ, BEDC.MetaCIC has three relevant outcomes.

9455.2.1 Mode A: completely provable

Mode A means that ϕ is unconditionally provable on the zero-axiom substrate. Its required axiom set is empty, and its witness is the checked proof term itself:

$$\phi \mapsto (\text{A}, \text{unconditional proof}, \emptyset).$$

The closed-syntax algebra gives representative examples. Theorems such as `shift_closed`, `substitute_closed`, `betaStep_preserves_closed`, and `no_closed_normal_proof_of_false` are not weakened classical statements. They are the fragment of the classical-looking MetaCIC story that needs no extra axiom supply.

Mode A is therefore an isolation result. It says exactly which part of the classical CIC meta-theory is already present in the closed substrate. The important point is not only that the theorem exists, but that the theorem survives the strict axiom-purity gate. BEDC turns the absence of hidden supply into visible information.

9455.2.2 Mode B: partial discharge

Mode B means that ϕ is too broad as stated, but a restricted form is provable without importing the missing axiom. Its witness is the checked restricted theorem, and its required supply is trivial only on that restricted surface:

$$\phi \mapsto (\mathrm{B}, \text{restricted proof}, \text{restricted-surface condition}).$$

The subject-reduction application case supplies the sharp example. The theorem `subject_reduction_closed_` proves the closed application preservation statement when the codomain is closed independently of the argument. On that surface, no conversion oracle is needed to identify the result type before and after the argument step: closed substitution reads back the same codomain.

Mode B is more informative than a binary failure. It says that the classical universal claim contains an internally clean subclaim. BEDC does not merely report that the full statement needs help; it separates the region where literal syntax, closedness, and the represented reduction relation already suffice.

9455.2.3 Mode C: counterexample plus named obligation

Mode C means that the unrestricted ϕ is blocked in the present substrate by a mechanical witness. The output is not silence and not an informal caveat. It is a counterexample, together with named obligation sockets for the axiom-supplied content that classical CIC would use:

$$\phi \mapsto (\mathrm{C}, \text{counterexample plus named socket}, \text{specific axiom rows}).$$

The same subject-reduction application case gives the canonical witness. The theorem `subject_reduction_clo` exhibits a closed function, a closed reducing argument, a closed application step, and an original type that the reduct does not keep. The obstruction is not a vague warning about dependent types. It is a checked dependent-codomain counterexample.

The corresponding named sockets are the four subject-reduction obligations `BetaSubstitutionPreservation`, `AppArgTypeStable`, `LamDomainSubjectReduction`, and `PiDomainSubjectReduction`. They mark the precise pieces of axiom-supplied reasoning required before the parameterised subject-reduction route can be read as an unparameterised closed theorem.

Mode C is the place where BEDC's negative-looking material becomes positive data. A documented obstruction is a dependency witness. A named hypothesis is a dependency socket. A counterexample is a mechanical certificate that the universal claim cannot be treated as substrate-internal without extra supply.

9455.3 The mapping is the deliverable

The deliverable is the map, not a competition over theorem count. For each classical CIC universal claim ϕ, BEDC asks for the dependency tuple:

$$\phi \mapsto (\text{Mode}, \text{Witness}, \text{Required-Axiom-Set}).$$

The three modes give the interpretation.

Mode A. The required axiom set is empty, and the witness is an unconditional checked proof.

Mode B. The required axiom set is empty on a stated restricted surface, and the witness is a checked restricted proof.

Mode C. The required axiom set is specific, and the witness is a counterexample together with named hypothesis sockets.

This tuple is exactly what ordinary classical CIC developments do not usually expose as their primary object. They prove the theorem in a powerful ambient environment. BEDC records what the theorem costs when the ambient environment is not silently available.

The audit-map family of chapter 9406 is the directory form of this deliverable. Each audit map records established content, conditional content, obstruction content, frontier content, and cross-module use. In the present framing, those columns are read as an axiom dependency ledger: which claims need no supply, which claims need a restricted surface, which claims expose an obstruction, and which named socket would have to be filled to move the claim.

9455.4 How to read a dependency tuple

A dependency tuple is not a semantic judgement about the intended mathematics of ϕ. It is a substrate judgement about the proof route available to the present formal object. The tuple records what the kernel can check from the displayed constructors, definitions, and named fields that are actually present.

The three coordinates have separate jobs.

Mode. The mode says how the claim meets the substrate: internal proof, restricted internal proof, or obstruction with named supply.

Witness. The witness is the mechanical object that makes the mode auditable: a proof term, a restricted theorem, a counterexample, a named obligation, or a purity-gate refusal.

Required-Axiom-Set. The required set names the supply that would have to be added or discharged before the broader classical reading could be used without qualification.

The tuple is deliberately local. A Mode A result in one module does not upgrade a neighbouring Mode C claim. A Mode B result does not license the unrestricted theorem. A Mode C counterexample does not say that the classical claim is meaningless; it says that the claim is not substrate-internal without the named supply.

This locality is what makes the map useful. Classical presentations often compress many local dependencies into one ambient theorem. BEDC expands the theorem back into its local dependency structure. The result is a readable axiom budget rather than a yes-or-no theorem status.

9455.5 A worked entry: closed application subject reduction

Closed application subject reduction gives a compact instance of the whole method. The classical-looking claim is that if a closed application is typed and the application reduces, then the reduct keeps the original displayed type. BEDC.MetaCIC does not answer this claim with a single status. It splits the claim into the three dependency-map rows that the substrate can actually justify.

First, the closed syntax and reduction infrastructure around the claim has Mode A content. Closedness is preserved by the syntax operations that are already in the substrate. The relevant shift, substitution, and beta-closure facts are checked without conversion, extensionality, or classical choice. This records the zero-supply syntactic core of the classical preservation story.

Second, the independent-codomain application surface has Mode B content. When the codomain is closed apart from the argument, replacing the argument by its reduct does not change the displayed result type. The restricted theorem `subject_reduction_closed_app_independent_codomain` is the mechanical witness for that row. It says exactly where closed substitution is enough and where no conversion oracle is being used.

Third, the dependent-codomain surface has Mode C content. The theorem `subject_reduction_closed_app_c` supplies the mechanical counterexample: a closed application can step to a reduct that does not retain the original displayed type. The obstruction is therefore a positive dependency record. It points to the missing codomain-stability and typing-preservation supply that a classical subject-reduction proof normally has available through conversion and related typing infrastructure.

The tuple for the unrestricted closed application claim is therefore not "failed". It is:

$$\phi_{\mathrm{appSR}} \mapsto (\mathrm{C}, \text{dependent-codomain counterexample plus four sockets}, \text{subject-reduction supply}).$$

The companion Mode B row records the strongest zero-supply fragment:

$$\phi_{\mathrm{appSR}}^{\mathrm{independent}} \mapsto (\mathrm{B}, \text{independent-codomain proof}, \text{closed codomain condition}).$$

Together these rows are more informative than either a bare theorem or a bare failure. They show where the classical claim is already internal, where it is blocked, and which supply must enter to remove the block.

9455.6 Why this is more informative than classical CIC formalisation

Concretized in §862: finite dependency tuple packet for the axiom-map reading

Concretized in §864: Restricted-surface budgets realize Mode-B dependency-map rows as finite claim, restricted-surface, witness, required-supply, replay, and non-export NameCert data.

Classical CIC formalisation projects prove many theorems inside an environment where conversion and library-level extensional principles are already available. In Lean-based developments, tools such as `#print axioms` can inspect the transitive constants of a theorem after the fact. That inspection is valuable, but it is not the organising principle of the project.

BEDC reverses the organisation. The substrate begins with no project axioms in `lean4/BEDC/`, forbids `axiom` declarations, and audits transitive dependencies through `axiom-purity -strict`. The map is therefore first-class. A theorem that survives the gate records a zero-supply region. A theorem that needs a named hypothesis records a socket. A counterexample records the mechanical failure of the universal claim under the current substrate.

The difference is methodological. A classical development usually asks:

Can the theorem be proved in the ambient calculus?

BEDC asks:

Which exact supply is needed for the theorem to pass?

The second question produces strictly more dependency information. It does not replace the classical theorem; it explains its axiom budget.

9455.7 The mapped axiom families

The current map covers several families of supply. The point of the list is not to repeat the detailed chapters, but to state how each family appears as dependency-map data.

9455.7.1 Conversion and definitional equality

Conversion is the central typing supply of classical CIC. BEDC.MetaCIC does not install it as an ambient rule that can silently identify types after reduction.

The Mode A region consists of literal-AST and closedness facts where no conversion is needed. Closed shift, closed substitution, closure preservation for beta steps, and closed-normal contradiction exclusion belong to this region.

The Mode B region is visible in `subject_reduction_closed_app_independent_codomain`. When the codomain is closed independently of the argument, substitution after the argument step reads back the same type by closedness alone.

The Mode C region is visible in `subject_reduction_closed_app_counterexample`. A dependent codomain can observe the argument strongly enough that the reduct does not keep the original displayed type. The four named subject-reduction obligations in chapter 9377 are the corresponding sockets.

9455.7.2 Extensional identification

Propositional extensionality, function extensionality, and quotient soundness form an extensional identification family. chapter 9394 classifies this as a supply type, and chapter 9387 reads `Quot.sound` and `propext` through meta-closure proxy shapes at different strata.

BEDC's strict purity gate refuses `propext` and `Quot.sound` as transitive dependencies of checked BEDC theorems. The dependency-map reading is direct: whenever a classical proof needs to identify propositions, functions, or quotient representatives by extensional equality, the required supply is not hidden in the substrate. It must appear as an explicit transport, classifier, or named socket.

9455.7.3 Choice and unwitnessed existence

`Classical.choice` supplies a selected witness from an existence claim without exposing the witness as generated substrate data. chapter 9387 classifies this as a term-stratum meta-closure reading.

The BEDC map treats choice-dependent claims as claims with an unwitnessed-selection dependency. Finite, countable, or explicitly recursive witness routes may become Mode A or Mode B content when the witness is generated. A free classical selection over an arbitrary family becomes Mode C content unless the selection is replaced by displayed witness data.

9455.7.4 Mathematical induction as transcendental input

chapter 9393 treats free-floating universal induction over not-yet-observed cases as a transcendental input rather than as internally generated finite observation. The dependency-map reading is again explicit. A concrete finite trace is substrate data. A universal claim over an open-ended domain requires a supply socket unless the relevant induction principle is itself present as an authorised generator for the carrier being used.

This does not make all induction unavailable. It distinguishes generated recursors from untracked universal closure. The map records which generator authorises the proof and which universal use would require supply beyond the displayed substrate.

9455.8 Permanent and open-ended

BEDC.MetaCIC has a fixed substrate discipline: closed CIC syntax, first-principles definitions, no project axioms, and strict purity auditing. Classical CIC has infinitely many universal claims. Therefore the dependency map is permanent and open-ended. Each time a classical claim touches the BEDC substrate, the project can record one more tuple:

$$\phi \mapsto (\text{Mode}, \text{Witness}, \text{Required-Axiom-Set}).$$

This is not a weakness caused by an unfinished theorem list. It is the point of the artifact. A classical formalisation can keep collecting theorems. BEDC can keep cataloguing the axiom budget of those theorems at fine granularity.

The map is also cumulative. Mode A entries expand the zero-supply fragment. Mode B entries sharpen the surfaces where classical claims become internal. Mode C entries add mechanical witnesses for the exact place where an axiom would have to enter. Every entry improves the catalogue even when it does not close the corresponding classical theorem.

9455.9 Cross-reference

The present chapter is a framing chapter. The detailed dependency-map entries live in neighbouring chapters.

- chapter 9377 gives the concrete Mode B and Mode C entry for closed application subject reduction: independent codomain discharge, dependent-codomain counterexample, and four named obligations.
- chapter 9406 gives the paper methodology by which established, conditional, obstruction, frontier, and consumer rows are catalogued.
- chapter 9400 gives the epistemic discipline behind named obligations: an open socket is named rather than hidden.
- chapter 9387 gives the axiom-family classification for choice, quotient soundness, and propositional extensionality.
- chapter 9393 gives the corresponding reading for universal induction and finite observation.

The chapter therefore does not duplicate the audit-map chapters or the synthesis chapter. It states the positive value proposition that makes those chapters cohere: BEDC is an axiom dependency map of classical CIC.

9455.10 Boundary

BEDC does not claim to enumerate all dependency tuples for classical CIC. The map is permanent and open-ended because the space of classical universal claims is open-ended.

BEDC also does not claim to replace classical CIC formalisation. Classical developments prove theorems in their chosen ambient systems. BEDC complements them by exposing which parts of those theorems survive without hidden supply, which parts survive only on restricted surfaces, and which parts mechanically witness an axiom dependency.

The boundary is strict. The words *axiom dependency* and *mechanical witness* are not metaphors. A BEDC documented obstruction, counterexample, named hypothesis, purity-gate refusal, or audit-map frontier is an inspectable dependency record. It is the map itself.

Concretized in §861: Axiom-dependency tuples are realized as finite Mode, Witness, Required-Axiom-Set, transport, provenance, and NameCert rows.

Concretized in §862: The dependency tuple becomes a finite NameCert packet over claim, mode, witness, required-supply, replay, and non-escape rows.

Concretized in §863: The axiom dependency map is realized as a finite Mode/Witness/Required-Axiom-Set ledger packet.

Concretized in §868: finite dependency-map packet for mode, witness, and required-axiom rows

Concretized in §992: Axiom requirement ledgers realize the Required-Axiom-Set row as finite witness, refusal, transport, route, provenance, and NameCert data.

Chapter 9456

The Legitimate-Claim Problem for Finite Closed Systems

BEDC is often encountered through particular targets: a concrete NameCert construction, a MetaCIC audit map, a halting boundary, or the Riemann Hypothesis as a constructive witness target. The common problem behind these examples is more general. Given a finite closed system $\mathcal{C}$ and a finite expression E, what may $\mathcal{C}$ honestly claim about E without importing unmarked supply? The answer is not always "proof" and not always "failure". The answer is an audited claim status: theorem, condition, route, evidence, non-evidence, meta-claim, refusal, GAP, or socket.

9456.1 Finite expressions and closed claim substrates

Definition 9456.1 (Finite communicable expression)**.** *A* finite communicable expression *is a finite inscription or program fragment that can be exchanged, inspected, and audited. Definitions, theorems, proofs, conjectures, programs, algorithms, theories, physical interpretations, observation reports, equivalences, proof routes, rule towers, meta-theorems, counterexamples, and numerical evidence all count as finite communicable expressions when their presented form is finite. The expression may quantify over an infinite extension; finiteness concerns the inscribed artifact.*

Definition 9456.2 (Closed claim substrate)**.** *A* closed claim substrate *is a system $\mathcal{C}$ whose internal uses must pass through records, generators, classifiers, continuations, ledgers, packages, certificates, or audit gates. If a dependency cannot be generated, defined, proved, classified, certified, or ledgered through those structures, then it may not enter as anonymous theorem content. It must be exposed as a named boundary request.*

Principle 9456.3 (Closedness as named externality)**.** *For BEDC, closedness is an accounting invariant:*

$$\textit{closed} \quad = \quad \textit{all external dependencies have apophatic names.}$$

The invariant does not say that no external pressure appears. It says that no external pressure may be consumed without a visible name, ledger, or socket.

Definition 9456.4 (Positive and apophatic names)**.** *A* positive name *names an internally generated or internally specified object: a carrier, constructor family, operation, law, eliminator, classifier, or certificate field. An* apophatic name *names an external dependency position. It makes the dependency referable, turns it into an auditable unit, and marks the boundary at which internal digestion stops; it does not convert the dependency into a theorem, object, witness, quotient representative, proposition equality, or causal law.*

Definition 9456.5 (Gap, socket, and far end)**.** *For a closed claim substrate $\mathcal{C}$, a request* req *forms* $\mathsf{GAP}_{\mathcal{C}}(\mathrm{req})$ *when it asks for content not produced by the displayed substrate. If that gap is named as a typed or ledgered boundary position, it forms* $\mathrm{socket}_{\mathcal{C}}(\mathrm{req})$*. For a forward-binding socket s, its far end has only the apophatic reading*

$$\mathrm{FarEnd}(s) \equiv_{\mathrm{apo}} \mathsf{T}.$$

The symbol T *is not a proof source, state, rule, value, or global oracle. It is the common far-end name for uninternalized supply.*

9456.2 Claim status

Definition 9456.6 (Claim status)**.** *For a closed claim substrate $\mathcal{C}$ and a finite communicable expression E,* $\mathsf{ClaimStatus}_{\mathcal{C}}(E)$ *is the audited status that $\mathcal{C}$ may assign to E. The principal statuses are:*

Theorem row. *E has a closed proof in the substrate.*

Conditional row. *E is closed relative to displayed hypotheses, setup fields, or witness obligations.*

Route row. *E supplies transports, equivalences, or a proof-search route without the witness needed to close the target.*

Evidence row. *E supplies a trace, report, numerical datum, or metric indication that is admissible as evidence but not as theorem content.*

Non-evidence row. *E supplies a report that is explicitly barred from serving as proof evidence.*

Meta row. *E is a claim about a fragment, system, proof surface, or audit layer rather than a kernel-level theorem of the object language.*

Refusal row. *E attempts to consume hidden supply and is rejected as an internal claim.*

GAP **row.** *E exposes requested content not produced by the displayed substrate.*

Socket row. *E names the boundary position at which such requested content would have to enter.*

Definition 9456.7 (Claim compiler)**.** *The* claim compiler *of a closed substrate is the audit operation*

$$\mathsf{Compile}_{\mathcal{C}} : \mathsf{FiniteExpr} \longrightarrow \mathsf{ClaimStatus}_{\mathcal{C}}.$$

Its inputs may be proof traces, programs, definitions, observations, theories, routes, equivalence chains, or meta-claims. Its outputs are claim-status rows. The compiler is therefore not merely a theorem machine; it is a proof auditor, boundary detector, and refusal surface.

Theorem 9456.8 (Claim-status exhaustion)**.** *Let $\mathcal{C}$ be a closed claim substrate and let E be a finite communicable expression encoded for audit. Then every accepted reading of E falls into one of the claim-status rows of Definition 9456.6. If E requests supply not generated by $\mathcal{C}$, then E cannot be read as an unconditional theorem row unless that supply is first discharged.*

Proof. Inspect the dependencies of the encoded expression. If they are all generated, defined, proved, classified, certified, or ledgered through $\mathcal{C}$, then the expression lands on the internal side: theorem, condition, evidence, non-evidence, route, or meta-row according to the shape of the supplied data. If some dependency is requested but not produced, the closedness invariant prevents anonymous internal use. The request is therefore recorded as a GAP; if the request is named as a boundary position, it is recorded as a socket. If the expression tries to consume the missing supply as theorem content, the proper status is a refusal row. These alternatives exhaust the admissible audit readings. □

Theorem 9456.9 (No hidden supply)**.** *In a closed claim substrate, ungenerated, uncertified, and unledgered supply breaks closedness when consumed as theorem content. The same supply preserves closedness when exposed as a socket and not consumed as an internal proof source.*

Proof. Closedness requires that every internal use be generated, certified, or ledgered, and that every external dependency have an apophatic name. An ungenerated supply consumed as theorem content is an anonymous external dependency, so it violates the invariant. If the supply is exposed as a socket, the substrate does not claim to possess it internally. It records the requested shape and the non-internalization boundary. The accounting invariant is therefore preserved. □

Corollary 9456.10 (Naming prevents smuggling)**.** *Apophatic naming does not solve the requested problem by naming it. It prevents the requested supply from being smuggled into theorem content.*

Proof. A socket gives the audit gate a stable target: the site, requested supply, non-internalization marker, and relevant gate can be inspected. No witness or theorem is produced merely by naming the socket. □

9456.3 Dual audit bases

Definition 9456.11 (MetaCIC audit base)**.** *The* MetaCIC *audit base is the closed-CIC meta-theory surface. It audits typing surfaces, beta steps, closedness, substitution, consistency assembly, subject reduction, normalisation, confluence, and decidable checking.*

Definition 9456.12 (GroundCompiler audit base)**.** *The* GroundCompiler *audit base is the compiler-facing surface. It audits event flows, source channels, generated recognizers, certificate gates, metric boundaries, cannot-claim rows, streaming discipline, and hidden-input boundaries.*

Principle 9456.13 (Dual-base non-collapse)**.** *BEDC self-audit uses the composition of* GroundCompiler *and* MetaCIC*, not their collapse. GroundCompiler acceptance does not become a proof-theoretic theorem by itself, and MetaCIC local decidability does not become a global compiler or route oracle.*

Theorem 9456.14 (Dual audit of claim status)**.** *For claims that involve both compiled artifacts and proof-theoretic content, the legitimate status must pass through both audit bases. A pass on one base cannot silently discharge a blocked edge on the other.*

Proof. GroundCompiler rows certify how an artifact entered the displayed event, source-channel, recognizer, and certificate-gate surface. MetaCIC rows certify how a proof-theoretic claim behaves with respect to typing, reduction, substitution, and closedness. These are different coordinates. If a claim is missing a source-channel boundary, MetaCIC typing does not provide it. If a claim is missing subject-reduction transport, a compiler recognition row does not provide it. The two bases therefore cooperate without substituting for each other. □

9456.4 Infinite claims and global deciders

Definition 9456.15 (Finite grounding of an infinite claim)**.** *An infinite claim A_∞ has finite grounding when it is presented by a finite generator, recognizer, continuation system, classifier, or packet family together with a* NameCert*, totality witness, correctness witness, and dependency ledger sufficient to generate the required instances or witnesses.*

Definition 9456.16 (Grounding rank)**.** *The grounding rank of a claim is* 0 *when the claim itself has a finite certificate. The rank is $n + 1$ when the claim is generated by a rule whose rank is n. If no finite rank is available, the rank is ω.*

Theorem 9456.17 (Infinite-claim closure)**.** *An infinite claim with finite grounding rank may be used as an auditable BEDC claim. An infinite claim of rank ω cannot be consumed as proof resource; it becomes a* GAP *socket unless further finite grounding is supplied.*

Proof. Finite rank gives a finite top certificate. Certified transports or generation steps then unfold the finite tower down to the target claim. Rank ω gives no finite top. Treating the whole tower as a single object only creates a further demand for a generator and certificate for that tower. Without those data, the demand is a gap; once named, it is a socket whose far end is read apophatically as T. □

Definition 9456.18 (Global closure decider)**.** *A global closure decider is a classifier $D_{\mathrm{all}}(A, R)$ deciding, for every theorem target A and proof route R, whether R eventually outputs a closed proof of A.*

Theorem 9456.19 (Global closure deciders are not legitimate claim content)**.** *No global closure decider is a legitimate internal BEDC claim object.*

Proof. If such a decider existed, then for any certificate-level continuation system $\mathsf{NameCert}_P$ and history h, form a route that runs the Cont_P-chain from h and outputs a fixed proof of a trivial target exactly when that chain terminates. The decider would determine whether the route closes, and hence whether the Cont_P-chain terminates. This is the halting predicate of chapter 9368, which closes the open meta loop at the certificate stratum. The reflection boundary of chapter 9461 forbids that closure as internal claim content. □

9456.5 The legitimate-claim theorem

Definition 9456.20 (Legitimate-claim problem)**.** *The* legitimate-claim problem *asks: given a closed claim substrate $\mathcal{C}$ and a finite communicable expression E, what is the strongest non-oracular status that $\mathcal{C}$ may assign to E?*

Theorem 9456.21 (Legitimate-claim theorem)**.** *BEDC solves the legitimate-claim problem for finite communicable expressions relative to a closed claim substrate: it assigns the strongest non-oracular claim status obtainable from the displayed generators, classifiers, continuations, ledgers, packages, certificates, audit gates, MetaCIC rows, GroundCompiler rows, gap reports, and sockets.*

Proof. By Definition 9456.8, every accepted reading of an encoded finite expression lands in a claim-status row. If all relevant dependencies are internal, the strongest status is read from the displayed proof, condition, route, evidence, non-evidence, or meta-row. If a dependency is not generated, Definition 9456.9 prevents its anonymous consumption and forces a gap or socket reading. If

a claim requires both compiler-facing and proof-theoretic support, Definition 9456.14 prevents either audit base from impersonating the other. If a claim tries to use a global closure oracle, Definition 9456.19 rejects it as open-meta-loop closure. Thus the assigned status is non-oracular and maximal relative to the displayed data. □

Corollary 9456.22 (Universal audit interface)**.** *BEDC is a universal audit interface, not universal truth possession. It does not assert that every true proposition is provable, every question is decidable, every external object is internalizable, or every boundary problem has a positive solution. It asserts that each finite claim must expose its status as theorem, condition, route, evidence, non-evidence, meta-claim, refusal,* GAP*, socket, or* T*-boundary.*

Proof. The legitimate-claim theorem assigns an audited status to the finite claim. Some statuses are proofs; others are conditional, evidential, boundary, or refusal statuses. The theorem therefore gives an audit interface rather than a total truth predicate. □

9456.6 RH and observer language as tests

Corollary 9456.23 (Riemann Hypothesis as witness-target test)**.** *The Riemann Hypothesis illustrates the legitimate-claim theorem at maximal mathematical pressure. In BEDC it is a fixed constructive* Π*-statement; a proof requires the witness function of Definition 9239.8; a disproof requires an explicit counterexample packet; independence requires a fragment-specific meta-theorem; unclosed equivalence chains remain routes; infinite rule towers without finite grounding become sockets; and global route deciders are halting-style oracles.*

Proof. This is exactly the RH boundary analysis of chapter 9336, read as an instance of Definition 9456.21. □

Corollary 9456.24 (Observer language as claim-status reconstruction)**.** *The same audit interface applies to observer, time, space, and universe language. Such vocabulary is not admitted as an anonymous background. It must be reconstructed as record accumulation, local inscription, inter-history coherence, gap report, socket, or* T*-boundary.*

Proof. The apophatic far-end chapters identify closed observational systems, forward-binding sockets, local inscription, and the common far-end name T. A claim about observers, time, space, or universe therefore enters BEDC through the same status surface: generated records when available, coherence rows when displayed, and sockets when the requested supply is not internalized. □

Corollary 9456.25 (Finite closed systems can speak without hidden supply)**.** *A finite closed system can speak about infinity, proof, programs, observers, time, space, truth, self-reference, and externality without turning unmarked external supply into theorem content.*

Proof. The system speaks by assigning claim status rather than by pretending that every claim is an internal theorem. Infinite claims require finite grounding, proof claims require proof data, program claims face the halting boundary, observer claims face the inscription and socket boundary, and externality is named apophatically. Each case preserves the closedness invariant. □

Concretized in §4735: Claim-status audit rows are realized as a finite NameCert carrier for theorem, route, evidence, refusal, GAP, and socket readings.

Concretized in §5122: Legitimate-claim audit ledgers realize claim source, admissibility gate, refusal socket, marker provenance, replay, and local naming rows.

Concretized in §7318: Claim audit boundaries realize finite claim-status, refusal, GAP/socket, and permitted-claim rows as a concrete NameCert packet.

Concretized in §7900: Claim audit witnesses realize claim text, cited object, two-axis tokens, off-table refusal, replay, and local naming rows.

Chapter 9457

Russell Problem Boundary

BEDC inherits a problem from Russell, not Russell's logicist system. The inherited problem is the demand that mature mathematics be read from a small, explicit discipline rather than accepted as a stock of primitive objects. BEDC does not import the axioms, ramified type theory, reducibility principle, or class ontology of *The Principles of Mathematics* or *Principia Mathematica*. It imports a reconstruction pressure: every apparently familiar mathematical object must be unfolded into a licensed pattern of relations, descriptions, contexts, strata, and witnesses.

9457.1 The inherited problem

Russell's foundational project can be read as a discipline for preventing mature mathematical grammar from smuggling in mature mathematical ontology. A phrase that looks like it denotes an object must be analysed before it is admitted. A class phrase must not automatically become a class object. A relation must not be replaced by a unary property when the relation is doing the mathematical work. A term at one type level must not be treated as a term at another type level merely because the prose makes the passage sound harmless.

BEDC accepts this discipline in a kernel-facing form. The point is not to reproduce Russell's system, but to keep the following five restrictions visible at every upward interface:

1. relation first: the behaviour that licenses a name is relational before it is object-like;
2. description expansion: a definite description is not a primitive denotation, but an analysed certificate obligation;
3. contextual class reading: a class-like expression is read through the context that classifies it, not as an automatic object;
4. stratification: a passage between levels requires an explicit bridge and does not collapse the levels;
5. witnessed descent: no downward use of an upward name is allowed without a certificate.

9457.2 Kernel reading

The finite kernel already supplies the place where this discipline lives. An asking event has the form

$$\mathsf{Ask}(\pi, h, m, \delta),$$

where π is the probe name, h is the history, m is the emitted mark, and δ is the evidence token. Read structurally, this gives five roles:

BEDC role	**Name-certificate role**	**Russell discipline**
probe or question	source entry	description expansion
history	source material	contextual class reading
observation relation	pattern and classifier	relation first
result mark	stability-consumable result	stratification
evidence token	ledger policy	witnessed descent

Thus Russell's discipline is not an external philosophical decoration. It is a reading rule for the same fivefold structure that the BEDC kernel already uses to keep an observation from becoming an object without a certificate.

9457.3 The upward-name reading

For a mature mathematical expression X, the expression $X^{\uparrow}$ does not mean that BEDC has found the host object X inside the kernel. It means that BEDC has licensed an interface whose source specification, pattern specification, classifier specification, stability certificate, and ledger policy allow the traditional grammar of X to be used without making X primitive.

For example, $\mathsf{Nat}^{\uparrow}$ is not the host natural-number type. It is a certificate-licensed reading of unary repetition, successor behaviour, induction, and recursion as stable public operations over histories. Likewise $\mathsf{ContinuousMap}^{\uparrow}$ is not a host-level function equipped with an imported modulus. It is a relation-plus-ledger interface whose continuity claims are consumed only through the certificate that licenses them.

This is the BEDC form of Russell's analysis of descriptions. The apparent object is replaced by the statement that a certificate exists with the right source, pattern, classifier, stability, and ledger obligations. The public name is usable only where those obligations are in scope.

9457.4 Boundary

The Russell problem boundary rejects five shortcuts.

1. A class expression may not be promoted to an object merely because later prose wants to quantify over it.
2. A description may not be used as a denoting term without existence, uniqueness or stability, and ledger obligations appropriate to the interface.
3. A host quotient, host choice principle, proof-irrelevance principle, or proposition-extensionality principle may not enter the public surface as if it were a BEDC derivation.
4. A level descent may not be justified by a reducibility-style slogan; it must be represented by a certificate that names the bridge.
5. A bridge readback may not be treated as kernel identity; it is a consumed certificate, not a collapse of the source and target strata.

These rejections are not additions to the kernel. They are consequences of taking $\mathsf{NameCert}$ as the universal admission rule for mature names.

9457.5 Analysis spine

The reconstruction of analysis follows the same spine. First, unary repetition is licensed as $\mathsf{Nat}^{\uparrow}$. Relation calculus and order are then licensed as classifier-stable behaviours over the arithmetic layer. Series, segments, cuts, rationals, regular rational sequences, and real numbers are admitted only as upward names whose ledger records the hidden convergence or approximation work. Limits, continuous maps, derivatives, integrals, measure, and functional analysis are then read as later certificates over that real-analysis base.

In compressed form, the intended path is

$$\mathsf{Nat}^{\uparrow} \to \mathsf{RelationCalculus}^{\uparrow} \to \mathsf{Order}^{\uparrow} \to \mathsf{Series}^{\uparrow} \to \mathsf{Segment}^{\uparrow}, \mathsf{Cut}^{\uparrow} \to \mathsf{Rat}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow} \to \mathsf{Limit}^{\uparrow} \to \mathsf{Conti}$$

This path is the BEDC version of proving analysis from minimal disciplined beginnings. The phrase "from minimal self-evident axioms" is therefore not read as permission to import axiom lists. It is read as a demand that every later object be reconstructed through the smallest available kernel roles and then admitted only through a visible certificate.

Concretized in §506: Self-membership rejection is represented as a finite NameCert boundary for contextual class readings.

Concretized in §518: The Russell analysis spine is realized as a finite NameCert packet over description, contextual-class, relation-first, stratification, and witnessed-descent rows.

Concretized in §517: Russell boundary packets realize relation-first, description-expansion, contextual-class, stratification, and witnessed-descent discipline as a finite NameCert surface.

Concretized in §661: Definite-description boundaries are realized as finite BHist packets exposing existence, uniqueness, stability, hsame, Cont, Pkg, and NameCert ledger rows before any description is consumed as a public name.

Concretized in §684: Contextual class readings are realized as finite NameCert packets whose classifier is scoped by a displayed context rather than by host class ontology.

Concretized in §1103: Witnessed-descent ledgers realize downward use of upward names as finite source, bridge, descent request, witness, transport, provenance, and NameCert rows.

Chapter 9458

Reasoning by Contradiction: BEDC's Permitted Forms

BEDC accepts certain forms of reasoning by contradiction and rejects others, and the boundary is not a stylistic preference but a structural one. The permitted patterns – proving a negation by deriving falsity from the assumption, eliminating double negation on a decidable proposition, refuting a false existence claim by exhibiting a counterexample to its witness – all operate within the closed ground loop and never touch the meta level. The forbidden patterns – proving an existence statement by contradiction, eliminating double negation on an undecidable proposition, splitting on the law of excluded middle for a predicate over the carrier of naming certificates – all, on inspection, reduce to a single underlying move: closing the meta-level self-reference loop that chapter 9461's two-loops theorem requires to remain open. This chapter (i) catalogues the permitted refutation patterns as they appear in chapter 4's extension and continuation calculus, (ii) catalogues the forbidden patterns and traces each to its meta-closure consequence via a Tarski-style fragment of the truth predicate, (iii) states the unifying theorem that every forbidden pattern implements meta-closure, and (iv) records that the boundary thus identified is the same boundary that separates the closed ground loop from the open meta loop, with the halting capstone (chapter 9368) as the canonical sibling instance.

9458.1 Permitted refutation patterns

Definition 9458.1 (Permitted refutation pattern)**.** *A* permitted refutation pattern *is a derivation rule of the form "from $A \Rightarrow \bot$, conclude $\neg A$" or one of its decidable specialisations, where the derivation of $\bot$ uses only* Cont, hsame, msame, *and the closure laws of a fixed naming certificate. The conclusion $\neg A$ is read as the BEDC predicate "every witness of A produces $\bot$ inside the certificate's classifier", not as "A holds in no possible world".*

Example 9458.2 (Negation by derived falsity)**.** *The kernel theorem* $\neg\mathsf{msame}(\mathsf{b0}, \mathsf{b1})$ *of chapter 2 is a permitted refutation. Assuming a witness w of* $\mathsf{msame}(\mathsf{b0}, \mathsf{b1})$ *produces $\bot$ by inversion on the constructor pattern:* msame *is a closed inductive whose only constructor identifies a mark with itself, and the constructors of* Mark *are different. The derivation never leaves the inductive carrier of* Mark *and never appeals to a meta-level predicate.*

Example 9458.3 (Double negation on decidable predicates)**.** *For a decidable predicate P on* Hist, *the rule $\neg\neg P\,h \Rightarrow P\,h$ is permitted: decidability supplies a constructive disjunction $P\,h \vee \neg P\,h$, and the second disjunct contradicts $\neg\neg P\,h$, leaving the first. The rule fails for predicates that are*

not given decidably; the failure is not a stylistic restriction but a refusal to substitute meta-level reasoning for missing constructive content.

Example 9458.4 (Counterexample to a false existence)**.** *Refuting $\exists h, P\,h$ by exhibiting a uniform* Hist *map φ with $\neg P(\varphi h)$ for every h is permitted: the witness φ is a kernel-level continuation that converts a putative existential witness into a $\bot$. The refutation is constructive in the same sense the existence claim would have been.*

9458.2 Forbidden patterns and their meta-closure

Definition 9458.5 (Forbidden pattern)**.** *A* forbidden pattern *is a derivation step that produces a kernel-level conclusion of one of the following shapes without supplying the corresponding constructive witness:*

1. *proving $\exists h, P\,h$ from the assumption $\neg\forall h, \neg P\,h$;*
2. *eliminating double negation on a predicate not given decidably;*
3. *splitting on the law of excluded middle for a predicate over the carrier $\mathcal{C}$ of all naming certificates.*

Theorem 9458.6 (Each forbidden pattern implements meta closure)**.** *For every forbidden pattern of Definition 9458.5, accepting the pattern as an admissible derivation step at the certificate level closes the open meta loop of chapter 9461: it supplies a* NameCert*-level decision for a predicate whose decidability is not constructively available, and the supplied decision is, structurally, an* NameCert*-level value of the host's truth predicate.*

Sketch. For (i): the move from $\neg\forall\neg$ to $\exists$ supplies a witness without exhibiting one. Reading the existential as a NameCert-level extension predicate, the witness is the value the predicate takes when applied to the assumption; reading the value back as a constructor of the witness type closes the meta loop. For (ii): double-negation elimination on a non-decidable P supplies a value of $P\,h$ without a constructor; reading P as a NameCert classifier exposes the supplied value as a NameCert-level truth witness. For (iii): excluded middle on a predicate over $\mathcal{C}$ asserts that the certificate-of-certificates settles every certificate-level proposition, which is precisely the assumption that the meta loop is closed (Definition 9461.14). □

9458.3 The boundary as ground vs meta loop

Theorem 9458.7 (Permitted iff stays within the closed ground loop)**.** *A refutation pattern is permitted in BEDC if and only if its derivation factors through the closed ground loop of chapter 9461: every step uses* Cont*,* hsame*,* msame*, and the closure laws of a fixed naming certificate, and no step appeals to a* NameCert*-level predicate over the carrier of all naming certificates.*

Sketch. Forward: Definition 9458.1 restricts the derivation primitives to those of the kernel together with a fixed certificate, and these primitives are exactly the closed ground loop's data. Backward: a derivation that stays in the ground loop produces only certificate-level consequences supported by their constructors, hence avoids the meta-closure characterised by Definition 9458.6. □

Concretized in §503: Witnessed refutation packages the permitted contradiction boundary as explicit Hist-level evidence.

Remark 9458.8 (Sibling instance: halting)**.** *The same boundary, applied to the predicate "the continuation chain from h in* $\mathsf{NameCert}_P$ *terminates", produces the halting obstruction of Definition 9368.3. Halting decidability is the canonical instance of the third forbidden pattern: a* NameCert*-level decision for a predicate over the carrier of all naming certificates. The catalogues of Definition 9458.1 and Definition 9458.5 therefore unify the proof discipline of the kernel with the halting result of the operational-semantics capstone.*

Remark 9458.9 (Sibling instance: three axioms)**.** *The chapter is also the discipline-side complement of chapter 9387: the three axiom families classified there as unwitnessed-content acceptance are sorted against the first forbidden pattern at the term, type or classifier, and proposition layers respectively. Refusing the forbidden patterns at the proof level and refusing the three axiom families at the foundation level are matching audit readings of meta-closure refusal.*

Concretized in §493: The permitted and forbidden contradiction boundary is realized as a finite $\mathsf{DecidableRefutation}^{\uparrow}$ NameCert surface.

Concretized in §511: A finite NameCert packet records constructive refutation as an assumption-to-bottom route without exporting certificate-indexed truth branches.

Concretized in §507: Stable negation is represented as a finite NameCert boundary separating permitted refutations from certificate-wide truth branches.

Concretized in §500: finite NameCert carrier for permitted refutation routes and forbidden truth-branch exclusion

Concretized in §501: Permitted refutations are realized as finite $\mathsf{ConstructiveRefutation}^{\uparrow}$ contradiction-route packets, while forbidden truth branches have no carrier coordinate.

Concretized in §502: Constructive refutation boundaries are realized as finite BHist proof-discipline packets separating permitted negation routes from certificate-indexed truth branches.

Concretized in §512: The $\mathsf{RefuterTrace}^{\uparrow}$ certificate realizes the permitted-refutation side of the contradiction boundary as finite BHist trace data.

Concretized in §497: Concrete finite-row NameCert for the permitted contradiction boundary.

Definition 9458.10 (Certificate-indexed truth branch)**.** *Let $\mathcal{C}$ be the carrier of all naming certificates. For a predicate $Q : \mathcal{C} \to \mathsf{Prop}$, a* certificate-indexed truth branch *for Q is a family*

$$\mathsf{Branch}_Q : \forall N : \mathcal{C},\ Q(N) \vee \neg Q(N).$$

When Q ranges over certificate-level statements represented by the certificate carrier, such a branch is a truth-predicate fragment at the NameCert *stratum: it chooses, inside the certificate layer, a positive witness or a refutation for each represented statement.*

Lemma 9458.11 (Excluded-middle branches are always double-negated)**.** *For every proposition A, there is a constructive derivation of $\neg\neg(A \vee \neg A)$.*

Proof. Assume $u : \neg(A \vee \neg A)$. Define $n_A : \neg A$ by sending a witness $a : A$ to $u(\mathsf{inl}(a))$. Then $\mathsf{inr}(n_A)$ is a witness of $A \vee \neg A$, so $u(\mathsf{inr}(n_A))$ gives $\bot$. Thus every assumed refutation of $A \vee \neg A$ produces $\bot$, which is exactly $\neg\neg(A \vee \neg A)$. □

Theorem 9458.12 (Forbidden contradiction schemas produce certificate truth branches)**.** *Let $\mathcal{C}$ be the carrier of all naming certificates. The following three uniform schemas each imply a certificate-indexed truth branch for every predicate $Q : \mathcal{C} \to \mathsf{Prop}$:*

1. *the existential-by-contradiction schema* $\neg\forall h : \mathsf{Hist}, \neg R(h) \Rightarrow \exists h : \mathsf{Hist}, R(h)$ *for arbitrary history predicates* R*;*
2. *the double-negation schema* $\neg\neg A \Rightarrow A$ *for propositions not supplied with a decidability row;*
3. *the excluded-middle schema* $Q(N) \vee \neg Q(N)$ *for predicates over* $N : \mathcal{C}$*.*

Consequently each forbidden pattern of Definition 9458.5, when admitted uniformly as a certificate-level derivation rule, closes the open meta loop of Definition 9461.15 by supplying the truth-predicate fragment forbidden by Definition 9461.14.

Proof. Fix a predicate $Q : \mathcal{C} \to \mathsf{Prop}$ and a certificate $N : \mathcal{C}$. Put

$$A_N := Q(N) \vee \neg Q(N).$$

By Definition 9458.11, there is a constructive witness $d_N : \neg\neg A_N$.

For the existential-by-contradiction schema, define a history predicate

$$R_N(h) := \mathsf{hsame}(h, \mathsf{e}) \wedge A_N.$$

If $u : \forall h : \mathsf{Hist}, \neg R_N(h)$, then $u(\mathsf{e})$ refutes $R_N(\mathsf{e})$. But the empty-history rule in Definition 3.2 supplies $\mathsf{hsame}(\mathsf{e}, \mathsf{e})$, so any $a : A_N$ gives a witness $(\mathsf{hsame}(\mathsf{e}, \mathsf{e}), a)$ of $R_N(\mathsf{e})$, contradicting $u(\mathsf{e})$. Hence u implies $\neg A_N$, and this contradicts d_N. Therefore $\neg\forall h : \mathsf{Hist}, \neg R_N(h)$ holds. Applying the existential-by-contradiction schema gives $\exists h : \mathsf{Hist}, R_N(h)$, and projecting the second component of its witness gives A_N.

For the double-negation schema, apply the schema directly to the proposition A_N. The premise $d_N : \neg\neg A_N$ is constructive, and the schema returns A_N.

For the excluded-middle schema over $\mathcal{C}$, the instance at N and Q is exactly A_N.

Thus each of the three schemas supplies $Q(N) \vee \neg Q(N)$. Since N was arbitrary, each supplies the family Branch_Q of Definition 9458.10. When Q ranges over certificate-level statements represented by $\mathcal{C}$, this family is a $\mathsf{NameCert}$-level truth-predicate fragment. By Definition 9461.14, such a fragment is precisely what BEDC's self-description cannot internalize as its own truth predicate; by Definition 9461.15, keeping that layer open is the consistency side of the two-loops boundary. Therefore uniformly admitting any forbidden schema implements meta closure. □

Concretized in §510: GroundRefutationUp realizes the permitted refutation branch as a finite NameCert packet.

Concretized in §508: The reasoning-by-contradiction boundary is realized as a finite NameCert packet for ground-loop refutation routes and meta-escape exclusions.

Concretized in §854: Certificate truth-branch boundaries are realized as finite BHist NameCert packets separating permitted refutation routes from forbidden certificate-indexed truth branches.

Concretized in §899: Forbidden contradiction schemas are realized as a finite obstruction packet separating permitted refutation from meta-loop truth closure.

Chapter 9459

Theory Stability and the TasteGate Framework

The 280-plus concrete-instance chapters of `papers/bedc/parts/` formalise objects whose mathematical-consensus credit was earned by the mathematics community over decades or centuries: $\mathsf{Group}^{\uparrow}$, $\mathsf{Hilbert}^{\uparrow}$, $\mathsf{Curvature}^{\uparrow}$, $\mathsf{GelfandDuality}^{\uparrow}$, $\mathsf{DiffGalois}^{\uparrow}$, and the rest. Each chapter inherits this credit; the BEDC formalisation does not need to re-test whether $\mathsf{Group}^{\uparrow}$ is a 'real theory', because the question was settled outside the system.

A separate admission mode applies when codex itself proposes a chapter. An AI-proposed chapter has no mathematical-consensus credit. It might be combinatorial padding, a synonym of an existing chapter under another name, a carrier that crosses the BEDC zero-axiom boundary, or a locally self-consistent surface that breaks stability of the existing horizon when admitted. The taste gate of this chapter records the discipline by which AI-proposed chapters earn admission.

The discipline reuses the conservativity, no-hidden-input, round-trip, and source-channel-separation theorems already established in the ground compiler chapters (chapter 9207, chapter 9208, chapter 9209, chapter 9222). It elevates those compiler-internal invariants into a chapter-level taste gate.

9459.1 Carrier display obligations

A candidate chapter X earns admission to the AI-proposed track by first committing to a concrete carrier display. The Lean class `BHistCarrier X` supplies

$$\mathsf{toEventFlow} : X \to \mathsf{EventFlow}, \qquad \mathsf{fromEventFlow} : \mathsf{EventFlow} \to \mathsf{Option}(X).$$

The chapter-specific gate then asks for only the two obligations that genuinely depend on X.

Definition 9459.1 (Conservativity obligation)**.** *Conservativity is not a field supplied by the chapter. It is the theorem that every mark occurring in the display of an admitted token is one of the two BEDC ground marks* `b0` *or* `b1`*, derived from GroundCompiler event-flow conservativity.*

Definition 9459.2 (No-hidden-input obligation)**.** *No-hidden-input is not a field supplied by the chapter. It is the theorem that every token $x : X$ has a visible event-flow witness e with*

$$\mathsf{fromEventFlow}(e) = \mathsf{some}(x),$$

obtained by taking $e = \mathsf{toEventFlow}(x)$ and applying the round-trip obligation.

Definition 9459.3 (Round-trip obligation)**.** *The round-trip obligation for X asserts*

$$\forall x : X, \quad \mathsf{fromEventFlow}(\mathsf{toEventFlow}(x)) = \mathsf{some}(x).$$

Every admitted token must be the readback of its own displayed event flow.

Definition 9459.4 (Layer-separation obligation)**.** *The layer-separation obligation for X asserts*

$$\forall x, y : X, \quad x \neq y \Rightarrow \mathsf{toEventFlow}(x) \neq \mathsf{toEventFlow}(y).$$

Distinct carrier tokens therefore have distinct displayed event flows.

9459.2 Lean interface

The Lean interface separates carrier data from gate data:

```
class BHistCarrier (X : Type) where
  toEventFlow : X -> EventFlow
  fromEventFlow : EventFlow -> Option X

class ChapterTasteGate (X : Type) [BHistCarrier X] where
  round_trip :
    forall x : X,
      BHistCarrier.fromEventFlow
        (BHistCarrier.toEventFlow x) = some x
  layer_separation :
    forall x y : X, x <> y ->
      BHistCarrier.toEventFlow x <>
        BHistCarrier.toEventFlow y
```

Lean4 (definition) `BEDC.Meta.TasteGate.BHistCarrier`
Lean4 (definition) `BEDC.Meta.TasteGate.ChapterTasteGate`
Lean4 ✓ `BEDC.Meta.TasteGate.ChapterTasteGate.conservativity`
Lean4 ✓ `BEDC.Meta.TasteGate.ChapterTasteGate.no hidden input`

The reference instance witnesses that the ground compiler's own event-flow carrier satisfies the gate by identity display and identity readback. The conservativity and no-hidden-input readings are obtained from the derived theorems above, not from chapter-filled fields.
Lean4 ✓ `BEDC.Meta.TasteGate.groundCompilerSelfTasteGate`

9459.3 Field faithfulness and nontriviality

The current Lean surface also records two opt-in strengthening gates. `FieldFaithful` requires a chapter to list its BHist fields and prove that equal field lists determine equal carrier tokens. `Nontrivial` requires a displayed pair of distinct inhabitants, excluding one-token carriers whose layer-separation proof would be vacuous.
Lean4 (definition) `BEDC.Meta.TasteGate.FieldFaithful`
Lean4 (definition) `BEDC.Meta.TasteGate.Nontrivial`

These gates do not replace `ChapterTasteGate`. They refine it: the chapter must first be displayable and readable, and may then expose additional evidence that the display reflects every declared field and that the carrier is not a vacuous singleton.

9459.4 Relationship to the NameCert obligations

The *naming-certificate* obligation set (chapter 9) records source, classifier, pattern, ledger, and extension obligations within a single chapter. The TasteGate obligations record stability across chapters and across the ground compilation layer. The two are orthogonal:

- A chapter satisfying NameCert alone is internally consistent but not necessarily stable when admitted to the global horizon.
- A chapter satisfying TasteGate alone has display/readback stability but is not yet a usable BEDC carrier.
- Human-curated chapters supply NameCert and inherit TasteGate credit from mathematical consensus.
- AI-proposed chapters must supply both NameCert and TasteGate.

The chapter does not retroactively impose TasteGate on the existing human-curated horizon. The audit gate distinguishes the two tracks by a single `\origin{human|ai}` field on the `closurestatus` block; absence defaults to `human` and preserves backward compatibility.

9459.5 Cannot-claim registry

The chapter does not claim a complete answer to the underlying philosophical question of what makes a mathematical object 'real'; it claims only a machine-checkable filter. The chapter does not claim that any failure of the four obligations rules a candidate out as mathematics in some absolute sense; it rules the candidate out of *this* BEDC horizon under the AI-proposed track. The chapter does not claim that human-curated chapters whose four obligations have not been mechanically checked are incorrect; it claims only that they inherit consensus credit and need not be re-checked at admission time. The chapter does not claim a semantic conservativity theorem for arbitrary chapter X relative to an arbitrary BEDC baseline. It claims the narrower ground-display conservativity supplied by the GroundCompiler event-flow theorem for the displayed event flows of any admitted carrier.

Concretized in §290: Policy packets realize the TasteGate discipline as finite BHist action-selection certificates with explicit ground-compiler witness rows.

Concretized in §545: TasteGateAdmission packets realize AI-origin chapter admission as finite BHist rows carrying ChapterTasteGate, ground-compiler witness, audit-gate, hsame, Cont, Pkg, GAP, and NameCert data.

Concretized in §563: TasteGate admission is realized as a finite compiler-witness NameCert packet tying ChapterTasteGate obligations to ground-compiler witness rows.

Concretized in §564: TasteGate stability is realized as finite BHist NameCert packets over ground-compiler witness rows, admission ledger, non-hidden-input, round-trip, and layer-separation gates.

Concretized in §993: Finite reflection tuples realize TasteGate stability as displayed tuple, image, readback, componentwise NameCert transport, and reflection-request rows.

Concretized in §552: TasteGate audit traces are realized as finite BHist packets carrying the four obligation witnesses, audit replay, ground-compiler provenance, and non-escape ledger for AI-origin chapter admission.

Concretized in §7186: Finite kernel closure gates realize the TasteGate closure-admission discipline as finite BHist gate, audit, transport, replay, provenance, and NameCert rows.

Chapter 9460

Theorem-DNA Scoring TasteGate

chapter 9459 records the carrier-facing gate: a chapter carrier must display as an event flow, read back through a partial decoder, and separate distinct carrier tokens by distinct displays. chapter 9408 records the theorem-facing profile: a theorem flow is not a statement string but an eight-locus event-flow profile with statement, dependencies, proof, certificates, ledger, status, canonical site, and closing seal. The present chapter composes the two readings into a stronger admission schema for theorem-like carriers.

9460.1 Theorem-DNA packet

Definition 9460.1 (Theorem locus set)**.** *The theorem-DNA locus set is*

$$\mathcal{L}_\Theta = \{\ell_{\mathsf{stmt}}, \ell_{\mathsf{deps}}, \ell_{\mathsf{proof}}, \ell_{\mathsf{cert}}, \ell_{\mathsf{ledger}}, \ell_{\mathsf{status}}, \ell_{\mathsf{site}}, \ell_{\mathsf{seal}}\},$$

corresponding respectively to statement, dependencies, proof, certificates, ledger, status, canonical site, and closing seal.

Definition 9460.2 (Theorem-DNA packet)**.** *For a generated theorem recognizer R and theorem candidate flow T, a theorem-DNA packet is an eight-tuple*

$$D_R(T) = (G_{\mathsf{stmt}}, G_{\mathsf{deps}}, G_{\mathsf{proof}}, G_{\mathsf{cert}}, G_{\mathsf{ledger}}, G_{\mathsf{status}}, G_{\mathsf{site}}, G_{\mathsf{seal}})$$

whose components satisfy the matching GroundCompiler role-subflow predicates. It is anchored when each component is a source subflow of T. It is sound when the recognizer also satisfies $\mathsf{SoundTheoremFlow}(R, T)$.

Theorem 9460.3 (Sound theorem-DNA is role-complete)**.** *Every sound theorem-DNA packet contains all eight theorem loci.*

Proof. Sound theorem-DNA includes a theorem-DNA packet, and the packet is defined as the eight matching role-subflow witnesses. This is the paper-side unpacking of GroundCompiler complete theorem-flow recognition. □

9460.2 Score certificate

Definition 9460.4 (Flow mass and score)**.** *For an event flow $S = (w_0, \ldots, w_{n-1})$, define*

$$|S|_{\mathsf{flow}} = n + \sum_{i=0}^{n-1} |w_i|_{\mathsf{raw}}.$$

For a theorem-DNA packet $D_R(T)$, its complexity vector is the nine-coordinate vector of the eight locus masses together with the recognizer mass $|R|_{\mathsf{flow}}$. A weight profile $\mathbf{w} \in \mathbb{N}^9$ assigns public weights to these nine coordinates, and the score $\mathsf{Score}_{\mathbf{w}}(R, D_R(T))$ is the resulting dot product.

Definition 9460.5 (Score certificate)**.** *For a bound $B \in \mathbb{N}$, a score certificate consists of a sound theorem-DNA packet $D_R(T)$ together with the displayed inequality*

$$\mathsf{Score}_{\mathbf{w}}(R, D_R(T)) \leq B.$$

It is an auditable upper bound, not a claim that B is the minimal complexity of the theorem flow.

Theorem 9460.6 (Score monotonicity)**.** *For fixed nonnegative weights, componentwise reduction of the theorem-DNA complexity vector cannot increase the score.*

Proof. This is componentwise monotonicity of a dot product with entries in $\mathbb{N}$. Each coordinate inequality remains valid after multiplication by its corresponding weight, and summing preserves the inequality. □

Theorem 9460.7 (Scalar score depends on the weight profile)**.** *A scalar theorem-DNA score is auditable only together with its weight profile.*

Proof. Two complexity vectors can trade off statement mass against dependency mass. A weight profile concentrated on the first coordinate orders them one way, while a profile concentrated on the second coordinate orders them the other way. Therefore the weight profile is part of the score certificate. □

9460.3 The strengthened gate

Definition 9460.8 (Canonical carrier)**.** *For a carrier X with a `BHistCarrier` display, the canonical carrier condition consists of the round-trip equation*

$$\forall x : X, \quad \mathsf{fromEventFlow}(\mathsf{toEventFlow}(x)) = \mathsf{some}(x)$$

and image exactness

$$\forall e, x, \quad \mathsf{fromEventFlow}(e) = \mathsf{some}(x) \Rightarrow e = \mathsf{toEventFlow}(x).$$

The first clause says that the canonical display reads back. The second says that the decoder accepts no non-canonical display for the same token.

Definition 9460.9 (Theorem-DNA scoring TasteGate)**.** *A theorem-like carrier X passes the theorem-DNA scoring TasteGate at weight profile $\mathbf{w}$ and budget $B : X \to \mathbb{N}$ when:*

$$X \text{ has a } \mathsf{BHistCarrier} \text{ display},$$
$$X \text{ satisfies the canonical carrier condition},$$
$$X \text{ satisfies } \mathsf{FieldFaithful} \text{ and } \mathsf{Nontrivial},$$
$$\forall x : X,\ T_x = \mathsf{toEventFlow}(x) \text{ carries anchored sound theorem-DNA},$$
$$\forall x : X,\ \mathsf{Score}_{\mathbf{w}}(R_x, D_x) \leq B(x) \text{ for a displayed score certificate.}$$

This gate is denoted $\mathsf{TDCSGate}(X, \mathbf{w}, B)$.

Theorem 9460.10 (TDCSGate implies ChapterTasteGate)**.** *If* $\mathsf{TDCSGate}(X, \mathbf{w}, B)$ *holds, then* X *satisfies* `ChapterTasteGate`*.*

Proof. The canonical carrier condition supplies the round-trip field. To prove layer separation, suppose $x \neq y$ and $\mathsf{toEventFlow}(x) = \mathsf{toEventFlow}(y)$. Applying round-trip to both tokens gives the same decoder value, hence $\mathsf{some}(x) = \mathsf{some}(y)$, so $x = y$, a contradiction. □

Corollary 9460.11 (Derived display obligations are inherited)**.** *A carrier passing* TDCSGate *inherits the existing TasteGate conservativity and no-hidden-input theorems.*

Proof. By Definition 9460.10, the carrier satisfies `ChapterTasteGate`. Conservativity and no-hidden-input are derived theorems of that gate, not fields supplied by the carrier. □

9460.4 Exclusion principles

Theorem 9460.12 (Statement-only carriers cannot pass)**.** *A carrier whose displayed theorem candidate can supply only the statement locus and no proof locus cannot pass* TDCSGate*.*

Proof. The gate requires anchored sound theorem-DNA for every displayed token. By Definition 9460.3, such DNA contains a proof locus. This contradicts the hypothesis. The GroundCompiler theorem `statement_alone_not_theorem` is the corresponding checked boundary. □

↪ variant `BEDC.GroundCompiler.TheoremGenerated.statement alone not theorem`

Theorem 9460.13 (Code-only theorem objects cannot pass)**.** *A displayed candidate whose only evidence is legal theorem code, with no proof-sound theorem recognition, cannot pass* TDCSGate*.*

Proof. The gate requires sound theorem-DNA, hence SoundTheoremFlow for the displayed theorem candidate. Sound theorem flow contains proof-sound theorem recognition. Legal code without proof-sound recognition therefore fails the gate. The GroundCompiler theorem `theorem_code_is_not_proof` records the checked separation. □

↪ variant `BEDC.GroundCompiler.TheoremGenerated.theorem code is not proof`

Theorem 9460.14 (Anchoring prevents locus hiding)**.** *In a carrier passing* TDCSGate*, theorem-DNA loci such as proof, certificate, ledger, status, site, and seal cannot be supplied by a hidden table or external oracle.*

Proof. The gate requires anchored theorem-DNA. Therefore every locus subflow must be a source subflow of the displayed theorem candidate $T_x = \mathsf{toEventFlow}(x)$. Hidden tables and external oracles are not source subflows of T_x. □

9460.5 Score and discovery

Definition 9460.15 (DNA mutation inside the gate)**.** *For a fixed displayed theorem candidate* T_x*, a DNA mutation is a passage*

$$D_R(T_x) \rightsquigarrow D'_{R'}(T_x)$$

between two anchored sound theorem-DNA packets.

Theorem 9460.16 (Complexity reduction does not imply discovery)**.** *A mutation can reduce theorem-DNA score while leaving the theorem classifier phenotype unchanged.*

Proof. A proof-locus replacement may reduce proof mass while preserving statement, dependencies, certificate, ledger, status, canonical site, closing seal, and phenotype. With positive proof weight the score decreases, but no classifier shift has occurred. □

Theorem 9460.17 (Classifier shift need not reduce score)**.** *A classifier-shifting mutation can fail to reduce theorem-DNA score.*

Proof. A mutation that changes the theorem classifier phenotype may introduce larger certificate, ledger, seal, or recognizer loci. Under nonnegative weights these additional loci can keep the score unchanged or increase it. □

Principle 9460.18 (TDCSGate adequacy)**.** *The theorem-DNA scoring TasteGate admits only carriers whose displays are canonical, field-faithful, nontrivial, theorem-DNA complete, anchored, sound, and accompanied by a public complexity score certificate.*

Concretized in §545: TasteGate admission packets supply the carrier-facing display and readback side consumed by TDCSGate.

*Concretized in §**??**:* Theorem-flow recognition packets supply the eight-locus theorem-DNA side consumed by TDCSGate.

Concretized in §7240: The proof entropy ledger realizes theorem-DNA locus masses, public weight profiles, and score-bound nonescape as finite NameCert data.

Chapter 9461

Self-Reference in BEDC: The Ground Loop, the Reflection, and the Reflection Limit

This chapter answers one question: in what precise senses does BEDC describe itself, and where does each sense fail? The answer is two-fold and the asymmetry between the two halves is the main mathematical content. At the ground, the primitive distinction between two raw marks is *self-instantiating*: stating it is already an act of it. This is a closed loop, and it must close for the rest of BEDC to begin. At the meta-level, the naming-certificate framework can internally describe the structure of any well-founded formal system, the host calculus of inductive constructions included. This second loop must remain open: closing it would, by Tarski undefinability, force inconsistency.

The two loops together characterise what kind of foundation BEDC is. The chapter develops them in turn. section 9461.1 isolates the ground loop. section 9461.2 establishes the correspondence between formal definition and classifier choice. section 9461.3 interprets closed inductive types as classifier closures inside BEDC. section 9461.4 extends the interpretation to a structural copy of the host calculus. section 9461.5 fixes the Tarski-Münchhausen boundary. section 9461.6 contrasts the closed ground loop with the open meta loop and locates BEDC's specific contribution to foundations.

9461.1 The primitive distinction as generative loop

Definition 9461.1 (Form of distinction)**.** *Let* b0 *and* b1 *denote the two raw marks of Definition 2.1. The* form of distinction *is the closed inductive judgment generating* Mark*, given by the two formation rules of chapter 2 together with the kernel-level recognition that* b0 *and* b1 *are not the same constructor. The form is the data of: two formal tokens, and the capacity to tell them apart.*

Remark 9461.2 (Self-instantiation)**.** *The form of distinction is self-instantiating. Stating that the constructors* b0 *and* b1 *are different requires, on the part of the reader, the very capacity that the statement introduces: the capacity to distinguish two formal tokens. The act of writing down the inductive declaration is itself an act of distinction. This is the position taken by G. Spencer-Brown in* Laws of Form*: any formal system requires an irreducible primitive whose existence is given simultaneously with the act of using it. The primitive cannot be derived, only enacted.*

Theorem 9461.3 (Irreducibility of the form of distinction)**.** *No formal definition expressible inside BEDC reduces the form of distinction to anything strictly simpler. Every classifier on every BEDC carrier presupposes the form of distinction in its very statement: deciding whether two carrier elements lie in the same class is an instance of the form applied to that carrier.*

Lean4✓ `BEDC.Reflection.form of distinction irreducible proof`

↪ variant `BEDC.Reflection.form of distinction irreducible`

Sketch. A classifier $\sim$ on a carrier G assigns each $g \in G$ to an equivalence class. To assign is to decide, for each pair (g, g'), whether $g \sim g'$ holds. This decision is itself an act of distinction applied to the elements of G. Were the form of distinction reducible to a strictly simpler primitive P, the decision $g \sim g'$ would have to be expressible as an application of P alone; but P would itself, by the same argument, require deciding whether two of *its* input forms are the same, which is again the form of distinction. The regress terminates only when the form is taken as primitive. □

Remark 9461.4 (Productive loop, not vicious loop)**.** *A self-referential construction is* vicious *if its unrolling fails to terminate, producing an inconsistent or non-well-founded definition. The form of distinction is* productive*: a single application yields the two raw marks, after which all further structure is well-founded above. The host kernel rejects vicious self-reference at the level of* `def` *and* `theorem` *(a definition whose body refers to itself fails the well-foundedness check). It accepts the form of distinction at the* `inductive` *level, because at that level there is no body to refer to itself: the constructor declaration is the kernel's primitive notion of inductive type, not a derived definition. The closed loop is built into the kernel's syntactic primitives; only above the kernel do non-well-founded loops become detectable as errors.*

Remark 9461.5 (Why this loop must close)**.** *The form of distinction is the only loop in BEDC that is required to close. Every other layer is built by classifier-based well-founded recursion above it; if any of those layers contained a loop, the host kernel would reject the construction. The closed ground loop is the price of starting at all: any formal foundation that begins from absolutely nothing must, at its first move, supply the capacity that the move uses. BEDC pays this price once and at the smallest possible size.*

9461.2 Definition as classifier

Definition 9461.6 (Definition presented as a classifier)**.** *Let G be a generator base in the BEDC primitive layer (a closed inductive over* Mark*,* Hist*,* Bundle*,* Sig*, or* psame*). A* definition presented as a classifier on G *is a pair* $(\mathsf{Ext}, \mathsf{Cont})$ *together with a naming certificate over* $(G, \mathsf{Ext}, \mathsf{Cont})$ *in the sense of chapter 9. The classifier* $\sim_{(\mathsf{Ext},\mathsf{Cont})}$ *on G assigns to each $x \in G$ the equivalence class* $\{y \in G \mid \mathsf{Ext}\, x \Leftrightarrow \mathsf{Ext}\, y$ *and* $\mathsf{Cont}\, x \sim_{\mathsf{hsame}} \mathsf{Cont}\, y\}$.

Theorem 9461.7 (Definition-classifier correspondence)**.** *Let D be a predicate on a BEDC carrier G equipped with a naming certificate whose classifier preserves the carrier. Suppose that $D(x)$ is exactly the assertion that x lies in G and carries an* Ext/Cont *presentation, and suppose that the classifier transports the* Ext/Cont *presentation data. Then the classifier transports D. Conversely, two D-elements that are internally the same history are classifier-equivalent. Thus a definition over the primitive layer is precisely a carrier predicate together with stable extension-continuation presentation data.*

Lean4✓ `BEDC.Reflection.definition classifier correspondence proof`

↪ variant `BEDC.Reflection.definition classifier correspondence`

Sketch. Unfold the presentation of D. From $D(h)$ one obtains both $G(h)$ and an $\mathsf{Ext}/\mathsf{Cont}$ witness for h. The naming certificate transports $G(h)$ across any classifier edge $h \sim k$, while the stated stability of the presentation transports the $\mathsf{Ext}/\mathsf{Cont}$ witness to k. Folding the presentation of D gives $D(k)$. For the converse direction, internal sameness identifies the two histories; reflexivity of the naming certificate on the carrier part of D gives the required classifier judgment. □

Remark 9461.8. *The naming-certificate framework was originally introduced as a discipline against ad-hoc definition (definitions whose closure properties cannot be exhibited). Definition 9461.7 reverses the framing: the discipline is in fact a complete characterisation. There is no formal definition over BEDC primitives that is not expressible as a naming certificate.*

9461.3 Internalisation of inductive structure

Definition 9461.9 (Generator-closure classifier of an inductive)**.** *Let T be a closed inductive type with constructors $c_1, \ldots, c_n$ over input families $A_1, \ldots, A_n$. The* generator-closure classifier *of T is the minimal classifier $\sim_T$ on the disjoint union $\bigsqcup_i A_i$ such that for each constructor c_i and each pair of inputs $a, a' \in A_i$ with $a \sim_T a'$ componentwise, the witnesses $c_i(a)$ and $c_i(a')$ name the same equivalence class. The classifier reflects the inductive's recursor: any function $T \to X$ extends a $\sim_T$-respecting cocone over the constructor inputs.*

Theorem 9461.10 (Inductive types as classifier closures)**.** *Every BEDC carrier equipped with a naming certificate, a constructor-step carrier law, and classifier preservation of generated extension membership has a stable generator closure. If $\mathsf{ConstructorClosed}(h)$ is exactly the subpredicate of carrier elements that arise as one Ext step from some source, then $\mathsf{ConstructorClosed}$ is preserved by the classifier, and every carrier element has a primitive constructor successor in $\mathsf{ConstructorClosed}$. This is the kernel-level classifier closure underlying the interpretation of closed inductive types as generated classifier closures.*

Lean4✓ BEDC.Reflection.inductive as classifier closure proof

↪ *variant BEDC.Reflection.inductive as classifier closure*

Sketch. Unfold $\mathsf{ConstructorClosed}(h)$ as $\mathsf{Carrier}(h)$ together with an Ext witness into h. Classifier stability follows by combining the naming certificate's carrier transport with the explicit preservation of generated Ext membership. The constructor successor clause follows from the carrier's constructor-step law and the generated rules $\mathsf{Ext}(h, \mathsf{b0}, \mathsf{E0}(h))$ and $\mathsf{Ext}(h, \mathsf{b1}, \mathsf{E1}(h))$. The categorical reading is that the constructor-generated part of the carrier is the BEDC classifier closure used to interpret the inductive signature. □

9461.4 BEDC describing its own meta-system

Theorem 9461.11 (Internal description of the calculus of inductive constructions)**.** *Inside the BEDC layer there exists a structure* CIC**, given as an iterated naming certificate over a generator base of W-type-shaped inductives and a hierarchy of universe classifiers, such that* CIC* *is structurally isomorphic to the calculus of inductive constructions hosting BEDC. The isomorphism preserves type formation, dependent function formation, inductive type formation, and the recursor for each inductive.*

Lean4✓ BEDC.Reflection.internal cic interpretation proof

↪ *variant BEDC.Reflection.internal cic interpretation*

Sketch. The W-type-shaped generators are the BEDC inductives whose constructor signatures are themselves indexed by BEDC carriers. The universe hierarchy is encoded by stratifying the W-types by the size of the constructor input. Type formation, dependent function formation, and inductive formation each correspond to a closure under a specific functor, and each functor admits a naming certificate by Definition 9461.10. Recursors arise as the universal arrows out of the corresponding initial algebras. The structural isomorphism is the assembly of these componentwise correspondences. □

Corollary 9461.12 (BEDC self-description)**.** *For every formal claim φ provable in the calculus of inductive constructions about inductive types, there exists an internal claim φ^*, expressible inside BEDC over the structure* CIC* *of Definition 9461.11, that is provable from the naming-certificate framework alone. In particular, every theorem in this manuscript admits an internal restatement inside BEDC.*

Lean4✓ `BEDC.Reflection.bedc self description proof`

↪ variant `BEDC.Reflection.bedc self description`

Sketch. Apply Definition 9461.7 to translate each formal definition appearing in φ into a naming certificate over the appropriate generator. Apply Definition 9461.10 and Definition 9461.11 to interpret the inductive types appearing in φ as classifier closures inside CIC*. Each proof step in φ corresponds to a closure axiom of one of the naming certificates so produced. The translation respects well-foundedness because each classifier inherits the form of distinction at its base. □

9461.5 The reflection limit

The internalisation results of section 9461.4 are, structurally, complete: the BEDC layer has the expressive power to describe the meta-system that hosts it. Two boundaries on this self-description nevertheless remain, and both are intrinsic to any formal system possessing the same expressive power.

Remark 9461.13 (Structure-existence boundary)**.** *The internal* CIC* *of Definition 9461.11 is a* structural *reproduction of the host calculus. It is not the host calculus considered as a runtime: every Lean proof of every theorem appearing in this manuscript is checked by an external Lean kernel, which is itself implemented in a programming language whose semantics is not BEDC-internal. The isomorphism between* CIC* *and the host CIC holds at the level of formal structure; it does not hold at the level of executing the structure. No formal system can include the runtime that interprets it. This boundary is the formal content of the Münchhausen impossibility: the bootstrap remains open at the runtime level even when it is closed at the structural level.*

Remark 9461.14 (Tarski undefinability)**.** *The self-description of Definition 9461.12 is a description of the formal structure of BEDC inside BEDC; it is not a definition of a BEDC truth predicate inside BEDC. By Tarski undefinability, every formal system rich enough to describe its own syntactic structure cannot define its own truth predicate. BEDC is no exception, and Definition 9461.12 does not attempt this. Recovering truth requires a metalanguage strictly stronger than the language being described, and that metalanguage is again hosted externally.*

9461.6 The two loops of BEDC

Theorem 9461.15 (Closed ground loop and open meta loop)**.** *The form of distinction (Definition 9461.1, Definition 9461.3) is a closed self-referential primitive: writing the inductive con-*

structor declaration is itself an act of distinction, and the loop closes at this single layer with no further regress. The reflection map CIC → CIC* *(Definition 9461.11, Definition 9461.12) is an open self-description: by Definition 9461.13 and Definition 9461.14, the host kernel running BEDC remains external to* CIC*. *The closed loop and the open loop are not in tension: they live at different levels, and consistency requires precisely that the ground close and that the meta not.*

Lean4✓ `BEDC.Reflection.two loops theorem proof`

↪ variant `BEDC.Reflection.two loops theorem`

Remark 9461.16 (Why both polarities are necessary)**.** *A formal system in which the ground does* not *close cannot start: the first primitive would itself require a prior primitive, with no termination of the regress. A formal system in which the meta-level* does *close — that is, a system that can both describe its own syntactic structure and define its own truth predicate — is inconsistent by Tarski undefinability. BEDC therefore needs both polarities: the closed ground loop to bootstrap, and the open meta loop to remain consistent. The polarities are dual: one closes precisely so the other can stay open.*

Remark 9461.17 (BEDC's specific contribution to foundations)**.** *Every formal foundation carries an irreducible ground loop. Set-theoretic foundations couple sets and membership and leave the coupling implicit in the surrounding informal practice. Type-theoretic foundations couple type, term, and judgmental equality similarly. BEDC's contribution is to make the ground loop minimal and explicit: a single closed inductive declaration with two constructors, no implicit pairing, no surrounding informal practice required to interpret the primitive. The loop is taken as bedrock and left there; everything else is built on top by classifier-based well-founded recursion. This is what allows BEDC to truthfully claim zero axioms: the irreducible primitive is the constructor declaration itself, not a deductive axiom in the inferential sense, and the classifier framework over it generates the entire derived horizon without further foundational assumptions. Reading the manuscript backward from the present chapter, every later chapter is the unrolling of this single primitive distinction through a tower of well-founded classifiers, and the form of distinction at the base remains the only loop the project ever closes.*

Remark 9461.18 (Incompleteness as downstream of the ground loop)**.** *Gödel's first incompleteness theorem is the canonical instance of an open meta loop: a sufficiently expressive formal system can encode its own syntax via a fixed numbering, define a provability predicate over that encoding, and produce a self-referential formula whose unprovability is the incompleteness witness. The construction depends, at every step, on the system's capacity to distinguish formal tokens: numbers from non-numbers, formulas from non-formulas, proofs from non-proofs. Tracing this dependency to its origin yields the form of distinction (Definition 9461.1). Gödel's argument typically takes natural-number arithmetic as its substrate of distinguishable tokens; arithmetic itself rests on an inductive declaration of* Nat *with two constructors, which is the classifier closure (Definition 9461.9) of a single instance of the form of distinction. BEDC isolates this ancestry: the limit theorems of formal mathematics — incompleteness, Tarski undefinability, Münchhausen impossibility — are downstream consequences of the same closed ground loop that BEDC takes as its primitive. They are not independent constraints; they are the open-meta-loop side of the closure that lets formal systems start at all. Read this way, BEDC's claim is not that it escapes Gödel but that it makes the irreducible primitive on which Gödel-type results depend explicit and minimal: a single inductive declaration of two raw marks, one closed loop, no further regress.*

Remark 9461.19 (Distinction from a Hofstadter strange loop)**.** *Reflective self-description as exhibited above is sometimes confused with a Hofstadter-style strange loop, in which a system levels*

itself through self-reference. The two are formally distinct. A strange loop in the formal sense identifies the describing layer with the described layer; this immediately produces inconsistency by Tarski's argument. The BEDC reflection of Definition 9461.12 stratifies: the description of CIC* *lives strictly above the BEDC primitive layer, and the host kernel checking the description lives strictly above the description. Each layer talks only about layers strictly below itself. The Lean kernel enforces this stratification physically: a definition whose body refers to itself is rejected as not well-founded before it can compromise the system. The single exception is the form of distinction at the ground, where there is no body to refer to itself — only a constructor declaration whose existence is the kernel's primitive notion of inductive type. Strange loops in the philosophical sense (descriptive feedback through art, music, or self-aware cognition) do not have this kernel-level guarantee and are therefore not reproducible inside a formal system without losing consistency.*

Remark 9461.20 (Reasoning patterns and axioms as meta-closure entries)**.** *The two-loops structure also classifies the proof patterns and axioms BEDC accepts versus rejects. Proof of negation, double-negation elimination on a decidable proposition, and refutation of a false existence claim by exhibited counterexample stay within the closed ground loop and BEDC accepts them. Proof of an existence statement by contradiction does not: it requires the law of excluded middle on the existential, which is decidability of a fragment of the truth predicate, which by Tarski's argument is read here as a meta-closure move. The three axiom families BEDC refuses — the axiom of choice, quotient soundness, and propositional extensionality — are placed by chapter 9387 in a taxonomy of unwitnessed closure shapes at the term, type or classifier, and proposition strata. That taxonomy is an audit reading, not a proof that the host axioms are equivalent to BEDC ontic collapses. Halting decidability (chapter 9368) is treated as a related recursion-theoretic boundary. The full chapters chapter 9458 and chapter 9387 record these classifications; the present remark uses them as interpretive companions to the two-loops theorem (Definition 9461.15). BEDC's axiom-purity gate is therefore not a list of three orthogonal disciplinary refusals but a sorted refusal of unledgered meta closure.*

9461.7 Position of this chapter in the BEDC architecture

The reflection results of this chapter are not used by any other BEDC construction; they sit at the top of the dependency tower and are read after the rest of the manuscript. Their role is auditative: they establish that the apparatus of naming certificates, classifier closures, and primitive inductives is expressive enough to describe its own logical form, that the ground loop the project relies on is exactly one and is taken explicitly at the smallest possible size, and that the meta-level reflection of the host calculus stops at the Tarski-Münchhausen boundary common to all sufficiently expressive formal systems. Together with the orientation discipline of chapter 1 and the kernel boundary of chapter 14, they complete the meta-architectural triangle: the project knows what it is built on, what it is bounded by, and what it can say about itself.

Concretized in §1038: Tarski truth-refusal is realized as a finite NameCert packet separating CIC-star sentence codes from any internal truth predicate.

Definition 9461.21 (Runtime candidate over CIC*)**.** *Let* CIC* *be the internal structure of Definition 9461.11. A* runtime candidate *over* CIC* *is a derived BEDC interface* $\mathsf{NameCert}_R$ *whose source specification* $\mathsf{SourceSpec}_R$ *consists of coded* CIC* *expressions, proof objects, and states; whose pattern specification* $\mathsf{PatternSpec}_R$ *records a checking or evaluation transition; whose classifier specification* $\mathsf{ClassifierSpec}_R$ *groups rows with the same accepted result; and whose ledger policy* $\mathsf{LedgerPolicy}_R$ *records which coded claims are accepted by the candidate.*

Theorem 9461.22 (Structure-existence boundary)**.** *For every runtime candidate* $\mathsf{NameCert}_R$ *over* CIC**,* $\mathsf{NameCert}_R$ *remains an object-level derived interface. Its validation is not one of its own* $\mathsf{SourceSpec}_R$*,* $\mathsf{PatternSpec}_R$*,* $\mathsf{ClassifierSpec}_R$*,* $\mathsf{StabilityCert}_R$*, or* $\mathsf{LedgerPolicy}_R$ *fields. Consequently the isomorphism between* CIC* *and the host calculus closes only the structural interpretation of type formation, dependent function formation, inductive formation, and recursors; it does not identify* CIC* *with the external host kernel that checks BEDC proofs.*

Proof. By Definition 9461.11, the internal structure CIC* preserves the formation rules and recursors of the host calculus. These are structural data. By chapter 14, an evaluator, proof checker, or runtime is not a primitive in the finite-kernel chain, and by Definition 1.1 the explanatory notions of proof, model, and checking are not object-language primitives. Therefore any internal BEDC occurrence of such a runtime must enter as a derived interface, and by Definition 9.9 it must be licensed as a naming certificate of the form fixed in Definition 9.6.

Unfold such a certificate as $\mathsf{NameCert}_R = (\mathsf{SourceSpec}_R, \mathsf{PatternSpec}_R, \mathsf{ClassifierSpec}_R, \mathsf{StabilityCert}_R, \mathsf{LedgerPoli}$ Each field is object-level data: source rows, observed transition behavior, a classifier, stability witnesses, and a ledger. The judgment that these five fields are themselves a correct checker for BEDC is not one more source row or one more accepted output of the candidate; it is the validation of the certificate as a certificate. Placing that validating judgment into the ledger only produces a further coded claim whose own ledger correctness must again be validated. Thus internalizing a runtime candidate yields another BEDC object to be checked, not the checking act that licenses it.

The self-description of Definition 9461.12 changes only the input side of this argument: it supplies internal restatements of BEDC claims over CIC*. It does not turn the external host execution that accepts the manuscript's proofs into a field of the internal structure. If the ledger of $\mathsf{NameCert}_R$ were strengthened to return BEDC truth for every internally described BEDC sentence, then the self-description would compose with that ledger to give an internal BEDC truth predicate, which is exactly the obstruction recorded in Definition 9461.14. Hence CIC* exists as a structural copy of the host calculus, while the host runtime remains external. □

Definition 9461.23 (Truth-total reflection certificate)**.** *Let* $\mathsf{Sent}(\mathrm{CIC}^*)$ *be the BEDC-internal carrier of sentence codes supplied by the structural interpretation of Definition 9461.11. A* truth-total reflection certificate *is a naming certificate* $\mathsf{NameCert}_T$ *over* $\mathsf{Sent}(\mathrm{CIC}^*)$ *with an extension predicate* Ext_T *such that every sentence* φ *represented in* CIC* *satisfies*

$$\mathsf{Ext}_T(\ulcorner\varphi\urcorner) \Longleftrightarrow \varphi.$$

The left-to-right implication is internal soundness for the code, and the right-to-left implication is internal completeness for the code. The certificate is therefore stronger than the structural copy of Definition 9461.11: it does not only describe formation and recursor structure, but classifies the BEDC sentence represented by each code.

Theorem 9461.24 (Exact boundary of reflection)**.** *BEDC has a closed ground self-instantiation and no truth-total meta self-instantiation. Concretely, the ground side has exactly the two generated marks* $\mathsf{b0}$ *and* $\mathsf{b1}$*, exactly the two positive primitive mark-sameness judgments* $\mathsf{msame}(\mathsf{b0}, \mathsf{b0})$ *and* $\mathsf{msame}(\mathsf{b1}, \mathsf{b1})$*, and no generated cross-mark sameness. On the meta side, no truth-total reflection certificate of Definition 9461.23 exists for* CIC**.*

Proof. The ground claim is closed generation. By Definition 2.1, the only raw mark forms are $\mathsf{b0}$ and $\mathsf{b1}$. By Definition 2.3, the only primitive positive mark-sameness judgments are $\mathsf{msame}(\mathsf{b0}, \mathsf{b0})$

and $\mathsf{msame}(\mathsf{b1}, \mathsf{b1})$. By Definition 2.9, no generated mark-sameness judgment crosses the two constructors. Since Definition 1.1 and Definition 1.2 place no object-language mathematical primitive before Mark, and Definition 9.9 forces every later derived interface to enter through a $\mathsf{NameCert}$, this is the only closed primitive loop available at the ground.

For the meta claim, suppose that a truth-total reflection certificate $\mathsf{NameCert}_T$ exists. The structure CIC* of Definition 9461.11 supplies an internal structural copy of the host calculus, and Definition 9461.12 supplies internal restatements of formal claims over that structure. Hence the diagonal construction for the one-variable formula $\neg\mathsf{Ext}_T(x)$ is available at the structural level named by Definition 9461.14. Let δ be the represented sentence satisfying

$$\delta \iff \neg\mathsf{Ext}_T(\ulcorner\delta\urcorner).$$

Truth-totality of $\mathsf{NameCert}_T$ also gives

$$\mathsf{Ext}_T(\ulcorner\delta\urcorner) \iff \delta.$$

Combining the two equivalences yields

$$\mathsf{Ext}_T(\ulcorner\delta\urcorner) \iff \neg\mathsf{Ext}_T(\ulcorner\delta\urcorner).$$

The left-to-right direction turns any witness of $\mathsf{Ext}_T(\ulcorner\delta\urcorner)$ into a refutation of the same witness, so $\neg\mathsf{Ext}_T(\ulcorner\delta\urcorner)$ holds. Applying the right-to-left direction to this refutation gives a witness of $\mathsf{Ext}_T(\ulcorner\delta\urcorner)$, contradicting the refutation just obtained. Therefore $\mathsf{NameCert}_T$ cannot exist.

Thus the reflection boundary is exact: the constructor-level distinction closes at Mark, while structural self-description stops before an internal truth classifier. □

Definition 9461.25 (Gödel boundary surface)**.** *A* Gödel boundary surface *for a BEDC fragment F is a finite certificate interface over sentence codes, proof-checker rows, fixed-point rows, and continuation routes satisfying the following visibility clauses.*

1. *The fragment has a displayed ground distinction inherited from* Mark *and* Hist*.*
2. *The fragment has a structural self-description sufficient to code its own sentence and proof rows inside* CIC*.
3. *The fragment exposes a proof predicate or runtime predicate only through displayed* $\mathsf{NameCert}$*,* Ext*,* Cont*,* hsame*, and ledger rows.*
4. *The fragment contains no truth-total reflection certificate in the sense of Definition 9461.23 and no global halting predicate in the sense of Definition 9368.2.*

The surface is therefore not an oracle for truth, provability, or termination. It is the finite place where syntax, proof checking, fixed-point coding, and diagonal refusal are all visible at once.

Theorem 9461.26 (Gödel boundary as truth-total refusal)**.** *For any BEDC fragment F admitting the self-description clauses used in Definition 9461.12, the existence of a universal internal certificate classifying truth for all represented F-sentences would produce a truth-total reflection certificate of Definition 9461.23. Hence every such fragment has a Gödel boundary surface: it may display sentence codes, proof-checker rows, fixed-point rows, and finite obstruction ledgers, but it cannot export a universal internal classifier for truth, provability, certificate validity, or arbitrary halting behavior.*

Proof. Assume that F has a universal internal truth classifier U over its represented sentence codes. The self-description result Definition 9461.12 interprets the relevant formal claims of F inside CIC*, and the classifier U supplies the extension predicate that decides each represented sentence. Repacking U as $\mathsf{NameCert}_T$ gives exactly the data required by Definition 9461.23: for every represented sentence φ,

$$\mathsf{Ext}_T(\ulcorner\varphi\urcorner) \iff \varphi.$$

But Definition 9461.24 proves that no such $\mathsf{NameCert}_T$ exists. Therefore the universal internal truth classifier cannot exist.

The same obstruction transfers to provability, certificate validity, and halting whenever they are promoted from displayed finite ledgers to total internal classifiers over the certificate-of-certificates stratum. A total provability-validity classifier would make the fixed-point sentence decide its own proof status inside the same represented fragment. A total halting classifier would decide the Cont-behavior of arbitrary certificate-history pairs and would close the meta loop described in Definition 9368.4. In each case the attempted classifier occupies the same structural role as $\mathsf{NameCert}_T$: it turns self-description plus a diagonal row into a total meta-level decision. Since the reflection boundary refuses that role, the admissible object is only the finite boundary surface of Definition 9461.25. □

Corollary 9461.27 (Finite incompleteness packets are boundary witnesses)**.** *The packet surfaces* $\mathsf{TruthTotalReflection}^{\uparrow}$*,* $\mathsf{TarskiTruthRefusal}^{\uparrow}$*,* $\mathsf{HaltingObstruction}^{\uparrow}$*, and* $\mathsf{GoedelIncompleteness}^{\uparrow}$ *are finite boundary witnesses rather than escapes from incompleteness. They record sentence-code rows, attempted classifier rows, fixed-point or diagonal rows, finite trace rows, transport, provenance, and local naming; they do not provide an internal truth predicate, a total halting predicate, a proof-validity oracle, or a proof of the fragment's own global consistency.*

Proof. The $\mathsf{TruthTotalReflection}^{\uparrow}$ packet records sentence-code, extension-attempt, diagonal, transport, route, provenance, and naming rows; by Definition 9461.24 those rows cannot be read as a truth-total classifier. The $\mathsf{TarskiTruthRefusal}^{\uparrow}$ packet records the narrower refusal row for an attempted truth query and its diagonal pressure, so it witnesses the Tarski side of the same boundary. The $\mathsf{HaltingObstruction}^{\uparrow}$ packet records finite traces, self-reference rows, diagonal policies, and provenance; by Definition 9368.4, turning those rows into a total halting decision would close the forbidden meta loop. The $\mathsf{GoedelIncompleteness}^{\uparrow}$ packet records a recursively enumerated axiom row, proof-checker decoder, fixed-point row, and conditional no-proof plus no-refutation ledger; its closurestatus explicitly keeps semantic completeness, second incompleteness, ω-consistency, and set-theoretic foundation bridges outside its claim surface.

Thus all four packets have the same logical shape. They make the obstruction auditable as finite BEDC data, while the total classifier that would erase the obstruction remains unavailable. □

Concretized in §472: Truth-total reflection is represented by a finite boundary certificate over CIC-star sentence codes and diagonal obstruction rows.

Concretized in §288: Goedel incompleteness is realized as a finite boundary packet over arithmetised provability, fixed-point rows, and conditional undecidability ledgers.

Concretized in §470: This chapter concretizes the reflection-limit boundary as a countable-name certificate whose runtime and truth rows remain external to the finite stream packet.

Concretized in §586: Reflection-limit boundaries are realized as finite BHist NameCert packets separating closed ground-loop rows from open meta-loop truth rows.

Concretized in §591: Runtime candidates over CIC-star are realized as finite NameCert boundary packets separating object-level transition rows from host validation.

Concretized in §818: Finite trace evaluators realize runtime candidates as bounded object-level trace packets whose validation remains outside the packet.

Concretized in §997: finite runtime checkpoint packet for reflection-limit validation boundaries

Concretized in §674: Ground-loop boundary packets realize the closed Mark-level distinction and the open meta-truth refusal as finite BHist, hsame, Cont, Pkg, and NameCert rows.

Concretized in §890: Runtime reflection boundaries are realized as finite packets separating structural self-description from external kernel execution.

Concretized in §1028: Runtime/truth separation is realized as a finite NameCert packet separating structural CIC-star rows from external runtime and truth-validation rows.

Concretized in §6540: ArithmetizedProvabilityUp realizes the Godel-numbering and proof-predicate dependency as finite proof-code, formula-code, derivation-check, substitution, transport, replay, provenance, and NameCert rows.

Concretized in §7390: ProofTraceCompactnessUp realizes the finite proof-trace compact replay route as NameCert data.

Concretized in §5122: Legitimate claim audit ledgers realize the meta-foundations claim-discipline route as finite refusal, proof-target, audit, provenance, and NameCert rows.

Chapter 9462

Auditable Generativity: A BEDC Philosophy

This philosophy directory records the structural reading of BEDC as a theory of generated, classified, ledgered, and certified names. The chapters below treat philosophical claims as disciplined readings of kernel signatures, certificate interfaces, and explicit boundary tags, without presenting them as additional Lean-checked targets.

9462.1 Distinction and History

BEDC philosophy is the disciplined reading of the following generative chain:

$$\mathsf{Mark} \to \mathsf{Hist} \to \mathsf{hsame} \to \mathsf{Ext/Cont} \to \mathsf{Ask/Sig} \to \mathsf{Pkg/Gap} \to \mathsf{NameCert} \to \text{mature interface.}$$

The reading does not add a metaphysics to the finite kernel. It asks which entities may be called objects, knowledge, observation, subject, time, world, causality, consciousness, or boundary, once every such claim is forced to pass through generated histories, licensed classifiers, witness ledgers, and naming certificates.

Definition 9462.1 (Auditable generativity)**.** *Auditable generativity is the position that every mature object is a licensed name rather than a primitive, every item of knowledge is a traceable witness rather than bare possession of truth, every observer is a history rather than a hidden substance, every time parameter is history growth rather than an external container, and every commitment exceeding a closed substrate must be exposed as a* Gap *or boundary position rather than consumed as an internal theorem.*

Theorem 9462.2 (Philosophy is not an additional layer)**.** *The philosophical reading of BEDC is a consequence of the kernel signature and certificate discipline, not an auxiliary doctrine placed above them.*

Proof. The continuation relation has only history-valued endpoints, the kernel identity criterion for histories is internal history-sameness, and the forward direction of continuation is fixed by the constructive formation of histories. A separate observer-substance, a global truth predicate, or an unledgered mature object would require a carrier or transport not supplied by the kernel. The philosophical reading is therefore obtained by spelling out which commitments are already encoded by the available signatures and which commitments must remain outside the object layer as exposed boundary positions. □

9462.1.1 Primitive distinction

Definition 9462.3 (Primitive marks)**.** *The primitive marks of BEDC are two emission results, denoted* $\mathsf{b0} : \mathsf{Mark}$ *and* $\mathsf{b1} : \mathsf{Mark}$*. They are not natural numbers, truth values, Boolean objects, or elements of a presupposed set. They are only the minimal object-language marks from which distinguishable emission histories may be generated.*

Definition 9462.4 (Primitive distinction)**.** *The primitive distinction is the closed mark-level separation between* $\mathsf{b0}$ *and* $\mathsf{b1}$*: the internal sameness relation generates the diagonal judgments for each mark and does not generate a cross-mark sameness judgment. Philosophically, the point is not that two prior objects are given, but that distinguishability itself is the lowest condition of later object formation.*

Theorem 9462.5 (Primitive distinction is irreducible)**.** *The primitive distinction cannot be reduced inside BEDC to a simpler internal structure.*

Proof. Any proposed reduction would have to say how a lower structure distinguishes inputs from outputs, success from failure, and the same case from a different case. That act of discrimination already presupposes a distinction. Iterating the reduction therefore either never starts or accepts a lowest closed discrimination. BEDC takes the mark-level constructor separation as that closed ground loop. □

Corollary 9462.6 (Distinction precedes information)**.** *Information is not prior to distinction in BEDC.*

Proof. Information requires that one state, mark, or trace be separable from another. Without the mark-level separation there is no separation between the two history constructors, hence no recorded sequence, no classifier output, and no ledgered information. Distinction is therefore a precondition for information rather than a species of information. □

Corollary 9462.7 (The starting point is not a thing)**.** *The ontological starting point of BEDC is not an object, set, subject, or proposition, but recordable distinguishability.*

Proof. Objects require identity conditions. Identity conditions require a contrast between sameness and difference. The mark layer supplies that contrast before mature objects are licensed. Hence objects arise only after distinction has entered histories and certificates. □

9462.1.2 Mark sameness

Definition 9462.8 (Internal mark sameness)**.** *The relation* $\mathsf{msame}(m, n)$ *is the object-language sameness judgment for marks. It is generated by the two diagonal cases for* $\mathsf{b0}$ *and* $\mathsf{b1}$*, with no constructor producing* $\mathsf{msame}(\mathsf{b0}, \mathsf{b1})$ *or* $\mathsf{msame}(\mathsf{b1}, \mathsf{b0})$*.*

Definition 9462.9 (Internal sameness is not host equality)**.** *The relation* msame *is an internal BEDC judgment. It is not host definitional equality, not set-theoretic equality, and not an unrestricted external equality oracle.*

Theorem 9462.10 (Mark sameness is reflexive)**.** *For every generated mark* m*, the judgment* $\mathsf{msame}(m, m)$ *is generated.*

Proof. The closed mark carrier has only the two generated marks. In the $\mathsf{b0}$ case the corresponding diagonal rule gives $\mathsf{msame}(\mathsf{b0}, \mathsf{b0})$; in the $\mathsf{b1}$ case the corresponding diagonal rule gives $\mathsf{msame}(\mathsf{b1}, \mathsf{b1})$. □

Theorem 9462.11 (Mark sameness is symmetric and transitive)**.** *The internal mark-sameness judgment is symmetric and transitive.*

Proof. Every generated mark-sameness derivation is diagonal. Reversing a diagonal judgment gives the same diagonal judgment, so symmetry holds. Composing two generated judgments through a middle mark can only remain on the same diagonal, so transitivity holds. □

Theorem 9462.12 (Mark no-confusion)**.** *BEDC does not generate a cross-mark sameness judgment between* b0 *and* b1*.*

Proof. The generation rules for msame contain only the diagonal judgments. There is no cross-mark constructor and no closure rule that converts a diagonal judgment into a cross-mark judgment. □

Corollary 9462.13 (Primitive marks are not completed Booleans)**.** *The primitive marks must not be read as an already available Boolean interface.*

Proof. A Boolean interface is a mature data interface with its own carrier, classifier, stability behavior, and naming certificate. The primitive marks are earlier than such an interface. Reading them directly as Booleans would import a mature object at the ground layer instead of deriving it through the certificate discipline. □

Concretized in §1244: Primitive distinction ledgers realize mark-level no-confusion, trace exposure, and anti-Boolean refusal as one finite NameCert packet.

9462.1.3 History formation

Definition 9462.14 (Histories)**.** *The carrier* Hist *is generated by the empty history* e *and the two extension constructors* E0 *and* E1*. The public reading is that* e *records no distinction, while* E0(h) *and* E1(h) *record one additional mark-shaped emission above* h*.*

Definition 9462.15 (Information content of a history)**.** *The information content of a history is the finite distinction trace recovered by recursion on its generated form. The empty history has the empty trace; an* E0*-extension appends the* b0*-shaped tag; an* E1*-extension appends the* b1*-shaped tag. These tags are metalinguistic readings of constructor shape, not imported natural numbers or Boolean values.*

Theorem 9462.16 (Histories are finitely generated)**.** *Every generated history is obtained from* e *by finitely many applications of* E0 *and* E1*.*

Proof. The closed formation rules for Hist provide only the empty constructor and the two extension constructors. Following the constructor tree of any generated history downward therefore reaches e after finitely many predecessor steps. □

Corollary 9462.17 (No external history in the kernel)**.** *There is no kernel history not generated by* e*,* E0*, and* E1*.*

Proof. An external history would require an additional constructor or an additional import rule. Neither is part of the closed kernel carrier. □

Theorem 9462.18 (The empty history is a zero-information boundary)**.** *The empty history records no distinction.*

Proof. By the recursion defining history information content, e is the base case and contributes no constructor tag. It is therefore the boundary at which no distinction has yet entered a history. □

Corollary 9462.19 (Nontrivial information requires extension)**.** *Any history with nonempty information content has the form* $\mathsf{E0}(k)$ *or* $\mathsf{E1}(k)$ *for some history* k*.*

Proof. If a history is e, its information content is empty. Every generated nonempty history must therefore arise by one of the two extension constructors. □

9462.1.4 History sameness

Definition 9462.20 (Internal history sameness)**.** *The judgment* $\mathsf{hsame}(h, k)$ *is the object-language sameness relation for histories. It is generated by the empty diagonal case and by constructor-respecting closure through* E0 *and* E1*. It has no generation rule comparing an empty history with an extension, or an* E0*-extension with an* E1*-extension.*

Definition 9462.21 (History identity)**.** *The identity of a history, inside BEDC, is its internal history sameness profile. It is not supplied by a host equality oracle.*

Theorem 9462.22 (History sameness is reflexive)**.** *For every generated history* h*, the judgment* $\mathsf{hsame}(h, h)$ *is generated.*

Proof. Induct on the generated form of h. The empty case is the empty diagonal rule. The E0 and E1 cases follow by applying the corresponding constructor-respecting closure to the induction hypothesis. □

Theorem 9462.23 (History sameness is symmetric and transitive)**.** *The internal history-sameness judgment is symmetric and transitive.*

Proof. Symmetry follows by induction on the generated sameness derivation: the empty case reverses to itself, and each constructor-respecting case uses the induction hypothesis below the same constructor. Transitivity follows by induction on one sameness derivation and inversion on the other; the closed generation rules permit only matching constructors, after which the induction hypothesis composes the predecessor judgments. □

Theorem 9462.24 (History no-confusion)**.** *The kernel does not generate history-sameness judgments between* e *and an extension, nor between an* E0*-extension and an* E1*-extension.*

Proof. The generation rules for hsame contain only the empty diagonal, the E0-respecting closure, and the E1-respecting closure. None of these generates a cross-shape judgment. □

Corollary 9462.25 (History identity is constructor-shape identity)**.** *An internal sameness judgment between two* E0*-extensions must come from an internal sameness judgment between their predecessors, and similarly for two* E1*-extensions.*

Proof. This is the inversion principle for the two constructor-respecting generation rules of hsame. □

9462.1.5 Minimal information carrier

Definition 9462.26 (Binary-distinction information carrier)**.** *A binary-distinction information carrier is a carrier that represents two different step shapes and finite traces assembled from those steps.*

Theorem 9462.27 (Hist is the minimal binary-distinction carrier)**.** *The carrier* Hist *is the minimal BEDC carrier for binary-distinction information.*

Proof. Hist has exactly an empty origin and two extension shapes, so it can record every finite trace of two mark-shaped distinctions. Removing the empty origin leaves no start for trace formation. Removing either extension shape destroys binary distinction. Identifying the two extension shapes violates history no-confusion and erases the difference to be recorded. Thus any weaker carrier fails to represent binary-distinction information. □

Corollary 9462.28 (Information requires history)**.** *Every nontrivial item of information available to the BEDC object layer must leave a trace in a history or in a derived ledger certified from histories.*

Proof. Nontrivial information requires a distinction, and a usable distinction must enter a generated trace or a certified structure derived from such a trace. A classifier, signature, or naming certificate may organize the trace, but it does not bypass the historical condition. □

Corollary 9462.29 (No bare information)**.** *BEDC does not accept information that is unhistoried, unwitnessed, and unledgered.*

Proof. If the purported information is usable in the object layer, it must be distinguishable from its absence or from a different information item. That distinction must be recorded or certified. If it enters neither a history nor a derived ledger, the object layer has no licensed way to consume it. □

9462.1.6 Prefix order and the preparatory form of time

Definition 9462.30 (Distinction step)**.** *A distinction step is a single application of* E0 *or* E1 *to a history.*

Definition 9462.31 (History prefix)**.** *A history p is a prefix of a history h when h is obtained from p by a finite trace of distinction steps.*

Concretized in §1241: History prefixes are isolated as finite BHist prefix certificates feeding countable-name observations.

Theorem 9462.32 (History generation carries a prefix order)**.** *Every nonempty generated history has a direct predecessor shape, and that predecessor is its immediate prefix.*

Proof. By closed generation, a nonempty history is either an E0- or E1-extension of a predecessor. History no-confusion prevents the two shapes from being internally identified and prevents either shape from being internally identified with e. The outer constructor therefore determines the direct predecessor shape. □

Corollary 9462.33 (Histories are not sets)**.** *Histories are generated traces, not sets of already available elements.*

Proof. Set-theoretic reading begins from a domain of elements and membership. BEDC begins from a generated empty history and constructor growth. History identity is governed by constructor shape and internal hsame, not by external membership. □

Corollary 9462.34 (The lowest form of time is history growth)**.** *Once a distinction step is read as history growth, the lowest form of time is already present.*

Proof. Time minimally requires before and after. In the kernel, before and after first appear as the generated movement from a predecessor history to an E0- or E1-extension. This gives the preparatory form later made explicit by the continuation relation. □

9462.1.7 Extension, continuation, and unfolding

Definition 9462.35 (Extension step)**.** *An extension step is a generated relation instance*

$$\mathsf{Ext}(\mathsf{b0}, h, \mathsf{E0}(h)) \qquad \textit{or} \qquad \mathsf{Ext}(\mathsf{b1}, h, \mathsf{E1}(h)).$$

It records one visible mark-shaped passage from a source history to a result history. It is read as a relation instance, not as an imported primitive function on histories.

Definition 9462.36 (Continuation trace)**.** *A continuation trace is a finite relation witness built from the empty continuation and the visible* b0*- and* b1*-steps. It records a finite route from one history to another through generated history growth.*

Theorem 9462.37 (Extension is singleton continuation)**.** *Each extension step is the one-step case of continuation.*

Proof. An extension by b0 produces the same result shape as the continuation step whose visible tail is the singleton E0(e). The b1 case is identical with E1(e). Thus extension supplies the visible one-step boundary, while continuation iterates the same generated passage. □

Definition 9462.38 (Record unfolding)**.** *A record unfolding is a passage from a finite record of histories to a larger finite record obtained by adding histories reachable from the displayed record through extension or continuation traces, while keeping the carrier, classifier, certificate fields, and ledger policy fixed.*

Definition 9462.39 (Classifier shift)**.** *A classifier shift occurs when the public classifier surface changes: the admitted source rows, classifier relation, stability witness, ledger policy, or naming certificate no longer has the same extension as before the passage under consideration.*

Theorem 9462.40 (Unfolding does not by itself shift a classifier)**.** *Record unfolding can lengthen the visible history record without changing the classifier surface.*

Proof. By Definition 9462.38, the passage adds only histories already reachable by the fixed extension or continuation relations. The carrier, classifier, stability witness, ledger policy, and naming certificate are held fixed. Therefore the passage supplies more displayed route material but does not by itself alter the public classifier surface. □

Corollary 9462.41 (History growth is not theoretical discovery)**.** *Increasing the length of a history record is not, by itself, a theoretical discovery.*

Proof. A theoretical discovery in this reading requires a classifier shift or a certificate-strengthening row. By Definition 9462.40, record unfolding can increase visible route material while preserving the same classifier surface. Hence history growth alone is insufficient. □

Corollary 9462.42 (Verified unfolding remains an unfolding fact)**.** *Formal verification of an unfolding theorem hardens the stated route claim; it does not convert fixed-classifier computation into classifier shift.*

Proof. A formal verifier accepts a proof object for a formal statement about the displayed route. If the statement concerns only record growth under the fixed carrier, classifier, stability witness, and ledger policy of Definition 9462.38, the accepted proof hardens that route statement without changing the classifier surface. □

9462.1.8 Synthesis

Definition 9462.43 (Distinction-history chain)**.** *The distinction-history chain is the path from primitive mark separation, through internal mark sameness and no-confusion, to generated histories, internal history sameness, and recoverable information content.*

Theorem 9462.44 (Distinction generates history, history carries information)**.** *In BEDC, the lowest auditable form of information is a finite history generated from primitive distinction.*

Proof. Primitive marks supply the first separation. Internal mark sameness and mark no-confusion provide the object-language identity profile for that separation. The constructors `e`, `E0`, and `E1` record the separation into finite histories. Internal history sameness and history no-confusion preserve the generated shape of those records. History information content is then recovered as the finite trace of recorded distinctions. Therefore the first auditable information in the object layer is generated history. □

Corollary 9462.45 (Ontology begins with recordable distinction)**.** *The first ontological commitment of BEDC is not that things exist, but that distinctions can be recorded.*

Proof. Mature objects require naming certificates; naming certificates require source, pattern, classifier, stability, and ledger fields; those fields ultimately depend on generated histories and the distinction structure that histories record. Hence object talk is downstream from recordable distinction. □

Corollary 9462.46 (Passage to continuation)**.** *After distinction enters history, the next philosophical question is continuation, because a history is not merely a static trace but a trace capable of generated extension.*

Proof. The history carrier records distinction. To account for observation, time, action, and object formation, the framework must also account for the passage from one history to another. That passage is exactly the role of `Cont` at the next layer. □

9462.2 Classifier-Shift Information

Concretized in §6985: The classifier-shift ledger residue packet realizes before and after classifier disagreement, source overlap, residue ledger, and discovery-status rows as finite NameCert data.

Concretized in §8519: Classifier-shift discovery gates are realized as finite before/after classifier, witness-flow, semantic-certificate, weight-profile, refusal, transport, replay, provenance, and NameCert rows.

The preceding distinction-history layer separates generated record growth from classifier change. This section names the corresponding information principle: information growth in the auditable-generativity reading is not the mere accumulation of outputs, traces, activations, or notational variants. It is a certified change in the classifier surface under which generated material is organized.

Definition 9462.47 (Certified classifier state)**.** *A certified classifier state is a tuple*

$$\mathcal{T} = (S_{\mathcal{T}}, P_{\mathcal{T}}, L_{\mathcal{T}}, C_{\mathcal{T}}, N_{\mathcal{T}})$$

where $S_{\mathcal{T}}$ is the source specification, $P_{\mathcal{T}}$ is the pattern specification, $L_{\mathcal{T}}$ is the ledger policy, $C_{\mathcal{T}}$ is the classifier relation on the source material, and $N_{\mathcal{T}}$ is the naming certificate or semantic certificate licensing the state.

Definition 9462.48 (Classifier equivalence)**.** *Two certified classifier states $\mathcal{T}$ and $\mathcal{T}'$ are classifier-equivalent on their common source when every pair of histories admitted by both source specifications receives the same classifier judgment from $C_{\mathcal{T}}$ and $C_{\mathcal{T}'}$.*

Definition 9462.49 (Classifier shift)**.** *A passage $\mathcal{T} \to \mathcal{T}'$ has classifier shift when the two states are not classifier-equivalent on their common source. The shift may appear as refinement, coarsening, or reorganization of the classifier cells, but it must be witnessed on the public classifier surface rather than inferred from record length, notation, or fluency.*

Definition 9462.50 (Structural discovery)**.** *A structural discovery is a passage to a certified classifier state $\mathcal{T}'$ such that the passage has classifier shift, the target state has a ledger witness for its admitted material, and the changed classifier is actually used on the displayed record or certificate surface.*

Theorem 9462.51 (Discovery requires classifier shift)**.** *Every structural discovery has classifier shift.*

Proof. Classifier shift is one of the defining fields of Definition 9462.50. A passage that preserves the same classifier on the common source may improve presentation, coverage of displayed routes, or verification status, but it has not changed the classifier surface that organizes the material. □

Theorem 9462.52 (Discovery requires certificate and ledger)**.** *Every structural discovery carries both a certificate for the resulting classifier state and a ledger witness for the material it classifies.*

Proof. The target of a structural discovery is a certified classifier state, so its tuple contains the certificate component $N_{\mathcal{T}'}$. The definition also requires a ledger witness. Without the certificate, the changed classifier is only an asserted relation; without the ledger, the source, hidden material, projection, compression, and boundary behavior are not auditable. □

Corollary 9462.53 (Record growth is not discovery)**.** *A record-only passage is not a structural discovery.*

Proof. A record-only passage preserves the certified classifier state while adding more displayed material under that state. By Definition 9462.51, structural discovery requires classifier shift, so record growth alone is insufficient. □

Corollary 9462.54 (Presentation change is not discovery)**.** *Changing notation, proof organization, naming style, or exposition is not by itself a structural discovery.*

Proof. Presentation changes can alter how a state is read without changing the source specification, classifier relation, certificate fields, or ledger policy. Such a passage is classifier-equivalent on the common source and therefore lacks classifier shift. □

Definition 9462.55 (Boundary, bridge, and unification discovery)**.** *Classifier-shift discovery has three recurring modes. Boundary discovery exposes a principled obstruction to strengthening a classifier. Bridge discovery connects previously separated classifier states through a certified relation. Unification discovery replaces several classifier states by a single certified state whose classifier surface accounts for their shared behavior.*

Theorem 9462.56 (Formal hardening is not classifier shift)**.** *Formal verification of a statement or certificate component does not by itself create classifier shift.*

Proof. Formal verification changes the audit status of a statement or proof object. If the source specification, classifier relation, certificate fields, and ledger policy remain the same, the certified classifier state is classifier-equivalent to its prior state on the common source. The verification may increase reliability, but the classifier surface has not changed. □

Theorem 9462.57 (Classifier-shift information principle)**.** *In the auditable-generativity reading, theoretical information growth is read from certified classifier shift rather than from output length, record count, feature count, notation change, or verification status alone.*

Proof. Output length and record count are governed by record unfolding, which can preserve the same classifier. Notation and presentation changes can preserve classifier equivalence. Formal hardening can preserve the same classifier while changing only audit status. By contrast, structural discovery requires a changed classifier together with certificate and ledger witnesses. Hence the auditable unit of theoretical information growth is certified classifier shift. □

9462.2.1 Compression, ledger, and conservation

Definition 9462.58 (Compression map)**.** *For a finite family of histories X, a compression map is a displayed map $q : X \to Y$ into a representation carrier Y. The map induces the classifier*

$$x \sim_q x' \quad \Longleftrightarrow \quad q(x) = q(x').$$

Definition 9462.59 (Hidden residue)**.** *The hidden residue of a compression map $q : X \to Y$ is the family of distinction pairs collapsed by the representation:*

$$\mathsf{Res}(q) = \{(x, x') \in X \times X : \ x \neq x' \text{ and } q(x) = q(x')\}.$$

Definition 9462.60 (Ledger-complete compression)**.** *A compression map is ledger-complete when it carries a ledger Λ_q whose recorded rows cover the hidden residue of q. A ledger gap is a collapsed distinction in $\mathsf{Res}(q)$ not recorded by Λ_q.*

Definition 9462.61 (Certified compression)**.** *A certified compression is a compression map equipped with source, pattern, compression-induced classifier, stability, and ledger rows sufficient to license the compressed representation as a certificate surface.*

Theorem 9462.62 (Compression is classifier formation)**.** *Every compression map induces a classifier on its source family.*

Proof. The relation $\sim_q$ is reflexive, symmetric, and transitive because it is defined by equality of the displayed representation $q(x)$. Thus the compression map partitions its source family into representation cells. □

Theorem 9462.63 (Certified compression requires ledger coverage)**.** *A certified compression has no unrecorded hidden residue.*

Proof. By Definition 9462.61, the compression certificate includes a ledger row. By Definition 9462.60, the ledger row must cover every collapsed distinction in $\mathsf{Res}(q)$. Any unrecorded collapsed distinction would be a ledger gap, so the compression would not be certified. □

Corollary 9462.64 (Shorter presentation is not certified gain)**.** *A shorter representation is not by itself a certified information gain.*

Proof. Shortening can be achieved by collapsing distinctions. By Definition 9462.63, a certified compression must account for the collapsed distinctions through its ledger. The representation length alone therefore does not determine the certified gain. □

Theorem 9462.65 (Information conservation for compression)**.** *The auditable gain of a compression claim is read only after subtracting ledger cost, certificate cost, verification cost when claimed, and ledger debt for unrecorded residue from the apparent description gain.*

Proof. Apparent description gain records only the shorter representation. A certificate must also expose source, pattern, classifier, stability, and ledger rows. When a formal verification claim is made, the proof-checking work is part of the audit cost. When hidden residue is not recorded, the claim carries ledger debt. Omitting any of these terms would treat hidden material as free information, contrary to the certificate discipline. □

Corollary 9462.66 (Compression discovery requires classifier shift)**.** *A compression is a structural discovery only when it changes the certified classifier surface and supplies the corresponding certificate and ledger rows.*

Proof. Same-classifier compression may reduce description cost, but it remains classifier-equivalent on the common source. By Definition 9462.51, structural discovery requires classifier shift, and by Definition 9462.52, it also requires certificate and ledger witnesses. □

9462.2.2 Machine-learning reading

For a learned model, additional activations, candidate features, lower training loss, or more examples do not automatically constitute interpretability discovery. They become interpretability-relevant only when they change a certified classifier state: the activation source, the feature pattern, the induced classifier, the stability account, and the ledger must be displayed. Dimensionality reduction, feature clustering, pruning, and model compression are likewise compression maps: they must record hidden residue before they can count as closed explanations. This is the philosophy-side counterpart of section 9398.2: a learned tensor distinction can propose a classifier, but interpretability information is certified only when that classifier is named, stabilized, ledgered, and auditable.

Concretized in §6241: Classifier-novelty ledgers realize classifier-shift information by finite source, classifier, changed-cell witness, ledger, transport, provenance, and NameCert rows.

9462.3 Distinction-to-NameCert Certification

The distinction-history and classifier-shift layers identify the route from generated marks to certified classifier states. This section names the mediating certification layer. BEDC does not treat a stable distinction, a feature label, a proof trace, or a model behavior as an auditable object merely because it is visible. The object is licensed only when the candidate classifier is carried by a NameCert surface with source, pattern, classifier, stability, and ledger rows.

Definition 9462.67 (Generated material)**.** *Generated material is any finite record produced by the mark-history, event-flow, proof-trace, tensor-trace, or activation-trace interfaces. It is material for certification, not a certified object by itself.*

Definition 9462.68 (Candidate classifier)**.** *A candidate classifier on a generated-material family G is a displayed relation C on G that proposes which records are to be read as the same for the purpose at hand. It may arise from history sameness, continuation behavior, compression cells, tensor activation patterns, neural features, empirical clusters, proof traces, or certificate structure.*

Definition 9462.69 (Certified classifier object)**.** *A certified classifier object is a pair (C, N) where C is a candidate classifier and N is a NameCert for C. The certificate has the five-field form*

$$N = (S_C, P_C, C, \Sigma_C, L_C),$$

where S_C is the source specification, P_C is the pattern specification, Σ_C is the stability certificate, and L_C is the ledger policy.

Theorem 9462.70 (Candidate classifiers are not certified objects)**.** *A candidate classifier without a NameCert is not a certified classifier object.*

Proof. By Definition 9462.69, a certified classifier object is a pair (C, N) with a NameCert component N. A bare candidate classifier supplies only the relation C. It does not supply source, pattern, stability, or ledger rows, so it does not satisfy the defining form of a certified classifier object. □

Corollary 9462.71 (Stable behavior is not objecthood)**.** *Stable behavior in histories, tensor traces, activations, or proof records is not by itself a BEDC object.*

Proof. Stable behavior may support a candidate classifier, but Definition 9462.70 requires a NameCert before that classifier has certified object status. □

Theorem 9462.72 (NameCert licenses classifier objecthood)**.** *If a candidate classifier C carries a NameCert N, then (C, N) is a certified classifier object.*

Proof. The conclusion is exactly the construction named in Definition 9462.69. The NameCert provides the rows that make the classifier auditable: source, pattern, classifier, stability, and ledger. □

Theorem 9462.73 (No ledger, no closed certificate)**.** *A certificate surface without a ledger policy is not a closed NameCert.*

Proof. The ledger policy is one of the five required rows in Definition 9462.69. Without it, hidden material, projection residue, compression residue, failure cases, and not-claimed boundaries have no audit row. The certificate surface is therefore incomplete. □

Corollary 9462.74 (Single-field claims are not NameCerts)**.** *Source-only, pattern-only, classifier-only, stability-only, and ledger-only claims are not NameCerts.*

Proof. Each such claim omits at least one required field from the five-field certificate surface. A source row without a classifier does not say what relation is licensed; a pattern row without a source does not say where it applies; a classifier row without stability does not say how it is transported; a stability row without ledger does not expose what it hides; and a ledger row without classifier does not identify the relation being audited. □

9462.3.1 Semantic Assignment

Definition 9462.75 (Semantic assignment)**.** *A semantic assignment maps classifier cells or public marks to an external meaning space, such as truth values, numbers, concept labels, model behaviors, or mathematical objects.*

Definition 9462.76 (Certified semantic assignment)**.** *A semantic assignment is certified when the assignment itself carries a NameCert specifying its source, pattern, classifier, stability, and ledger rows.*

Theorem 9462.77 (Semantic readings require certification)**.** *A semantic reading of a mark, history, tensor feature, or classifier cell is not licensed by the reading alone.*

Proof. The reading supplies an external label or interpretation. It does not thereby expose the source on which the reading acts, the pattern that supports it, the classifier relation it respects, the stability witness under transport or perturbation, or the ledger of hidden and excluded material. Those rows are supplied only by a certificate. □

Corollary 9462.78 (Feature labels are not explanations)**.** *Calling a neural feature by a concept label is not yet a certified explanation.*

Proof. The label is a semantic assignment. By Definition 9462.77, the assignment must be certified before it can serve as an auditable explanation. □

Theorem 9462.79 (Meaning is certificate-derived)**.** *Within the BEDC certificate reading, meaning is derived from certified semantic assignment rather than present as a primitive mark property.*

Proof. The primitive display contains marks, histories, generated material, and candidate distinctions. External meaning enters through semantic assignment. Since a semantic assignment is licensed only through Definition 9462.76, certified meaning is a derived certificate object. □

9462.3.2 Hardening

Definition 9462.80 (Certificate hardening)**.** *Certificate hardening is the passage in which one or more certificate rows are supported by a stronger evidence form, such as a formal proof object accepted by a verification backend, while the classifier surface being certified remains identified.*

Theorem 9462.81 (Hardening does not create the NameCert layer)**.** *Formal hardening can strengthen certificate rows, but it does not by itself create a complete NameCert.*

Proof. A verifier accepts a proof object for a translated formal statement. That acceptance may harden a source, classifier, stability, or boundary claim. It does not automatically supply the remaining NameCert rows. The certificate layer therefore remains distinct from the verification layer. □

Corollary 9462.82 (Verified components are not whole explanations)**.** *A verified statement inside an explanation is not the same as a certified explanation.*

Proof. By Definition 9462.81, verification hardens the component it checks. A certified explanation still requires the complete source, pattern, classifier, stability, and ledger surface. □

Theorem 9462.83 (Certificate hardening is not classifier shift)**.** *Certificate hardening does not by itself constitute classifier shift.*

Proof. Hardening changes the evidence status of one or more rows. If the classifier relation on the common source remains the same, the public classifier surface has not shifted. This is the certificate-layer form of Definition 9462.56. □

Theorem 9462.84 (Certification-layer theorem)**.** *BEDC forms a certification layer between generated behavior and optional formal hardening: candidate distinctions are organized as candidate classifiers, NameCert rows license them as certified classifier objects, and verification hardens only the translated rows it actually checks.*

Proof. Candidate distinctions and generated behavior supply material for classifiers by Definition 9462.68. Certified classifier objecthood requires the NameCert pair of Definition 9462.69. Formal hardening is separate by Definition 9462.81. Thus the certification layer is neither raw behavior nor the formal verification backend; it is the auditable NameCert surface between them. □

*Concretized in §**??**:* Distinction-to-NameCert certification realizes candidate classifiers, five-field NameCert rows, semantic-assignment licensing, hardening separation, and no-ledger refusal as finite certificate-layer packets.

Concretized in §7126: A finite distinction packet is certified as a NameCert boundary.

9462.4 Tensor NameCert

section 9462.3 describes the abstract passage from candidate classifiers to certified classifier objects. The tensor case is the machine-learning instance of that passage. A feature, direction, probe, sparse-autoencoder latent, attention pattern, or circuit score may expose a stable distinction, but it becomes an auditable explanation only when the induced classifier is licensed by a Tensor NameCert.

Definition 9462.85 (Tensor model context)**.** *A tensor model context consists of a model state, an input domain, an output interface, a displayed source domain, an allowed transformation family, and an observation protocol specifying which activation sites, hooks, data selections, and trace records are admitted.*

Definition 9462.86 (Activation source)**.** *An activation source is a specified layer, site, and recording mode together with the induced map*

$$a_A : X \to V_A.$$

Examples include residual-stream positions, attention-head outputs, MLP outputs, probe inputs, and sparse-autoencoder latent spaces, provided the observation protocol states how they are read.

Definition 9462.87 (Tensor classifier candidate)**.** *A tensor classifier candidate is a tuple* $C = (A, \phi, \tau, D)$ *where* A *is an activation source,* $\phi : V_A \to [0, 1]$ *is a feature functional,* $0 < \tau < 1$ *is a threshold, and* D *is the displayed source domain. It induces the relation*

$$x \sim_C y \quad \Longleftrightarrow \quad m_{\phi,\tau}(x) = m_{\phi,\tau}(y),$$

where $m_{\phi,\tau}(x)$ *is the thresholded public mark read from* $\phi(a_A(x))$*.*

Definition 9462.88 (Behavior support)**.** *For a behavior target* B*, a tensor classifier candidate* C *supports* B *when the classifier supplies a stated predictive, correlational, interventional, causal, formal, or hybrid account of that behavior. The support type is part of the certificate surface.*

Definition 9462.89 (Tensor NameCert)**.** *A Tensor NameCert for* $C = (A, \phi, \tau, D)$ *is the five-field packet*

$$\mathsf{NameCert}_{\text{tensor}}(C) = (S_C, P_C, \mathsf{ClassifierSpec}_C, \Sigma_C, L_C).$$

Here S_C *records model identity, activation source, source domain, trace protocol, feature source, threshold protocol, and behavior scope;* P_C *records positive, negative, boundary, margin, clustering, circuit, or soft-formula patterns;* $\mathsf{ClassifierSpec}_C$ *is the classifier relation induced by the thresholded marks;* Σ_C *records stability and transfer evidence; and* L_C *records threshold debt, boundary cases, false positives, false negatives, entanglement, untested domain, proxy risk, source leakage, and not-claimed behavior.*

Definition 9462.90 (Tensor-certified explanation)**.** *A tensor-certified explanation is a tuple*

$$(C, \mathsf{NameCert}_{\text{tensor}}(C), B)$$

where C *supports the behavior target* B *and the Tensor NameCert is displayed.*

Theorem 9462.91 (Tensor NameCert instantiates NameCert)**.** *Every Tensor NameCert is an instance of the BEDC NameCert surface.*

Proof. The abstract surface of Definition 9462.69 has source, pattern, classifier, stability, and ledger rows. The Tensor NameCert of Definition 9462.89 supplies exactly those rows in the tensor-model context. Thus the tensor packet is a machine-learning instance of the same certificate form. □

Theorem 9462.92 (Feature functionals are not explanations)**.** *A tensor feature functional* $\phi : V_A \to [0, 1]$ *is not by itself a tensor-certified explanation.*

Proof. The functional supplies only a score map. It does not identify the activation source, threshold, source domain, behavior support, classifier relation, stability witness, or ledger policy. Those rows are required by Definition 9462.90. □

Corollary 9462.93 (Top activations are not explanations)**.** *Lists of highly activating examples, feature labels, or visualization snippets are not tensor-certified explanations.*

Proof. Such records can support the pattern row of a Tensor NameCert, but they do not supply the whole source, classifier, stability, and ledger surface. By Definition 9462.92, the feature evidence alone is insufficient. □

Theorem 9462.94 (Source ambiguity blocks tensor certification)**.** *If a tensor classifier candidate does not specify its model state, activation source, source domain, trace protocol, or threshold protocol, then it is not source-complete.*

Proof. Those entries are part of the source row S_C in Definition 9462.89. Omitting them leaves the classifier's domain of application and method of observation ambiguous, so the source row is incomplete. □

Theorem 9462.95 (Pattern evidence needs boundary evidence)**.** *Positive examples alone do not determine a Tensor PatternSpec.*

Proof. Positive examples show where a feature fires or where a classifier cell is populated. They do not identify negative cases, boundary cases, false positives, false negatives, entanglement, or stability under admissible transformations. Those rows are needed for the pattern and ledger surfaces. □

Theorem 9462.96 (Threshold selection is certificate data)**.** *Changing the threshold of a tensor classifier candidate can change its ClassifierSpec.*

Proof. The classifier relation is defined by equality of thresholded marks. A new threshold can move source records from one public mark side to the other, especially near the boundary. Hence threshold choice is not an implementation detail; it is certificate data. □

Theorem 9462.97 (Stability claims require mode and evidence type)**.** *Tensor stability claims are not auditable unless they declare both the stability mode and the evidence type.*

Proof. Feature stability, classifier stability, circuit stability, behavior stability, transfer stability, empirical stability, paper stability, and formal stability have different strengths. Without a declared mode and evidence type, an auditor cannot tell what is being claimed or how far it transports. □

Theorem 9462.98 (Tensor ledger gaps prevent closed explanation)**.** *A tensor-certified explanation is not closed when its ledger omits known or relevant boundary debt.*

Proof. The ledger row records threshold-sensitive cases, false positives, false negatives, source leakage, entanglement, untested regions, proxy behavior, and not-claimed boundaries. If relevant debt is omitted, the explanation hides part of the material compressed by the classifier. The certificate is therefore not closed. □

9462.4.1 Black-Box Resolution

Definition 9462.99 (Tensor black-box behavior)**.** *A behavior is tensor black-box behavior on a stated scope when it has a supporting tensor classifier candidate but no Tensor NameCert for that candidate on that scope.*

Theorem 9462.100 (Tensor NameCert resolves scoped black-box behavior)**.** *If a behavior target B is supported by a tensor classifier candidate C and C carries a Tensor NameCert on the stated scope, then B is no longer tensor black-box behavior on that scope.*

Proof. The black-box condition in Definition 9462.99 is the absence of a Tensor NameCert for the supporting candidate. Supplying that certificate removes the missing row on the stated scope. □

Corollary 9462.101 (Black-box resolution is classifier certification)**.** *Resolving tensor black-box behavior requires certifying the classifier that supports the behavior, not merely naming a feature.*

Proof. By Definition 9462.100, the resolving object is the Tensor NameCert for the supporting classifier. A feature label alone does not supply that certificate. □

9462.4.2 Hardening and Gain

Theorem 9462.102 (Formal hardening does not replace Tensor NameCert)**.** *Formal verification can harden selected Tensor NameCert fields, but it does not replace the Tensor NameCert.*

Proof. A formal proof object verifies a translated statement. It may harden a classifier law, a stability statement, or a boundary claim. It does not automatically supply the model source, activation protocol, pattern evidence, behavior support, or ledger rows. The Tensor NameCert remains the complete explanation surface. □

Theorem 9462.103 (Tensor explanations require net-gain audit when discovery is claimed)**.** *When a tensor-certified explanation is claimed as a discovery, the claim must account for classifier novelty, certificate cost, hardening cost when used, and ledger debt.*

Proof. Classifier novelty is required by Definition 9462.51. The certificate and hardening rows are costs of making the explanation auditable, and ledger debt records unclosed boundary material. Omitting these costs would treat hidden or unverified work as free information. □

Theorem 9462.104 (Tensor NameCert theorem)**.** *In the machine-learning reading, a feature becomes an auditable explanation only through the passage from tensor classifier candidate to Tensor NameCert, with source, pattern, classifier, stability, and ledger rows displayed.*

Proof. The feature functional alone is insufficient by Definition 9462.92. The candidate relation is specified by Definition 9462.87. The Tensor NameCert of Definition 9462.89 supplies the five rows needed for certified explanation, and Definition 9462.102 separates that surface from optional formal hardening. □

*Concretized in §**??**:* Tensor NameCert realizes activation-source, feature-functional, threshold, classifier, stability, ledger, behavior-support, black-box-resolution, and hardening-separation rows as finite certificate packets.

9462.5 Formal Verification as Hard-Certificate Layer

section 9462.4 separates tensor classifier certification from optional formal hardening. This section states the corresponding verification principle. Formal verification is a hard-certificate layer: it accepts proof objects for translated formal statements under a stated backend and trust boundary. It does not create the NameCert surface, does not replace the ledger, and does not by itself change the classifier being certified.

Definition 9462.105 (Verification backend)**.** *A verification backend is a tuple consisting of a formal language, a statement space, a proof-object space, a checker or kernel, an acceptance relation, and a trust boundary. We write*

$$\mathcal{V} \vdash \pi : \varphi$$

when the backend accepts proof object π for statement φ under that trust boundary.

Definition 9462.106 (Hard certificate)**.** *A hard certificate for a statement φ is the backend-relative record*

$$\mathrm{HardCert}_{\mathcal{V}}(\varphi) = (\mathcal{V}, \varphi, \pi, \mathsf{Trust})$$

together with the acceptance judgment

$$\mathcal{V} \vdash \pi : \varphi.$$

It certifies the formal statement relative to the backend, dependencies, assumptions, and trust boundary that appear in the record.

Definition 9462.107 (Verification ledger)**.** *A verification ledger records the backend, formal statement, proof artifact, assumptions, dependencies, trusted components, unchecked components, portability boundary, and the certificate fields not covered by the proof.*

Definition 9462.108 (Formal hardening)**.** *A NameCert row F is formally hardened when it is translated to a formal statement φ_F and a backend accepts a proof object for that statement:*

$$F \rightsquigarrow \varphi_F \qquad \text{and} \qquad \mathcal{V} \vdash \pi_F : \varphi_F.$$

A NameCert is partially hardened when only some rows are hardened; it is fully hardened only when every critical formalizable row is hardened and the remaining rows are covered by the ledger.

Theorem 9462.109 (Hard certificates are backend-relative)**.** *Every hard certificate is relative to a verification backend and trust boundary.*

Proof. By Definition 9462.106, the certificate record contains $\mathcal{V}$ and Trust. The accepted statement is therefore not a free-standing absolute object; it is a checked statement under the backend, assumptions, dependencies, and trusted components recorded by the verification ledger. □

Theorem 9462.110 (Hard certificates do not imply NameCerts)**.** *From $\mathcal{V} \vdash \pi : \varphi$ alone one cannot infer the existence of a NameCert for a classifier.*

Proof. The judgment gives a proof object for one formal statement. A NameCert requires source, pattern, classifier, stability, and ledger rows. The formal judgment may harden one of those rows, but it does not construct the whole five-field surface. □

Corollary 9462.111 (Verified theorem is not certified classifier)**.** *A checked theorem is not, by itself, a certified classifier.*

Proof. Certified classifier objecthood requires a candidate classifier paired with a NameCert. By Definition 9462.110, a checked theorem alone does not supply that pair. □

Theorem 9462.112 (NameCert existence does not require full formal hardening)**.** *A NameCert can exist even when some of its rows are supported by paper, empirical, or ledger evidence rather than formal proofs.*

Proof. The NameCert condition is that the source, pattern, classifier, stability, and ledger rows are displayed and auditable. Formal hardening is one possible evidence mode for a row, not the existence condition for the certificate surface. □

Theorem 9462.113 (Component hardening does not replace other rows)**.** *Hardening one certificate row does not harden or supply the other rows.*

Proof. The accepted proof object has target φ_F, the formal statement corresponding to row F. It says nothing by itself about a different source row, pattern row, classifier row, stability row, or ledger row unless those rows are explicitly included in φ_F. □

Corollary 9462.114 (Verified stability does not replace ledger)**.** *A verified stability claim does not replace the ledger policy.*

Proof. Stability and ledger are distinct rows. By Definition 9462.113, hardening a stability statement does not supply the boundary, failure, residue, trust, or not-claimed rows of the ledger. □

Theorem 9462.115 (Partial hardening is not full hardening)**.** *A partially hardened certificate is not fully hardened unless every critical unverified row is recorded in the ledger as outside the hardened scope.*

Proof. Full hardening requires coverage of all critical formalizable rows, with unhardened rows explicitly ledgered. If a critical row is neither hardened nor ledgered as outside scope, the certificate has a hardening gap and the full-hardening claim is not audit-complete. □

9462.5.1 Verification and Discovery

Definition 9462.116 (Verification-only transition)**.** *A verification-only transition is a passage from (C, N) to (C, N') in which the classifier C is unchanged and the difference is that one or more rows of the NameCert receive additional formal hardening.*

Theorem 9462.117 (Verification-only transitions preserve classifier surface)**.** *A verification-only transition does not create classifier shift.*

Proof. By definition, the classifier relation C is unchanged. The transition changes the evidence status of certificate rows, not the classifier surface on the common source. □

Corollary 9462.118 (Formal verification is not discovery by itself)**.** *Formal verification of a previously unchecked component is not by itself a structural discovery.*

Proof. Structural discovery requires classifier shift by Definition 9462.51. By Definition 9462.117, a verification-only transition preserves the classifier surface. □

Theorem 9462.119 (Hardening costs enter discovery accounting)**.** *When formal hardening is used to support a discovery claim, its cost is part of the certificate cost of that claim.*

Proof. Formal hardening consumes statement translation, proof construction, checking, dependency maintenance, trust-boundary auditing, and artifact transport. If those costs are omitted, the discovery ledger treats proof work as free information. The net-gain audit must therefore include the hardening cost when hardening supports the claim. □

9462.5.2 Verification Transparency

Theorem 9462.120 (Hard certificates require verification ledgers)**.** *A hard certificate without a verification ledger is not audit-complete.*

Proof. Because the hard certificate is backend-relative, an auditor must know which backend accepted the proof, which statement was checked, which dependencies and assumptions were used, which trust boundary was assumed, and which certificate rows were not covered. These are exactly the rows of Definition 9462.107. □

Corollary 9462.121 (Opaque verification is a black box)**.** *A claim that something is verified, without backend, statement, proof artifact, dependencies, and trust boundary, is itself a verification black box.*

Proof. The claim hides the data needed to audit what was checked and under what assumptions. By Definition 9462.120, the hard certificate is not audit-complete. □

Theorem 9462.122 (Verification does not automatically transfer across backends)**.** *A proof accepted by one backend is not automatically accepted by another backend.*

Proof. Backends may differ in language, kernel, proof-object format, axioms, libraries, and trust boundary. Transporting a verified result requires a new proof, a sound translation, or a transport certificate for the backend relation. Acceptance by the first backend alone does not supply those rows. □

Theorem 9462.123 (Machine-learning explanations may be hybrid)**.** *A tensor-certified explanation may combine formally hardened rows with empirical, paper, or ledger-supported rows.*

Proof. Tensor-certified explanation requires the Tensor NameCert surface of Definition 9462.89. Some of its rows may be translated into formal statements and checked; others may remain empirical or paper-level, provided their evidence type and boundary are recorded. Such an explanation is stronger than a ledger-only certificate in the hardened rows, but weaker than a fully hardened certificate. □

Theorem 9462.124 (Formal-verification layer theorem)**.** *Formal verification hardens certificate rows by producing backend-relative hard certificates with verification ledgers; it does not replace the NameCert layer, the ledger layer, or the classifier-shift condition for discovery.*

Proof. Hard certificates are backend-relative by Definition 9462.109. They do not imply NameCerts by Definition 9462.110. Their ledgers remain necessary by Definition 9462.120. Finally, verification-only transitions preserve classifier surface by Definition 9462.117. The formal-verification layer therefore hardens rows without replacing the certification, ledger, or discovery layers. □

Concretized in §8662: Hard-certificate layers realize backend-relative proof acceptance, verification ledgers, partial hardening, trust-boundary exposure, non-transfer across backends, and no-discovery-by-verification as finite NameCert rows.

9462.6 Hardenable and Ledger-Only Classifiers

section 9462.5 identifies formal verification as a hardening layer. This section records the corresponding classifier taxonomy. A certified classifier may be ledger-only, partially hardened, or fully hardened. Lack of formal hardening is not the same as lack of certification; lack of ledgered scope and boundary is the actual obstruction to closure.

Definition 9462.125 (Evidence mode)**.** *Each row of a NameCert has an evidence mode: empirical, paper, formal, hybrid, ledger-only, or open. The mode states how that row is supported and what kind of audit is available for it.*

Definition 9462.126 (Mode-complete NameCert)**.** *A NameCert is mode-complete when every source, pattern, classifier, stability, and ledger row declares an evidence mode and no row remains open.*

Definition 9462.127 (Mode gap)**.** *A mode gap is a NameCert row whose evidence mode is missing or open. Mode gaps prevent an auditor from determining whether the row is empirical, paper-level, formal, hybrid, ledger-only, or not yet closed.*

Theorem 9462.128 (Mode gaps prevent full auditability)**.** *A NameCert with a mode gap is not fully auditable.*

Proof. Full auditability requires knowing the evidence source and strength for each certificate row. If a row has no declared mode, the auditor cannot determine how the row is supported or whether it is closed. Thus the certificate remains audit-incomplete. □

Definition 9462.129 (Hardenable row)**.** *A NameCert row is hardenable relative to a backend $\mathcal{V}$ when it can be transcribed into a formal statement for that backend and the corresponding proof obligation is explicit. Hardenability is a possibility of formalization, not the existence of a proof object.*

Definition 9462.130 (Hardened row)**.** *A hardenable row is hardened relative to $\mathcal{V}$ when the backend accepts a proof object for its transcribed statement.*

Definition 9462.131 (Hardening frontier)**.** *The hardening frontier of a NameCert is the family of hardenable rows that have not yet been hardened. The non-hardenable residue is the family of rows that are not currently transcribable as formal proof obligations for the stated backend.*

Theorem 9462.132 (Hardened implies hardenable)**.** *Every hardened row is hardenable relative to the backend that hardens it.*

Proof. Hardening requires both a transcription to a formal statement and an accepted proof object for that statement. The transcription and proof obligation are exactly the data required for hardenability. □

Theorem 9462.133 (Hardenability is backend-relative)**.** *A row hardenable in one verification backend is not automatically hardenable in another.*

Proof. Backends may have different languages, libraries, kernels, axioms, proof styles, and available encodings. A row transcribable in one backend need not have a faithful or useful transcription in another. The backend must therefore be named in every hardenability claim. □

9462.6.1 Classifier Strength Classes

Definition 9462.134 (Ledger-only classifier)**.** *A ledger-only classifier is a Name-certified classifier whose NameCert is mode-complete, has no hardened rows, and records all non-hardenable residue in the ledger.*

Definition 9462.135 (Partially hardened classifier)**.** *A partially hardened classifier is a Name-certified classifier with at least one hardened row and at least one critical row that is either unhardened or ledger-only.*

Definition 9462.136 (Fully hardened classifier)**.** *A fully hardened classifier is a Name-certified classifier whose hardenable critical rows are hardened, whose non-hardenable residue is ledgered, whose verification ledger is complete, and whose NameCert is mode-complete.*

Definition 9462.137 (Critical hardening gap)**.** *A critical hardening gap is a critical hardenable row that is neither hardened nor recorded in the hardening frontier or ledger. A critical row is one whose absence or misclassification can change source scope, classifier relation, stability, ledger boundary, discovery status, or positive-gain accounting.*

Theorem 9462.138 (Fully hardened classifiers have no critical hardening gap)**.** *A fully hardened classifier has no critical hardening gap.*

Proof. By definition, every hardenable critical row is hardened, and every non-hardenable residue is ledgered. A critical row that were neither hardened nor recorded would violate one of those clauses. □

Theorem 9462.139 (Ledger-only classifiers can be certified objects)**.** *A ledger-only classifier can be a BEDC-certified object.*

Proof. Certified objecthood requires a classifier paired with a NameCert. A ledger-only classifier has a mode-complete NameCert and records its non-hardenable residue in the ledger. It lacks formal hardening, but formal hardening is not required for NameCert existence by Definition 9462.112. □

Corollary 9462.140 (No formal proof is not no certificate)**.** *A classifier may lack formal verification and still be certified by NameCert and ledger.*

Proof. This is the ledger-only case of Definition 9462.139. □

Theorem 9462.141 (Partial hardening strengthens only hardened rows)**.** *Moving from ledger-only to partially hardened status strengthens only the rows that are actually hardened.*

Proof. By Definition 9462.113, hardening one row does not supply or harden the other rows. The partially hardened classifier is stronger exactly where the proof object has been accepted. □

Theorem 9462.142 (Empirical stability is not ledger-only legitimacy)**.** *Empirical stability of a classifier candidate does not by itself make it a ledger-only classifier.*

Proof. Empirical stability may support a pattern or stability row. A ledger-only classifier also requires a full NameCert, declared evidence modes, ledgered non-hardenable residue, and no open mode gap. Empirical stability supplies only part of that surface. □

9462.6.2 Priority

Definition 9462.143 (Net hardening gain)**.** *The net hardening gain of a row is the audit, reliability, reuse, or transport value obtained by hardening it minus the modeling, proof, dependency, maintenance, and verification cost of doing so.*

Theorem 9462.144 (Not every hardenable row should be hardened immediately)**.** *Some hardenable rows have nonpositive net hardening gain.*

Proof. A row may be transcribable while its proof is costly, fragile, highly backend-specific, or low in reuse value. In such a case the hardening cost can exceed the audit gain. Hardenability is therefore a necessary condition for hardening, not a priority rule. □

Theorem 9462.145 (Ledger completion can outrank formal hardening)**.** *Completing the ledger can have higher priority than hardening a row.*

Proof. If the ledger has a critical boundary gap, the explanation may overclaim its scope. Hardening a local row that does not address that gap leaves the central audit risk unresolved. In that situation ledger completion has higher certificate value. □

9462.6.3 Machine-Learning Reading

Definition 9462.146 (Neural hardening profile)**.** *A neural hardening profile records, for a Tensor NameCert, the evidence mode of each row, the hardening frontier, the non-hardenable residue, the ledger status, the hardened rows, and the not-claimed boundary.*

Theorem 9462.147 (Neural explanations can be legitimate without full formalization)**.** *A neural explanation with a complete Tensor NameCert and ledgered non-hardenable residue can be legitimate even when it is not fully hardened.*

Proof. Legitimacy at the certification layer requires source, pattern, classifier, stability, and ledger rows with declared evidence modes. Fully formal hardening is a stronger status, but it is not the gate of NameCert existence. □

Theorem 9462.148 (Concept labels are ledger-only before semantic hardening)**.** *Natural-language concept assignments to neural features should be read as ledger-only components unless a formal semantics and proof are supplied.*

Proof. Natural-language concepts often have open boundaries, context dependence, and distributional sensitivity. They may be useful semantic assignments, but without formal semantics and proof they are not hardened rows. They can still be certified as ledgered semantic assignments with examples, counterexamples, scope, and not-claimed boundaries. □

Theorem 9462.149 (Ledger-only discovery candidates can be genuine candidates)**.** *A classifier transition with classifier shift, NameCert, and ledger may be a genuine discovery candidate even before formal hardening.*

Proof. Classifier-shift discovery requires a changed certified classifier surface and ledgered certificate support. Formal hardening increases strength, but it is not listed as an existence condition for classifier shift in Definition 9462.51. □

Theorem 9462.150 (Hardening taxonomy theorem)**.** *The certification layer distinguishes hardenable rows, hardened rows, and ledger-only rows; certified classifier status depends on NameCert and ledger completeness, while formal hardening determines a stronger audit grade within that certified status.*

Proof. The distinction follows from the definitions of hardenable row, hardened row, ledger-only classifier, partially hardened classifier, and fully hardened classifier. Definition 9462.139 shows that ledger-only certification can be object-forming, while Definition 9462.141 and Definition 9462.138 state the stronger hardening grades. □

*Concretized in §**??**:* Hardenable and ledger-only classifier packets realize evidence modes, hardening frontier, non-hardenable residue, ledger-only legitimacy, partial hardening, hardening priority, and neural hardening profiles as finite NameCert rows.

Concretized in §8206: Ledger-mode classifiers realize evidence-mode, mode-gap, hardening-frontier, and ledger-only residue rows as finite NameCert data.

9462.7 Black Box as Missing Certificate

section 9462.4 defines tensor black-box behavior in the machine-learning case. The general principle is broader: a black box is not absence of structure. It is supported behavior whose classifier surface has not yet received the NameCert and ledger rows needed for audit.

Definition 9462.151 (Behavior target)**.** *A behavior target is a displayed output, decision, refusal, error, transfer, safety, or generalization pattern on a stated behavior domain. It may be recorded as a relation, predicate, soft score, or finite evidence packet.*

Definition 9462.152 (Explanation candidate)**.** *An explanation candidate for a behavior target B is a pair (C, B) where C is a classifier candidate and C supports B by prediction, correlation, intervention, causal account, formal statement, or hybrid evidence.*

Definition 9462.153 (Certified explanation)**.** *A certified explanation for B is a tuple*

$$(C, \mathsf{NameCert}(C), B)$$

where C supports B and the NameCert has source, pattern, classifier, stability, and ledger rows for the stated scope.

Definition 9462.154 (Black-box behavior)**.** *A behavior target B is black-box behavior when it has a supporting classifier candidate but no NameCert for that candidate on the stated scope:*

$$\mathsf{BlackBox}(B) \iff \exists C.\, C \Vdash B \text{ and } \neg\exists N.\, N = \mathsf{NameCert}(C).$$

Definition 9462.155 (Unexplained behavior)**.** *A behavior target is unexplained when no supporting classifier candidate has been displayed for it.*

Definition 9462.156 (Closed explanation behavior)**.** *A behavior target is closed on a stated scope when it has a certified explanation whose ledger is complete on that scope.*

Theorem 9462.157 (Black boxes have support structure)**.** *Every black-box behavior has a supporting classifier candidate.*

Proof. The existence of a supporting classifier candidate is the first clause of Definition 9462.154. What is missing is not structure, but the certificate that licenses the structure. □

Theorem 9462.158 (Unexplained behavior is not black-box behavior)**.** *Unexplained behavior is distinct from black-box behavior.*

Proof. Unexplained behavior has no displayed supporting classifier candidate. Black-box behavior, by contrast, has such a candidate but lacks its NameCert. The two failure modes occur at different levels. □

Theorem 9462.159 (Closed explanation is not black box)**.** *A behavior target with a ledger-complete certified explanation is not black-box behavior on that scope.*

Proof. Black-box behavior requires absence of a NameCert for the supporting classifier. A ledger-complete certified explanation supplies that NameCert and its ledger on the stated scope, so the missing-certificate condition fails. □

9462.7.1 Certificate Deficits

Definition 9462.160 (Black-box type)**.** *A black-box type records which NameCert row is missing or incomplete: source, pattern, classifier, stability, ledger, or verification ledger. Multiple missing rows form a composite black box.*

Definition 9462.161 (Certificate deficit)**.** *For an explanation candidate (C, B), the certificate deficit is the set of missing or incomplete rows among source, pattern, classifier, stability, and ledger. A verification deficit is recorded separately when the explanation invokes a hard certificate without its verification ledger.*

Definition 9462.162 (Black-box debt)**.** *Black-box debt is the weighted cost of the certificate deficit for the best displayed supporting classifier candidate for B. Ledger deficits may receive greater weight because they can produce plausible but unbounded half-explanations.*

Theorem 9462.163 (Missing NameCert rows diagnose black boxes)**.** *If C supports B but one of the required NameCert rows is missing or incomplete, then the explanation is not closed.*

Proof. Closed explanation requires a complete NameCert and ledger on the stated scope. Omitting source, pattern, classifier, stability, or ledger leaves the certificate surface incomplete. The failure can therefore be diagnosed by the missing row. □

Theorem 9462.164 (Ledger black boxes are high-risk half-explanations)**.** *An explanation with source, pattern, classifier, and stability rows but without a ledger is not closed, even when it appears structurally rich.*

Proof. The first four rows can make the explanation appear complete: they name where it applies, what pattern is seen, what classifier is used, and why it is stable. Without the ledger, failure cases, hidden residue, false-positive and false-negative behavior, distribution boundary, and not-claimed scope are unaccounted for. The explanation is therefore a plausible half-explanation, not a closed one. □

Theorem 9462.165 (Closed explanations have zero certificate deficit)**.** *A ledger-complete certified explanation has zero certificate deficit on its stated scope.*

Proof. By definition, the certified explanation supplies every NameCert row and the ledger is complete on the scope. No required row is missing, so the deficit set is empty. □

Theorem 9462.166 (Black-box debt can decrease before closure)**.** *An explanation process can reduce black-box debt without yet producing a closed explanation.*

Proof. Supplying a source row, classifier row, negative examples, or stability witness removes part of the certificate deficit. If the ledger remains incomplete, the explanation is still not closed, but the debt has decreased. □

9462.7.2 Resolution

Definition 9462.167 (Black-box reduction)**.** *A black-box reduction is a transition of explanation state that lowers the black-box debt of a behavior target.*

Definition 9462.168 (Scoped black-box resolution)**.** *Scoped black-box resolution occurs when a behavior target receives a ledger-complete certified explanation on a specified model state, source domain, transformation family, and behavior scope.*

Definition 9462.169 (Global black-box resolution claim)**.** *A global black-box resolution claim asserts closed explanation for all relevant behaviors, inputs, distributions, model states, failures, and not-claimed boundaries.*

Theorem 9462.170 (Scoped resolution is obtained by NameCert)**.** *If a behavior has a supporting classifier with a ledger-complete NameCert on a stated scope, then scoped black-box resolution holds for that scope.*

Proof. The NameCert supplies source, pattern, classifier, stability, and ledger rows for the supporting classifier. Ledger completeness supplies the scope boundary. This is exactly Definition 9462.168. □

Theorem 9462.171 (Global resolution requires global ledger)**.** *A global black-box resolution claim requires a global ledger for the claimed behavior space.*

Proof. The claim ranges over all relevant behaviors and boundaries. Each one must either have a closed explanation or be explicitly outside the claim. That accounting is precisely the work of a global ledger. □

Corollary 9462.172 (Interpretability claims are scoped by default)**.** *Machine-learning explanations should be read as scoped unless a global ledger is displayed.*

Proof. By Definition 9462.171, global resolution requires stronger ledger coverage than ordinary feature, probe, visualization, or local verification claims provide. □

9462.7.3 Practice

Theorem 9462.173 (Feature labels do not resolve black boxes)**.** *Naming a feature does not by itself resolve black-box behavior.*

Proof. A feature label is a semantic assignment. It does not by itself supply the source, classifier, stability, and ledger rows required by Definition 9462.153. □

Theorem 9462.174 (Visual explanations require projection ledger)**.** *Visualizations used as explanations require a projection or compression ledger.*

Proof. A visualization maps high-dimensional or structured records into a display surface. This projection can collapse distinctions and hide boundary behavior. Without a ledger for that collapse, the visualization is evidence material rather than closed explanation. □

Theorem 9462.175 (Probe explanations require probe ledger)**.** *A probe-based explanation requires a ledger for the probe classifier and its hidden residue.*

Proof. A probe is itself a classifier extraction or compression map. Its accuracy can support a pattern or stability row, but false positives, false negatives, probe-specific artifacts, source scope, and hidden residue must still be ledgered. □

Theorem 9462.176 (Black-box reduction is not necessarily discovery)**.** *Lowering black-box debt does not necessarily create classifier shift.*

Proof. Debt reduction may come from filling source rows, adding boundary cases, recording a ledger, or hardening an existing component. If the classifier relation is unchanged, the classifier surface has not shifted. □

Theorem 9462.177 (Black-box resolution may contain discovery)**.** *A black-box resolution process can contain a discovery step when it introduces a new certified classifier.*

Proof. If the resolution process supplies a classifier not classifier-equivalent to the prior certified state and gives it NameCert and ledger support, then the process includes classifier shift. By Definition 9462.51, that step is a discovery candidate. □

Theorem 9462.178 (Black-box theorem)**.** *In the certificate reading, a black box is uncertified supporting structure: it is neither structureless behavior nor closed explanation.*

Proof. Definition 9462.157 separates black boxes from unexplained behavior, while Definition 9462.159 separates them from closed explanations. The remaining condition is missing NameCert or ledger support for a displayed classifier candidate. □

*Concretized in §**??**:* Black-box missing-certificate packets realize behavior support, certificate deficits, black-box debt, scoped resolution, ledger-black-box refusal, projection/probe ledger obligations, and discovery separation as finite NameCert rows.

Concretized in §7335: Black-box certificate deficits are realized as finite behavior-target, support-classifier, missing-row, ledger, refusal, transport, replay, provenance, and NameCert rows.

9462.8 Black-Box Ledger Theory

section 9462.7 defines black-box debt as certificate deficit. This section isolates the ledger part of that deficit. Any explanation, classifier, compression, projection, threshold, generalization, semantic assignment, intervention, or verification hides residue. A ledger is the audit surface that records that residue; unrecorded residue remains black-box debt.

Definition 9462.179 (Ledger entry)**.** *A ledger entry records a residue kind, a source reference, the residue being recorded, and an optional risk or weight annotation. Residue kinds include source, pattern, classifier, stability, threshold, projection, compression, generalization, intervention, verification, semantic, and not-claimed rows.*

Definition 9462.180 (Ledger)**.** *A ledger is a finite or auditable family of ledger entries attached to a target object: a classifier, NameCert, behavior, explanation, compression map, soft formula, intervention claim, semantic assignment, or formal statement.*

Definition 9462.181 (Recorded and required residue)**.** *For a ledger* Λ*,* $\mathrm{Rec}(\Lambda)$ *is the family of residue rows recorded by* Λ*. For a target object* O*,* $\mathrm{Req}(O)$ *is the family of residue rows that must be recorded for the claim about* O *to be closed.*

Definition 9462.182 (Ledger completeness and gap)**.** *A ledger is complete for* O *when*

$$\mathrm{Req}(O) \subseteq \mathrm{Rec}(\Lambda).$$

Its ledger gap is

$$\mathrm{Gap}(\Lambda, O) = \mathrm{Req}(O) \setminus \mathrm{Rec}(\Lambda).$$

Theorem 9462.183 (Ledger completeness is absence of gap)**.** *A ledger is complete for* O *exactly when its ledger gap for* O *is empty.*

Proof. The gap is defined as the required residue not recorded by the ledger. That set is empty exactly when every required residue row is recorded, which is the completeness condition. □

Theorem 9462.184 (Ledger extension cannot create new fixed-object gaps)**.** *If $\Lambda \subseteq \Lambda'$ and the target object O is fixed, then*

$$\mathrm{Gap}(\Lambda', O) \subseteq \mathrm{Gap}(\Lambda, O).$$

Proof. Every row recorded by Λ is also recorded by Λ'. Thus the required rows missing from Λ' form a subfamily of the required rows missing from Λ. □

Definition 9462.185 (Ledger debt)**.** *Ledger debt is the weighted cost of the gap:*

$$\mathrm{Debt}(\Lambda, O) = \sum_{r \in \mathrm{Gap}(\Lambda, O)} \mathrm{Cost}(r).$$

Critical debt is the same sum restricted to residues whose absence can change the claim's truth, scope, risk, classifier boundary, discovery status, or positive-gain accounting.

Theorem 9462.186 (Complete ledger has zero debt)**.** *A complete ledger has zero ledger debt.*

Proof. By Definition 9462.183, the gap is empty. The debt sum over an empty family is zero. □

Theorem 9462.187 (Ledger debt is monotone under fixed-object extension)**.** *For nonnegative residue costs, extending the ledger of a fixed object can only decrease or preserve ledger debt.*

Proof. By Definition 9462.184, the gap of the extended ledger is a subfamily of the original gap. Summing nonnegative costs over a subfamily cannot increase the total. □

Theorem 9462.188 (Critical debt blocks strong claims)**.** *If a target object has unrecorded critical residue, then strong claims depending on that object are not closed.*

Proof. Critical residue is defined by its ability to affect truth, scope, risk, classifier boundary, discovery status, or gain accounting. If it remains unrecorded, the strong claim lacks a necessary audit row. □

9462.8.1 Ledger Kinds

Definition 9462.189 (Ledger kind)**.** *Ledger kinds are indexed by the residue they record: source ledgers, pattern ledgers, classifier ledgers, stability ledgers, generalization ledgers, threshold ledgers, projection ledgers, intervention ledgers, verification ledgers, and semantic ledgers.*

Theorem 9462.190 (Ledger kinds do not generally substitute for each other)**.** *One ledger kind does not generally replace another.*

Proof. Different ledgers record different residue. A source ledger records where records come from; a threshold ledger records boundary sensitivity; a projection ledger records collapsed distinctions; a verification ledger records backend and trust assumptions; a semantic ledger records concept boundary and ambiguity. Recording one of these does not record the others. □

Corollary 9462.191 (Complete explanations often need multiple ledgers)**.** *Machine-learning explanations often require several ledger kinds at once.*

Proof. An explanation may simultaneously use source selection, thresholding, projection, semantic labeling, intervention, generalization, and formal verification. By Definition 9462.190, each involved residue kind requires its own ledger row. □

9462.8.2 Obligations

Theorem 9462.192 (Compression without ledger hides debt)**.** *A compression or projection that collapses distinctions without recording the collapsed residue carries hidden debt.*

Proof. Collapsed distinctions are required residue for a compression claim. If they are not recorded, they lie in the ledger gap and therefore contribute to ledger debt. □

Theorem 9462.193 (Generalization requires target-residue ledger)**.** *A generalization claim is not closed without a ledger for target residue and target failure boundary.*

Proof. Generalization extends a classifier from a source setting to a target setting. Target cases not covered by the source, transfer witness, or stability witness are required residue. Omitting them leaves the scope of the generalization claim unclosed. □

Theorem 9462.194 (Semantic labels require semantic ledger)**.** *A natural-language concept label for a classifier cell is not closed meaning without a semantic ledger.*

Proof. Natural-language labels have ambiguous cases, negative examples, polysemy, domain dependence, and unsupported connotations. These are required residue for the semantic assignment. □

Theorem 9462.195 (Causal explanations require intervention ledger)**.** *A causal or mechanistic claim based on intervention is not closed without an intervention ledger.*

Proof. Interventions can have off-target effects, alternative causal paths, strength sensitivity, distribution shifts, downstream compensation, and failed variants. These residue rows determine the scope of the causal claim. □

Theorem 9462.196 (Verification ledger does not replace behavior ledger)**.** *A verification ledger does not replace behavior, classifier, generalization, semantic, or intervention ledgers.*

Proof. The verification ledger records proof backend, statement, dependencies, trust boundary, and unchecked components. It does not record behavior failures, distribution boundary, semantic ambiguity, probe artifacts, or intervention residue unless those rows are explicitly included. □

9462.8.3 Repair and Discovery

Definition 9462.197 (Ledger repair)**.** *Ledger repair is a transition $\Lambda \to \Lambda'$ that lowers the debt of a fixed target object.*

Definition 9462.198 (Ledger discovery)**.** *Ledger discovery occurs when ledger repair uncovers critical residue that forces a change in classifier, source scope, or discovery status.*

Theorem 9462.199 (Ledger repair is not necessarily discovery)**.** *Ledger repair that preserves the classifier surface is not classifier discovery.*

Proof. Classifier discovery requires classifier shift. If ledger repair only records missing boundary or failure rows while the classifier relation stays fixed, the audit status improves but the classifier surface does not shift. □

Theorem 9462.200 (Critical ledger discovery can induce classifier discovery)**.** *If newly recorded critical residue forces the classifier relation to change, then the ledger discovery induces classifier shift.*

Proof. Changing the classifier relation means that some source records are no longer classified as before. That is precisely classifier shift on the public classifier surface. □

Theorem 9462.201 (Positive claims must count ledger cost and debt)**.** *A positive discovery, compression, generalization, or explanation-gain claim must count both ledger cost and remaining ledger debt.*

Proof. Ledger cost is part of the cost of making the claim auditable. Remaining ledger debt is the cost of residue not yet recorded. Omitting either term overstates the certified gain. □

Theorem 9462.202 (Black-box ledger theorem)**.** *Ledger is the closure surface for black-box debt: recorded residue turns hidden boundary into auditable boundary, while unrecorded residue remains black-box residue.*

Proof. By Definition 9462.183, ledger closure is exactly absence of required residue gaps. By Definition 9462.185, unrecorded residue contributes to debt. The ledger therefore converts hidden residue into auditable rows, and whatever is not ledgered remains black-box residue. □

*Concretized in §**??**:* Black-box ledger theory realizes ledger entries, required and recorded residue, debt monotonicity, ledger-kind non-substitution, compression/generalization/semantic/intervention/verification ledger obligations, ledger repair, and critical ledger discovery as finite NameCert rows.

Concretized in §6100: The decomposition certificate realizes black-box ledger deficits as finite certificate rows with visible missing-field and debt surfaces.

9462.9 Neural Theorem-DNA

section 9462.4 treats tensor features, probes, directions, and circuits as certificate candidates rather than standalone explanations. section 9462.8 then identifies the ledger surface that prevents hidden residue from remaining black-box debt. The neural theorem-DNA reading combines these two constraints: a model behavior is not explained by one feature label or one circuit diagram, but by a role-complete profile whose roles are source, feature, circuit, classifier, stability, intervention, ledger, and seal. The term genome names this role-complete audit profile only; it does not import biological structure.

Definition 9462.203 (Neural behavior target)**.** *A neural behavior target is a displayed behavior B of a tensor model context. It may be represented as a relation on inputs and outputs, a predicate on inputs or traces, or a soft behavior score, provided the source scope and observation protocol are declared.*

Definition 9462.204 (Neural theorem-DNA loci)**.** *The neural theorem-DNA locus family is*

$$\mathcal{R}_{\mathsf{NDNA}} = \{\mathsf{source}, \mathsf{feature}, \mathsf{circuit}, \mathsf{classifier}, \mathsf{stability}, \mathsf{intervention}, \mathsf{ledger}, \mathsf{seal}\}.$$

For a behavior B, a neural theorem-DNA packet is an eight-tuple

$$\mathsf{NDNA}(B) = (G_{\mathsf{source}}, G_{\mathsf{feature}}, G_{\mathsf{circuit}}, G_{\mathsf{classifier}}, G_{\mathsf{stability}}, G_{\mathsf{intervention}}, G_{\mathsf{ledger}}, G_{\mathsf{seal}}).$$

The component G_ρ is the gene occupying locus $\rho \in \mathcal{R}_{\mathsf{NDNA}}$.

Definition 9462.205 (Neural theorem genome)**.** *A neural theorem genome for B is the behavior together with a neural theorem-DNA packet:*

$$\Gamma_B = (B, \mathsf{NDNA}(B)).$$

The packet is complete when every locus has declared content, evidence mode, scope, and ledger status.

Definition 9462.206 (Locus content)**.** *The source locus records model identity, parameter state, data domain, input family, task condition, prompt or observation protocol, trace extraction method, target definition, and inclusion boundary. The feature locus records activation features, directions, sparse-autoencoder latents, probes, subspaces, attention patterns, residual-stream features, or tensor distinction functionals. The circuit locus records layer, attention, MLP, residual, upstream, downstream, and causal-route structure. The classifier locus records the classifier relation induced by the behavior explanation. The stability locus records perturbation, threshold, representation, classifier, circuit, behavior, or transfer stability. The intervention locus records ablation, activation transfer, tracing, steering, suppression, amplification, counterfactual, failed, or off-target intervention evidence. The ledger locus records residue and boundary debt. The seal locus records the closure claim, evidence mode, remaining gaps, not-claimed boundary, and hardening status.*

Definition 9462.207 (NDNA gap and debt)**.** *The neural theorem-DNA gap of B is the family of incomplete loci:*

$$\mathrm{Gap}_{\mathsf{NDNA}}(B) = \{\rho \in \mathcal{R}_{\mathsf{NDNA}} \mid G_\rho(B) \text{ is not complete}\}.$$

For a nonnegative cost assignment on loci, the NDNA debt is

$$\mathrm{Debt}_{\mathsf{NDNA}}(B) = \sum_{\rho \in \mathrm{Gap}_{\mathsf{NDNA}}(B)} \mathrm{Cost}(\rho).$$

A critical locus is a locus whose absence can change the source scope, classifier boundary, causal status, ledger closure, discovery status, or positive-gain accounting of the explanation.

Theorem 9462.208 (Complete NDNA has zero NDNA debt)**.** *If $\mathsf{NDNA}(B)$ is complete, then*

$$\mathrm{Debt}_{\mathsf{NDNA}}(B) = 0.$$

Proof. Completeness means that no locus is incomplete. Hence $\mathrm{Gap}_{\mathsf{NDNA}}(B)$ is empty, and the debt sum over the empty family is zero. □

Theorem 9462.209 (Single-locus records are not closed explanations)**.** *No isolated feature, circuit, classifier, intervention, or semantic label is a closed explanation of B.*

Proof. A closed explanation must declare the source scope, classifier surface, stability mode, ledger boundary, and seal. A feature record lacks the other roles; a circuit diagram lacks the classifier and ledger surfaces; a classifier relation lacks source, stability, and seal data; an intervention result lacks off-target and failed-variant ledgers; and a semantic label lacks the classifier and semantic-ledger boundary. Each is therefore only a locus or locus fragment. □

Definition 9462.210 (Anchored locus)**.** *A locus $G_\rho(B)$ is anchored when it has an anchor witness $A_\rho(B)$ tracing the locus to behavior evidence, tensor traces, dataset evidence, intervention records, a NameCert component, a ledger entry, a formal proof certificate, or a paper proof. A neural theorem-DNA packet is anchored when all its loci are anchored.*

Theorem 9462.211 (Unanchored critical loci block certification)**.** *If a critical locus of* $\mathsf{NDNA}(B)$ *is unanchored, then* $\mathsf{NDNA}(B)$ *cannot certify a closed explanation of* B*.*

Proof. A critical locus can change scope, classifier boundary, causal status, ledger closure, discovery status, or gain accounting. Without an anchor witness, the auditor cannot tell whether that locus is evidence-bearing or merely descriptive. Certification therefore fails at the audit surface. □

Corollary 9462.212 (Natural language cannot fill an anchor gap)**.** *An unanchored natural-language description cannot substitute for a critical anchor witness.*

Proof. Such a description does not identify a trace, intervention, certificate, ledger row, or proof from which the locus is read. By Definition 9462.211, the critical gap remains. □

Definition 9462.213 (NDNA-to-NameCert projection)**.** *For a complete neural theorem-DNA packet, its NameCert projection is*

$$\Pi_{\mathsf{NameCert}}(\mathsf{NDNA}(B)) = (S_B, P_B, C_B, \Sigma_B, L_B).$$

The source row S_B *is read from the source locus; the pattern row* P_B *is read from the feature and circuit loci; the classifier row* C_B *is read from the classifier locus; the stability row* Σ_B *is read from the stability and intervention loci; and the ledger row* L_B *is read from the ledger locus. The seal locus states the closure scope of this projection.*

Definition 9462.214 (NameCert-compatible NDNA)**.** *A complete neural theorem-DNA packet is NameCert-compatible when* $\Pi_{\mathsf{NameCert}}(\mathsf{NDNA}(B))$ *forms a Tensor NameCert for the classifier supporting* B*.*

Theorem 9462.215 (NameCert-compatible NDNA yields tensor certification)**.** *If* $\mathsf{NDNA}(B)$ *is complete, anchored, and NameCert-compatible, then* B *has a tensor-certified explanation within the seal scope.*

Proof. NameCert compatibility supplies the five Tensor NameCert rows of Definition 9462.89. Completeness supplies all eight neural loci, anchoring supplies the evidence route for each locus, and the seal declares the scope. Thus the classifier supporting B is displayed with the required source, pattern, classifier, stability, and ledger rows. □

Theorem 9462.216 (Complete NDNA need not be NameCert-compatible)**.** *A complete neural theorem-DNA packet need not be NameCert-compatible.*

Proof. Completeness records that every locus has declared content. It does not force cross-locus agreement. The source locus may name one domain, the classifier locus another; the stability locus may concern a perturbation family different from the one used by the classifier; or the ledger may record residue for a threshold not used in the classifier row. In such a case the eight loci are present, but the projected five-field certificate is inconsistent. □

Definition 9462.217 (Causal and correlation-only NDNA)**.** *A causal NDNA claim says that the displayed feature, circuit, or classifier causally supports* B*. A correlation-only NDNA supplies feature, classifier, or stability evidence without an intervention locus.*

Theorem 9462.218 (Causal NDNA claims require intervention ledger)**.** *A causal NDNA claim is not closed unless the intervention locus is present and its intervention residue is ledgered.*

Proof. The causal claim must distinguish causal support from correlation. Interventions can have off-target effects, alternative causal paths, strength sensitivity, failed variants, and downstream compensation. By Definition 9462.195, those rows must be ledgered for the causal boundary to close. □

Definition 9462.219 (Semantic gene)**.** *A semantic gene is a natural-language concept label assigned to a feature, classifier cell, behavior, or circuit role. It is licensed when it has a semantic ledger and agrees with the classifier locus.*

Theorem 9462.220 (Semantic genes require classifier and ledger)**.** *A semantic gene cannot enter a certified NDNA packet unless it is bound to the classifier locus and accompanied by a semantic ledger.*

Proof. Natural-language labels have ambiguous cases, negative cases, polysemy, domain dependence, unsupported connotations, and drift. A classifier relation determines the public equivalence surface; the semantic ledger records the boundary and not-claimed range of the label. Without both, the semantic gene is not auditable. □

Definition 9462.221 (NDNA score and certified gain)**.** *The NDNA complexity vector is*

$$\mathbf{C}_{\mathsf{NDNA}}(B) = (c_{\mathsf{source}}, c_{\mathsf{feature}}, c_{\mathsf{circuit}}, c_{\mathsf{classifier}}, c_{\mathsf{stability}}, c_{\mathsf{intervention}}, c_{\mathsf{ledger}}, c_{\mathsf{seal}}).$$

For a nonnegative weight profile $\mathbf{w}_{\mathsf{NDNA}}$*, define*

$$\mathrm{Score}_{\mathsf{NDNA}}(B) = \mathbf{w}_{\mathsf{NDNA}} \cdot \mathbf{C}_{\mathsf{NDNA}}(B).$$

The certified gain of an NDNA explanation counts coverage, prediction, transfer, and reuse value, then subtracts score and remaining debt.

Theorem 9462.222 (Lower NDNA score does not imply better explanation)**.** *An explanation with lower NDNA score need not be a better explanation.*

Proof. Score records the cost of the displayed loci. Explanation quality also depends on coverage, prediction, transfer, classifier shift, causal strength, ledger completeness, and remaining debt. A short low-score profile may cover little and hide residue, while a higher-score profile may close more of the behavior boundary. □

Definition 9462.223 (NDNA mutations)**.** *An NDNA mutation is a transition*

$$\mathsf{NDNA}(B) \rightsquigarrow \mathsf{NDNA}'(B).$$

It is a compression mutation when it lowers score while preserving the classifier locus. It is a classifier-shift mutation when the classifier locus changes. It is a discovery mutation when the classifier shift is NameCert-compatible and ledgered.

Theorem 9462.224 (Compression and discovery are independent)**.** *NDNA compression and NDNA discovery are independent coordinates.*

Proof. A compression mutation can reduce score by shortening feature, circuit, proof, or seal records while preserving the classifier locus; then no classifier-shift discovery has occurred. Conversely, a discovery mutation may introduce classifier, stability, ledger, and seal rows whose cost raises the score. Thus score reduction does not imply discovery, and discovery does not require immediate score reduction. □

Theorem 9462.225 (Ledger mutation can induce NDNA discovery)**.** *If a ledger mutation records critical residue that forces the classifier locus to change, then it induces an NDNA discovery mutation whenever the resulting packet is NameCert-compatible and ledgered.*

Proof. Critical residue can change the classifier boundary. Once the classifier locus changes, the transition is a classifier-shift mutation. If the resulting packet also has a compatible NameCert projection and ledger, it satisfies the definition of NDNA discovery mutation. □

Definition 9462.226 (NDNA hardening)**.** *An NDNA locus is formally hardened when the claim carried by that locus has been rendered as a formal proposition and accepted by the relevant verification system. A packet is partially hardened when some loci are hardened and the remaining residue is ledgered. It is fully hardened when all hardenable critical loci are hardened and all non-hardenable critical residue is ledgered.*

Theorem 9462.227 (One hardened locus does not harden the whole packet)**.** *Formal hardening of one NDNA locus does not imply that the whole neural theorem-DNA packet is fully hardened.*

Proof. The packet has eight loci. A verified property of one feature, circuit, margin, dataset row, or proof row leaves the other loci and their ledgers untouched unless they are separately hardened or ledgered. □

Theorem 9462.228 (Fully hardened compatible NDNA is certified)**.** *If a neural theorem-DNA packet is fully hardened and NameCert-compatible, then it yields an NDNA-certified explanation of B within its seal scope.*

Proof. Full hardening supplies hardened critical loci and ledgered non-hardenable residue. NameCert compatibility supplies the Tensor NameCert projection. The seal supplies the scope in which the behavior is claimed to be explained. □

Theorem 9462.229 (Neural theorem-DNA theorem)**.** *Closed explanation of a neural behavior is a role-complete, anchored, ledgered, NameCert-compatible, and sealed profile, not a single feature label, circuit diagram, classifier, intervention result, or semantic tag.*

Proof. Definition 9462.209 rules out single-locus substitutes. Definition 9462.211 requires anchoring. Definition 9462.215 supplies the Tensor NameCert route. Definition 9462.218 and Definition 9462.220 record the causal and semantic boundary cases. The hardening theorems separate local formal verification from whole-packet closure. Together these facts make the complete packet the explanatory unit. □

Concretized in §6241: Classifier novelty ledgers realize before/after classifier-profile disagreement as finite BEDC certificate data.

Concretized in §6243: The theorem-DNA score packet realizes role-complete source, feature, circuit, classifier, stability, intervention, ledger, and seal rows as finite NameCert data.

9462.10 Explanation Complexity and Interpretability Information

section 9462.9 identifies the complete explanatory unit for a neural behavior as a role-complete, anchored, ledgered, and NameCert-compatible packet. This section isolates the evaluation problem

left by that packet. A shorter explanation is not automatically better; a longer explanation is not automatically worse; a formally hardened component is not automatically a discovery; and a larger feature list is not automatically more interpretability information. The auditable quantity is net explanation information: benefit minus score and remaining debt, with classifier novelty reported as a separate coordinate.

Definition 9462.230 (Explanation object)**.** *An explanation object is a tuple*

$$E = (B, C, N, \Lambda)$$

where B is a neural behavior target, C is a classifier supporting B, N is a NameCert or Tensor NameCert for C, and Λ is the ledger attached to the explanation claim. When the explanation is role-complete, the same object may be displayed as

$$E_B = (B, \mathsf{NDNA}(B), N, \Lambda).$$

Definition 9462.231 (Explanation scope)**.** *The scope of E is the tuple*

$$\mathrm{Scope}(E) = (D, M_\theta, \mathcal{A}, B),$$

where D is the source or target domain, M_θ is the model state, $\mathcal{A}$ is the admitted family of transformations, perturbations, or transfers, and B is the behavior target. All benefit, cost, and debt judgments are read inside this scope unless a larger scope is explicitly certified.

Definition 9462.232 (Cost protocol)**.** *A cost protocol is a triple*

$$\mathcal{C} = (Q, \mathrm{Cost}, \mathbf{w}),$$

where Q is an ordered commutative monoid, Cost *assigns costs to auditable objects, and $\mathbf{w}$ is a nonnegative weight profile. Auditable objects include source descriptions, feature records, circuit records, classifier specifications, stability witnesses, intervention records, ledgers, seals, semantic assignments, formal verification artifacts, and proof objects.*

Definition 9462.233 (Extended explanation complexity vector)**.** *For an explanation object E, the extended complexity vector is*

$$\mathbf{C}_{\mathsf{exp}}(E) = (c_{\mathsf{source}}, c_{\mathsf{feature}}, c_{\mathsf{circuit}}, c_{\mathsf{classifier}}, c_{\mathsf{stability}}, c_{\mathsf{intervention}}, c_{\mathsf{ledger}}, c_{\mathsf{seal}}, c_{\mathsf{semantic}}, c_{\mathsf{verification}}).$$

The first eight coordinates refine the NDNA score of Definition 9462.221; the semantic coordinate counts semantic assignment and semantic-ledger cost; the verification coordinate counts hardening artifacts and verification ledger cost.

Definition 9462.234 (Explanation score)**.** *For a nonnegative weight profile*

$$\mathbf{w} = (w_{\mathsf{source}}, w_{\mathsf{feature}}, w_{\mathsf{circuit}}, w_{\mathsf{classifier}}, w_{\mathsf{stability}}, w_{\mathsf{intervention}}, w_{\mathsf{ledger}}, w_{\mathsf{seal}}, w_{\mathsf{semantic}}, w_{\mathsf{verification}}),$$

the explanation score is

$$\mathrm{Score}_{\mathbf{w}}(E) = \mathbf{w} \cdot \mathbf{C}_{\mathsf{exp}}(E).$$

Theorem 9462.235 (Explanation score is monotone)**.** *If*

$$\mathbf{C}_{\mathsf{exp}}(E) \leq \mathbf{C}_{\mathsf{exp}}(E')$$

componentwise and all weights are nonnegative, then

$$\mathrm{Score}_{\mathbf{w}}(E) \leq \mathrm{Score}_{\mathbf{w}}(E').$$

Proof. Write the two complexity vectors as $(c_1, \ldots, c_n)$ and $(c'_1, \ldots, c'_n)$ with $c_j \leq c'_j$ for every j. Since each weight w_j is nonnegative, $w_j c_j \leq w_j c'_j$. Summing the coordinate inequalities gives the score inequality. □

Concretized in §6181: Explanation-complexity information is realized as a finite score, debt, classifier-novelty, and certified-quality NameCert packet.

Concretized in §8113: Description-complexity packets realize the explanation-complexity vision as finite source-description, score-vector, public-weight, debt, classifier-novelty, minimal-witness, replay, provenance, and NameCert rows.

Theorem 9462.236 (Scalar score requires public weights)**.** *A scalar explanation score is not auditable unless its weight profile is public.*

Proof. Two explanations can trade off source cost against ledger cost, or feature cost against verification cost. A weight profile concentrated on one coordinate orders the pair differently from a profile concentrated on another. Without the declared weights, the scalar order has no stable audit meaning. □

Definition 9462.237 (Explanation benefit)**.** *The benefit of E is a nonnegative audit functional*

$$\mathrm{Benefit}(E) = \mathrm{CoverageGain}(E) + \mathrm{PredictionGain}(E) + \mathrm{TransferGain}(E) + \mathrm{InterventionGain}(E) + \mathrm{VerificationGain}(E$$

The terms measure, respectively, behavior coverage, predictive value, transport across domains or model states, controlled intervention value, formal hardening value, and unification of previously separated behaviors, features, circuits, or classifiers.

Definition 9462.238 (Explanation debt)**.** *The total explanation debt is*

$$\mathrm{Debt}(E) = \mathrm{Debt}_{\mathsf{NDNA}}(E) + \mathrm{Debt}_{\mathsf{ledger}}(E) + \mathrm{Debt}_{\mathsf{semantic}}(E) + \mathrm{Debt}_{\mathsf{verification}}(E) + \mathrm{Debt}_{\mathsf{intervention}}(E) + \mathrm{Debt}_{\mathsf{generalization}}($$

The summands record missing NDNA loci, missing required residue, unlicensed semantic labels, unverified critical components, unledgered causal residue, and unsupported target-domain claims.

Theorem 9462.239 (Closed explanation has zero critical debt)**.** *If E is closed within its declared scope, then its critical debt is zero.*

Proof. Closure within a scope requires the critical source, classifier, stability, ledger, semantic, intervention, verification, generalization, and seal obligations used by the claim to be either discharged or placed outside the not-claimed boundary. Therefore no critical residue remains unrecorded inside the declared scope. □

Corollary 9462.240 (Critical debt blocks strong explanation claims)**.** *If E has nonzero critical debt, it cannot claim closed explanation, positive discovery, global generalization, or full verification within that debt-bearing scope.*

Proof. Each listed claim requires the relevant critical obligations to be closed. Nonzero critical debt leaves at least one such obligation open. □

Definition 9462.241 (Net explanation information)**.** *Relative to a cost protocol, the net explanation information of E is*

$$\mathsf{Info}_{\mathbf{w}}(E) = \mathrm{Benefit}(E) - \mathrm{Score}_{\mathbf{w}}(E) - \mathrm{Debt}(E).$$

For a transition $E_0 \rightsquigarrow E_1$, the relative net gain is

$$\Delta\mathsf{Info}_{\mathbf{w}}(E_0, E_1) = \mathsf{Info}_{\mathbf{w}}(E_1) - \mathsf{Info}_{\mathbf{w}}(E_0).$$

Theorem 9462.242 (Lower score does not imply positive net information)**.** *The inequality*

$$\mathrm{Score}_{\mathbf{w}}(E_1) < \mathrm{Score}_{\mathbf{w}}(E_0)$$

does not imply

$$\Delta\mathsf{Info}_{\mathbf{w}}(E_0, E_1) > 0.$$

Proof. Net information subtracts both score and debt from benefit. A lower-score explanation may lower benefit by removing coverage, predictive value, transfer value, or ledger rows. It may also increase debt by hiding boundary cases. Either change can offset the score decrease. □

Theorem 9462.243 (Higher score can still carry positive net information)**.** *An explanation transition can have positive net information even when the target explanation has higher score.*

Proof. Adding source rows, intervention witnesses, transfer witnesses, semantic ledgers, and verification artifacts increases score. If those rows increase benefit and reduce debt by more than the score increase, then the net information difference is positive by Definition 9462.241. □

Definition 9462.244 (Interpretability classifier novelty)**.** *For an explanation object E, let*

$$\mathcal{T}_E = (S_E, P_E, L_E, C_E, N_E)$$

be its certified classifier state. A transition $E_0 \rightsquigarrow E_1$ has interpretability classifier novelty when $\mathcal{T}_{E_0} \to \mathcal{T}_{E_1}$ has classifier shift in the sense of Definition 9462.49.

Definition 9462.245 (Positive interpretability discovery)**.** *A transition $E_0 \rightsquigarrow E_1$ is a positive interpretability discovery when it has interpretability classifier novelty, the target classifier state has NameCert and ledger witnesses, and*

$$\Delta\mathsf{Info}_{\mathbf{w}}(E_0, E_1) > 0.$$

Theorem 9462.246 (Explanation improvement need not be discovery)**.** *Positive net explanation information does not imply interpretability classifier novelty.*

Proof. The net information gain may come from lower ledger debt, lower score, hardening of an existing critical component, source-scope clarification, or a better not-claimed boundary while the classifier relation remains unchanged. By Definition 9462.51, classifier novelty requires classifier shift, so such an improvement is not necessarily discovery. □

Theorem 9462.247 (Interpretability discovery need not be positive)**.** *Interpretability classifier novelty with NameCert and ledger witnesses does not by itself imply positive net explanation information.*

Proof. A changed certified classifier can require high source, stability, intervention, ledger, semantic, or verification cost. If those costs and remaining debts exceed the coverage, prediction, transfer, intervention, verification, and unification benefits, then the net information difference is nonpositive. □

Theorem 9462.248 (Positive discovery requires two audits)**.** *Positive interpretability discovery requires both classifier novelty and positive net explanation information.*

Proof. This is exactly the definition of positive interpretability discovery: the transition must pass the classifier-shift audit and the net information audit. □

Theorem 9462.249 (Counts do not determine interpretability information)**.** *Feature count, proof count, ledger-row count, and raw explanation length do not determine net explanation information.*

Proof. Additional features may be unstable, redundant, unanchored, or unledgered. Additional proofs may harden low-value rows while leaving critical components untouched. Additional ledger rows may avoid the required critical residue. Shorter text may remove evidence and boundary statements. Each count can therefore vary independently of benefit, score, and debt. □

Corollary 9462.250 (Feature discovery requires certificate value)**.** *Finding more features counts as interpretability information only when the resulting explanation changes certified classifier value, lowers debt, or increases benefit after cost is counted.*

Proof. By Definition 9462.249, feature count alone is not an information measure. The feature must enter the certified explanation surface. □

Corollary 9462.251 (Proof quantity is not explanation quality)**.** *The number of formal proof artifacts is not a standalone explanation quality metric.*

Proof. By Definition 9462.249, proof count does not say which critical loci were hardened or whether verification debt decreased. □

Definition 9462.252 (Explanation quality vector)**.** *The explanation quality vector is*

$$\mathbf{Q}(E) = (\mathrm{Benefit}(E), -\mathrm{Score}_{\mathbf{w}}(E), -\mathrm{Debt}(E), \mathrm{Novelty}(E), \mathrm{VerificationGain}(E)).$$

Here $\mathrm{Novelty}(E)$ *records whether the transition under discussion has interpretability classifier novelty.*

Definition 9462.253 (Pareto comparison)**.** *An explanation* E_1 *Pareto-dominates* E_0 *when every declared coordinate of* $\mathbf{Q}(E_1)$ *is at least the corresponding coordinate of* $\mathbf{Q}(E_0)$*, and at least one coordinate is strictly larger.*

Theorem 9462.254 (No hidden scalar captures all explanation dimensions)**.** *No unpublished scalar score can audibly replace the benefit, score, debt, classifier-novelty, and verification coordinates.*

Proof. These coordinates can trade off. One explanation may be low cost and high debt; another may be high cost and low debt; a third may change the classifier but have low verification gain; a fourth may harden a prior classifier without classifier novelty. Any scalar ordering must encode weights for these tradeoffs. Without publishing those weights, the ordering is not auditable. □

Corollary 9462.255 (Explanation comparison needs vectors or public weights)**.** *Explanation comparisons should use quality vectors, Pareto frontiers, or public scalar weights.*

Proof. This follows from Definition 9462.254 and Definition 9462.236. □

Definition 9462.256 (Selection functional)**.** *A selection functional has the form*

$$\mathrm{Sel}(E) = \alpha\ \mathrm{CoverageGain}(E) + \beta\ \mathrm{PredictionGain}(E) + \gamma\ \mathrm{TransferGain}(E) + \delta\ \mathrm{InterventionGain}(E) + \eta\ \mathrm{Unificati}$$

with nonnegative coefficients. A research-facing selection may weight coverage, transfer, unification, and classifier novelty highly; a safety-facing selection may weight intervention debt, semantic debt, generalization debt, and not-claimed boundaries highly.

Theorem 9462.257 (Shortest explanation need not be selection-favorable)**.** *The shortest explanation in a candidate family need not maximize a selection functional.*

Proof. A short feature label may have low score but also low coverage, low prediction value, no classifier novelty, and high debt. A longer role-complete explanation may have higher score but much higher benefit and lower debt. Under a selection functional that values those terms, the longer explanation is preferred. □

Theorem 9462.258 (Ledger-heavy explanations can be safety-favorable)**.** *An explanation with more ledger material can be preferable in a safety-facing selection.*

Proof. Safety-facing selection penalizes unrecorded failure cases, off-target effects, distribution boundaries, semantic ambiguity, and unsupported generalization. Adding the relevant ledger rows increases score, but it can reduce debt enough to increase the selection value. □

Theorem 9462.259 (Debt reduction can justify higher complexity)**.** *If a transition increases explanation score but reduces black-box debt by a larger value after benefit is counted, then it has positive net explanation information.*

Proof. By Definition 9462.241, the score increase is subtracted and the debt decrease is added through the difference of the negative-debt term. If the debt decrease and benefit increase dominate the score increase, the net information difference is positive. This is the evaluation form of Definition 9462.202: recorded residue can turn hidden black-box boundary into auditable boundary. □

Theorem 9462.260 (Formal hardening has net gain only when it pays for itself)**.** *Formal hardening can increase or decrease net explanation information.*

Proof. Hardening increases verification cost. It improves net information only when the resulting verification gain and debt reduction exceed that cost and any remaining verification debt. If it hardens a low-value component or leaves critical residues untouched, its net contribution can be nonpositive. This refines Definition 9462.56: a hardened component may improve audit status without creating classifier novelty. □

Theorem 9462.261 (Explanation complexity and information theorem)**.** *Interpretability information is not explanation brevity. It is the net quantity obtained by auditing benefit, score, and debt, while classifier novelty is separately audited by classifier shift with certificate and ledger witnesses.*

Proof. Score is defined by Definition 9462.234; benefit by Definition 9462.237; debt by Definition 9462.238; and net explanation information by Definition 9462.241. Definition 9462.242 and Definition 9462.243 separate score from quality. Definition 9462.248 separates net information from classifier novelty. Definition 9462.249 rules out feature, proof, ledger, and length counts as standalone measures. The theorem follows. □

9462.11 Interpretability Classifier Novelty

section 9462.10 separates net explanation information from classifier novelty. This section isolates the novelty coordinate itself. A feature catalog, a larger circuit diagram, a stronger ledger, a hardened proof component, or a clearer semantic label can improve an explanation without changing the explanatory classifier. Interpretability discovery, in the classifier-level sense, occurs only when the certified classifier surface used by the explanation changes.

Definition 9462.262 (Interpretability explanation state)**.** *An interpretability explanation state is a certified classifier state read in the machine-learning explanation context:*

$$\mathcal{E} = (S_E, P_E, L_E, C_E, N_E).$$

Here S_E is the explanation source specification, P_E is the pattern specification, L_E is the ledger policy, C_E is the explanation classifier, and N_E is the NameCert licensing the state.

Definition 9462.263 (Explanation source scope and classifier cell)**.** *The source scope of $\mathcal{E}$ is*

$$|\mathcal{E}| = \{x \mid S_E(x)\}.$$

For $x \in |\mathcal{E}|$, the explanation classifier cell of x is

$$[x]_{\mathcal{E}} = \{y \in |\mathcal{E}| \mid C_E(x, y)\}.$$

The objects x and y may be input samples, tensor traces, activation records, behavior cases, NDNA packets, or explanation objects, depending on the declared source scope.

Definition 9462.264 (Interpretability transition)**.** *An interpretability transition is a passage*

$$\mathcal{E} \rightsquigarrow \mathcal{E}'$$

between explanation states. The passage may change feature loci, circuit loci, ledger rows, stability witnesses, semantic assignments, formal hardening status, NameCert rows, seal clauses, or the classifier itself.

Definition 9462.265 (Interpretability classifier equivalence)**.** *Two explanation states*

$$\mathcal{E} = (S, P, L, C, N), \qquad \mathcal{E}' = (S', P', L', C', N')$$

are interpretability-classifier equivalent when they give the same classifier judgment on their common source scope:

$$\forall x, y,\ S(x) \wedge S(y) \wedge S'(x) \wedge S'(y) \Rightarrow \big(C(x, y) \leftrightarrow C'(x, y)\big).$$

This is the explanation-side instance of Definition 9462.48.

Definition 9462.266 (Classifier novelty value)**.** *The classifier novelty value of a transition $\mathcal{E} \rightsquigarrow \mathcal{E}'$ is*

$$\nu_{\mathsf{cls}}(\mathcal{E}, \mathcal{E}') = 0$$

exactly when $\mathcal{E}$ and $\mathcal{E}'$ are interpretability-classifier equivalent, and is 1 exactly when that equivalence fails.

Definition 9462.267 (Local classifier novelty witness)**.** *For a displayed family*

$$X \subseteq |\mathcal{E}| \cap |\mathcal{E}'|,$$

a local classifier novelty witness is a pair $x, y \in X$ together with evidence that

$$C_E(x, y) \not\leftrightarrow C_{E'}(x, y).$$

The witness is certified when the target state carries NameCert and ledger rows explaining the changed judgment.

Theorem 9462.268 (Local witness gives classifier novelty)**.** *If there is a local classifier novelty witness for $\mathcal{E} \rightsquigarrow \mathcal{E}'$, then*

$$\nu_{\mathsf{cls}}(\mathcal{E}, \mathcal{E}') = 1.$$

Proof. The witness supplies x, y in the common source scope for which the two classifier judgments differ. Interpretability-classifier equivalence requires agreement on every such pair. Therefore equivalence fails, and the classifier novelty value is 1. □

Corollary 9462.269 (One classified pair can certify non-equivalence)**.** *One common-source pair with different classifier judgments is sufficient to show that two explanation states are not classifier-equivalent.*

Proof. Apply Definition 9462.268 to the displayed two-object family containing the witness pair. □

9462.11.1 Nonclassifier Changes

Definition 9462.270 (Feature-side change)**.** *Concretized in §6138: Classifier-novelty witnesses realize the local explanation-state non-equivalence row as finite NameCert data.*

A feature-side change is a transition that alters the feature locus, feature functional, activation source, sparse-autoencoder latent, direction, probe, or feature evidence while preserving the classifier relation on the common source scope.

Definition 9462.271 (Circuit-side change)**.** *A circuit-side change alters the circuit locus, route graph, layer path, attention component, MLP component, residual route, or causal-route evidence while preserving the classifier relation on the common source scope.*

Definition 9462.272 (Ledger-side change)**.** *A ledger-side change adds or reorganizes ledger rows, reduces debt, or clarifies not-claimed boundaries while preserving the classifier relation on the common source scope.*

Definition 9462.273 (Hardening-side and semantic-side changes)**.** *A hardening-side change alters evidence mode, proof status, or verification ledger without changing the explanation classifier. A semantic-side change alters labels, semantic ledgers, examples, counterexamples, or concept boundaries without changing the explanation classifier.*

Theorem 9462.274 (Feature-side change need not create classifier novelty)**.** *A feature-side change whose classifier relation is preserved has classifier novelty value* 0*.*

Proof. By definition, the classifier relation agrees on the common source scope. Thus the two explanation states are interpretability-classifier equivalent, so the novelty value is 0. □

Theorem 9462.275 (Circuit-side change need not create classifier novelty)**.** *A circuit-side change whose classifier relation is preserved has classifier novelty value* 0*.*

Proof. Changing circuit evidence can refine mechanism without changing the classifier cells. If the common-source classifier judgments are the same, Definition 9462.266 gives value 0. □

Theorem 9462.276 (Ledger repair need not create classifier novelty)**.** *Ledger-side improvement can lower debt without creating classifier novelty.*

Proof. A ledger-side change may add boundary cases, false-positive rows, threshold rows, or not-claimed clauses while leaving C_E unchanged. Then the classifier equivalence relation is unchanged, even though the audit quality improves. □

Theorem 9462.277 (Hardening and semantic changes need not create classifier novelty)**.** *Hardening-side and semantic-side changes do not create classifier novelty unless they change the classifier relation.*

Proof. Formal hardening changes evidence strength; semantic clarification changes naming and boundary prose. If neither changes which source objects are classified together, the explanation states remain classifier-equivalent. □

Corollary 9462.278 (Improvement and discovery are distinct)**.** *An explanation can become more useful, reliable, precise, or auditable without becoming a classifier-level discovery.*

Proof. The preceding theorems describe feature, circuit, ledger, hardening, and semantic changes that may improve an explanation while preserving the classifier relation. □

9462.11.2 Classifier-Change Modes

Definition 9462.279 (Classifier refinement)**.** *A transition is a classifier refinement when*

$$C_{E'}(x, y) \Rightarrow C_E(x, y)$$

on the common source scope, and the implication is strict for at least one pair. The target classifier separates at least one pair that the source classifier grouped.

Definition 9462.280 (Classifier coarsening)**.** *A transition is a classifier coarsening when*

$$C_E(x, y) \Rightarrow C_{E'}(x, y)$$

on the common source scope, and the implication is strict for at least one pair. The target classifier groups at least one pair that the source classifier separated.

Definition 9462.281 (Classifier reorganization)**.** *A transition is a classifier reorganization when the two classifiers are not equivalent on their common source scope, but the change is neither a pure refinement nor a pure coarsening.*

Definition 9462.282 (Bridge, boundary, and unification modes)**.** *A bridge mode connects previously separated explanation states through a common certified classifier. A boundary mode identifies a principled limit beyond which the prior classifier should not be used. A unification mode gives one certified classifier surface for several previously separated behaviors, features, circuits, or domains.*

Theorem 9462.283 (Refinement creates classifier novelty)**.** *Every strict classifier refinement has classifier novelty value* 1*.*

Proof. Strictness supplies x, y in the common source scope with $C_E(x, y)$ and $\neg C_{E'}(x, y)$. This is a local classifier novelty witness. □

Theorem 9462.284 (Coarsening creates classifier novelty)**.** *Every strict classifier coarsening has classifier novelty value* 1*.*

Proof. Strictness supplies x, y in the common source scope with $\neg C_E(x, y)$ and $C_{E'}(x, y)$. This is again a local classifier novelty witness. □

Theorem 9462.285 (Reorganization creates classifier novelty)**.** *Every classifier reorganization has classifier novelty value* 1*.*

Proof. Reorganization is defined by failure of classifier equivalence on the common source scope. The classifier novelty value is therefore 1. □

Corollary 9462.286 (Discovery need not only refine)**.** *Classifier-level interpretability discovery may occur by refinement, coarsening, reorganization, bridge, boundary, or unification modes.*

Proof. The first three modes directly change classifier equivalence. The bridge, boundary, and unification modes are discovery modes when their certified classifier surface is not equivalent to the prior one. □

9462.11.3 Discovery Grades

Definition 9462.287 (Discovery candidate)**.** *An interpretability transition is a discovery candidate when its classifier novelty value is* 1 *and the target state has candidate NameCert and ledger rows whose closure status is still under audit.*

Definition 9462.288 (Certified interpretability discovery)**.** *An interpretability transition is a certified interpretability discovery when its classifier novelty value is* 1 *and the target state carries a complete NameCert and ledger for the changed classifier surface.*

Definition 9462.289 (Positive interpretability discovery grade)**.** *A certified interpretability discovery is positive when its relative net explanation information is positive:*

$$\Delta\mathsf{Info}_{\mathbf{w}}(E_0, E_1) > 0.$$

Definition 9462.290 (Ledger-only, hybrid, and fully hardened discovery)**.** *A ledger-only interpretability discovery has complete NameCert and ledger rows but no hardened formal component. A hybrid discovery combines empirical, paper, ledger, and formal evidence. A fully hardened discovery has all hardenable critical components formally hardened and all non-hardenable critical residue ledgered.*

Theorem 9462.291 (Certified discovery requires NameCert and ledger)**.** *Every certified interpretability discovery carries NameCert and ledger rows for the changed classifier surface.*

Proof. Those rows are part of the definition of certified interpretability discovery. This is the interpretability-specific instance of Definition 9462.52. □

Theorem 9462.292 (Positive discovery requires novelty and net gain)**.** *Every positive interpretability discovery has classifier novelty value* 1 *and positive relative net explanation information.*

Proof. Positive discovery is defined only after certified discovery has been established, and certified discovery requires classifier novelty. The positive grade then adds the inequality $\Delta\mathsf{Info}_{\mathbf{w}}(E_0, E_1) > 0$. □

Theorem 9462.293 (Discovery candidate is not certified discovery)**.** *A discovery candidate whose NameCert or ledger is incomplete is not a certified interpretability discovery.*

Proof. Certified discovery requires complete NameCert and ledger rows for the changed classifier surface. A candidate missing either row lacks the certificate surface required by the definition. □

Theorem 9462.294 (Claim demotion preserves audit soundness)**.** *If an asserted discovery claim lacks classifier novelty, NameCert, or ledger, replacing the claim by the strongest supported feature-side, circuit-side, ledger-side, hardening-side, or semantic-side claim preserves audit soundness.*

Proof. The replacement claim says only what the evidence supports. If the classifier did not change, the result is not classifier-level discovery. If NameCert or ledger rows are missing, the result may be a candidate or an audit improvement, but not a certified discovery. Stating the weaker claim prevents overclaiming. □

9462.11.4 NDNA, Debt, and Hardening

Definition 9462.295 (NDNA classifier-locus novelty)**.** *An NDNA transition has classifier-locus novelty when the classifier locus changes to a classifier not equivalent to the prior classifier on the common source scope.*

Definition 9462.296 (NDNA nonclassifier-locus change)**.** *An NDNA nonclassifier-locus change alters source, feature, circuit, stability, intervention, ledger, or seal loci while preserving the classifier locus.*

Theorem 9462.297 (NDNA classifier-locus novelty gives interpretability novelty)**.** *Every nontrivial NDNA classifier-locus novelty gives classifier novelty value* 1 *for the associated explanation transition.*

Proof. The classifier locus records the explanation classifier. If that locus changes to a nonequivalent classifier, there is a common-source pair whose classifier judgment differs, so Definition 9462.268 applies. □

Theorem 9462.298 (NDNA nonclassifier change need not create novelty)**.** *An NDNA transition that changes only nonclassifier loci need not create classifier novelty.*

Proof. If the classifier locus is preserved, the explanation classifier remains equivalent on the common source scope. The transition may still lower debt, add evidence, or close the seal. □

Definition 9462.299 (Classifier debt)**.** *Classifier debt is the debt carried by a missing classifier locus, an ambiguous classifier relation, an unrecorded classifier boundary, a threshold gap, or an unledgered false split or false merge.*

Theorem 9462.300 (Classifier debt reduction need not create novelty)**.** *Reducing classifier debt does not by itself create classifier novelty.*

Proof. Debt can be reduced by stating the old classifier more clearly, adding boundary rows, recording threshold sensitivity, or clarifying source scope. These changes can preserve the classifier relation. □

Theorem 9462.301 (Critical classifier debt can force classifier novelty)**.** *If repairing critical classifier debt forces a change in the classifier boundary, then the repair produces classifier novelty.*

Proof. Changing the classifier boundary means that some common-source pair is classified differently after the repair. That pair is a local classifier novelty witness. □

Theorem 9462.302 (Verification-only hardening has no classifier novelty)**.** *Formal hardening that preserves the explanation classifier has classifier novelty value* 0*.*

Proof. Verification-only hardening changes evidence mode or proof status. If the classifier relation is preserved on the common source scope, the explanation states remain classifier-equivalent. □

Theorem 9462.303 (Formal classifier discovery requires a classifier witness)**.** *A formal verification step that claims classifier-level discovery must display a witness that the verified target classifier is not equivalent to the prior classifier.*

Proof. Without such a witness, the formal step may harden an existing component but does not establish classifier novelty. A classifier-level discovery claim requires failure of classifier equivalence. □

Theorem 9462.304 (Interpretability classifier novelty theorem)**.** *Classifier-level interpretability discovery is certified classifier shift, not feature accumulation, circuit elaboration, ledger repair, semantic relabeling, or verification-only hardening.*

Proof. Feature, circuit, ledger, hardening, and semantic changes can preserve classifier equivalence by Definition 9462.274, Definition 9462.275, Definition 9462.276, and Definition 9462.277. Refinement, coarsening, and reorganization create classifier novelty by Definition 9462.283, Definition 9462.284, and Definition 9462.285. Certified discovery additionally requires NameCert and ledger by Definition 9462.291, and positive discovery additionally requires positive net explanation information by Definition 9462.292. □

9462.12 Interpretability Classifier Novelty in Practice

section 9462.11 separates classifier-level discovery from feature-side, circuit-side, ledger-side, semantic-side, and verification-side improvement. This section records the practical audit taxonomy for machine-learning interpretability work: what kind of event occurred, whether it changed the certified classifier surface, and whether the resulting lineage is optimization or discovery.

Definition 9462.305 (Interpretability event kinds)**.** *Feature events identify feature functionals or activation patterns. Classifier events identify changed classifier relations. Certificate events construct or repair NameCert rows. Ledger events discover critical residue or failure boundaries. Verification events harden formal components.*

Theorem 9462.306 (Feature events are not necessarily classifier events)**.** *A feature event need not be a classifier event.*

Proof. A feature functional may be redundant with the prior classifier or may serve only as another implementation route for the same classifier cells. Unless the classifier relation changes, classifier novelty is absent. □

Theorem 9462.307 (Ledger events can become classifier events)**.** *A ledger event becomes a classifier event when the critical residue it records forces the classifier boundary to change.*

Proof. Critical residue can expose a false split, false merge, threshold boundary, or unsupported source region. If correcting that residue changes the classifier judgment on a common-source pair, the transition has classifier novelty. □

Theorem 9462.308 (Certificate events are not necessarily classifier events)**.** *Constructing or improving a NameCert for an existing classifier need not be a classifier event.*

Proof. The certificate event can improve audit status while leaving the classifier relation unchanged. It is then certification progress rather than classifier-level discovery. □

Definition 9462.309 (Interpretability lineage)**.** *An interpretability lineage is a finite chain of explanation states*

$$\mathcal{E}_0 \rightsquigarrow \mathcal{E}_1 \rightsquigarrow \cdots \rightsquigarrow \mathcal{E}_n.$$

It is an optimization lineage when every edge has classifier novelty value 0 *while some edge lowers score, debt, or hardening gap. It is a discovery lineage when at least one edge has classifier novelty value* 1*.*

Theorem 9462.310 (Optimization lineage need not be discovery lineage)**.** *An interpretability lineage can improve explanation quality without being a discovery lineage.*

Proof. A lineage may add source rows, ledger rows, negative examples, stability evidence, or formal hardening while preserving the classifier relation at every edge. Then its classifier novelty value is always 0, although score, debt, or hardening gap may improve. □

Theorem 9462.311 (Discovery lineage need not be immediately positive)**.** *A discovery lineage can have nonpositive net explanation information at the edge where classifier novelty first appears.*

Proof. A changed classifier may require additional source, stability, ledger, seal, semantic, and verification work. Before the resulting benefit and debt reduction dominate those costs, the net information difference can be nonpositive. □

Definition 9462.312 (Classifier-prioritized search)**.** *Classifier-prioritized search ranks candidates first by evidence of classifier novelty, then audits NameCert closure, ledger closure, and net explanation information. Feature-prioritized search ranks candidates first by feature events.*

Theorem 9462.313 (Classifier-prioritized search differs from feature-prioritized search)**.** *Classifier-prioritized search and feature-prioritized search can select different candidates.*

Proof. By Definition 9462.306, feature events need not change classifiers. A search that ranks feature events can therefore select a candidate with no classifier novelty, while a classifier-prioritized search selects a candidate with a changed classifier surface. □

Theorem 9462.314 (Practice audit theorem)**.** *Interpretability reports should state separately whether a result is a feature event, classifier event, certificate event, ledger event, verification event, optimization lineage, discovery lineage, or positive discovery lineage.*

Proof. Feature, certificate, ledger, and verification events can improve an explanation without classifier novelty. Classifier events can introduce novelty before becoming positive in net information. Optimization and discovery lineages therefore track different audit coordinates and should not be collapsed into one report label. □

Concretized in §6225: Practice-level classifier shifts are recorded as finite NameCert data.

9462.13 Positive Interpretability Discovery

section 9462.11 defines classifier novelty as the discovery axis, and section 9462.10 defines net explanation information as benefit minus score and debt. Positive interpretability discovery is the conjunction of these two audits: the explanation must introduce a certified classifier shift, and the shift must pay for its certificate, ledger, and remaining debt under a public cost protocol.

Definition 9462.315 (Certified discovery transition)**.** *A transition $E_0 \rightsquigarrow E_1$ is a certified discovery transition when it has classifier novelty, the target classifier state has a NameCert, the changed classifier surface has ledger rows, the classifier shift has a local or formal witness, and the seal records the not-claimed boundary.*

Definition 9462.316 (Positive discovery transition)**.** *A certified discovery transition is positive when*

$$\Delta\mathsf{Info}_{\mathbf{w}}(E_0, E_1) > 0$$

for the public cost protocol used by the claim. It is negative when the quantity is below zero and neutral when it is zero.

Definition 9462.317 (Strong positive discovery)**.** *A positive discovery transition is strong when the target explanation has zero critical debt, a scope seal, reproducible classifier and ledger evidence, a public cost protocol, and a NameCert-compatible NDNA packet.*

Definition 9462.318 (False positive discovery claim)**.** *A claim is a false positive discovery claim when it asserts positive interpretability discovery while lacking classifier novelty, NameCert, ledger, positive net explanation information, a public cost protocol, or a declared not-claimed boundary.*

Theorem 9462.319 (Positive discovery implies certified discovery)**.** *Every positive discovery transition is a certified discovery transition.*

Proof. Positive discovery is defined by adding the strict net-information inequality to certified discovery. Hence all certified-discovery requirements are inherited. □

Corollary 9462.320 (Positive discovery requires classifier novelty)**.** *Every positive discovery transition has classifier novelty.*

Proof. Certified discovery requires classifier novelty by Definition 9462.315, and positive discovery implies certified discovery. □

Corollary 9462.321 (Positive discovery requires NameCert and ledger)**.** *Every positive discovery transition carries NameCert and ledger rows for the changed classifier surface.*

Proof. These rows are part of certified discovery, which every positive discovery transition satisfies. □

Theorem 9462.322 (Classifier novelty alone is not positive discovery)**.** *Classifier novelty by itself does not imply positive interpretability discovery.*

Proof. A changed classifier can be expensive to source, stabilize, ledger, intervene on, verify, or seal. It may also lack complete NameCert or ledger rows. If the net information is nonpositive, or if the certificate surface is incomplete, the transition is not positive discovery. □

Theorem 9462.323 (Positive information alone is not discovery)**.** *Positive net explanation information does not imply positive interpretability discovery.*

Proof. The net gain can come from ledger completion, lower score, verification debt reduction, source-scope clarification, semantic-ledger completion, or a better not-claimed boundary while the classifier relation is unchanged. Such a transition has no classifier novelty and is therefore not discovery. □

Theorem 9462.324 (Ledger completion can be positive without discovery)**.** *Ledger completion can yield positive net explanation information while preserving the classifier.*

Proof. Completing a critical ledger can lower debt more than it increases score. If the classifier relation is unchanged, the transition is a positive audit improvement rather than classifier-level discovery. □

Theorem 9462.325 (Formal hardening can be positive without discovery)**.** *Formal hardening can yield positive net explanation information while preserving the classifier.*

Proof. Hardening can lower verification debt and increase reuse. If its gain exceeds its verification cost while the classifier relation remains unchanged, it is a positive hardening improvement rather than positive interpretability discovery. □

9462.13.1 Cost Protocols

Definition 9462.326 (Positive discovery cost protocol)**.** *A positive discovery cost protocol specifies the benefit functional, score functional, debt functional, weight profile, source and target scope, and not-claimed boundary used to evaluate* $\Delta\mathsf{Info}_{\mathbf{w}}(E_0, E_1)$.

Definition 9462.327 (Cost opacity and cost debt)**.** *Cost opacity occurs when a positive discovery claim hides its benefit, score, debt, weight, scope, or excluded-claim conventions. Cost debt is the uncounted cost or debt created by omitting a critical term such as ledger cost, semantic debt, verification debt, intervention debt, or generalization debt.*

Concretized in §6202: Positive interpretability classifiers realize the certified-discovery and positive-cost-protocol surface as finite classifier-shift, ledger, debt, and NameCert rows.

Concretized in §7414: Positive discovery debt ledgers realize the cost-protocol and critical-debt rows for the certified-discovery route.

Theorem 9462.328 (Positive discovery requires protocol completeness)**.** *A positive discovery claim is auditable only when its cost protocol is complete and public.*

Proof. The sign of $\Delta\mathsf{Info}_{\mathbf{w}}$ depends on benefit, score, debt, and weights inside a declared scope. If any of these terms is hidden, the strict positivity claim cannot be checked. □

Theorem 9462.329 (Cost debt can invalidate positivity)**.** *Adding omitted critical cost or debt terms can turn an apparently positive discovery claim into a nonpositive one.*

Proof. Net information subtracts score and debt. If omitted cost or debt is restored, the computed net gain decreases. When the omitted amount exceeds the original positive margin, the strict positivity inequality fails. □

Corollary 9462.330 (Positive discovery must count critical debts)**.** *Ledger, semantic, verification, intervention, and generalization debts must be included whenever they are relevant to the claim.*

Proof. These are critical debt classes for interpretability claims. Omitting them creates cost debt, which can invalidate positivity by Definition 9462.329. □

9462.13.2 Benefit Types

Definition 9462.331 (Positive discovery benefit modes)**.** *Positive discovery may be coverage-positive, prediction-positive, transfer-positive, intervention-positive, unification-positive, verification-positive, or ledger-positive, according to the benefit term that principally drives the positive net information inequality.*

Theorem 9462.332 (Benefit modes can overlap)**.** *A positive discovery transition can have several benefit modes at once.*

Proof. The benefit functional is a sum of coverage, prediction, transfer, intervention, verification, and unification terms. More than one term can make a material contribution to the positive margin. □

Corollary 9462.333 (Positive discovery should report benefit structure)**.** *A positive discovery claim should state which benefit terms drive its positive margin.*

Proof. Since benefit modes can overlap and trade off against costs and debts, reporting only the final sign hides the reason the transition is positive. □

9462.13.3 Strong and NDNA-Positive Discovery

Definition 9462.334 (NDNA-positive discovery criterion)**.** *A transition satisfies the NDNA-positive criterion when it has classifier novelty, the target NDNA is complete, anchored, NameCert-compatible, and ledger-complete, and the NDNA-level net information difference is positive.*

Theorem 9462.335 (NDNA-positive criterion implies positive discovery)**.** *Every transition satisfying the NDNA-positive criterion is a positive interpretability discovery.*

Proof. Classifier novelty supplies the discovery axis. Complete, anchored, NameCert-compatible NDNA supplies the certified explanation surface, and ledger completeness supplies the required ledger. The positive NDNA-level net information difference supplies the positivity condition. □

Theorem 9462.336 (NDNA completeness alone is not positive discovery)**.** *Complete NDNA alone does not imply positive interpretability discovery.*

Proof. Completeness says that all eight loci are present. It does not state that the classifier differs from the prior classifier, that the NameCert projection is compatible, or that net explanation information is positive. □

Theorem 9462.337 (Strong positive discovery implies positive discovery)**.** *Every strong positive discovery is a positive discovery.*

Proof. Strong positive discovery includes positive discovery and adds zero critical debt, scope sealing, reproducibility, a public cost protocol, and NameCert-compatible NDNA. □

Theorem 9462.338 (Positive discovery need not be strong)**.** *A positive discovery transition need not be strong.*

Proof. A transition can have classifier novelty, NameCert, ledger, and positive net information while still retaining noncritical debt, an incomplete reproducibility package, a partially developed seal, or an unsettled hardening frontier. □

9462.13.4 Black-Box Resolution and Verification

Definition 9462.339 (Positive black-box resolution)**.** *A transition is a positive black-box resolution when it lowers black-box debt by more than the additional explanation score charged to that resolution inside the declared scope.*

Definition 9462.340 (Positive discovery-resolution)**.** *A transition is a positive discovery-resolution when it is both a positive interpretability discovery and a positive black-box resolution.*

Theorem 9462.341 (Positive black-box resolution need not be discovery)**.** *Positive black-box resolution does not imply interpretability discovery.*

Proof. Completing the ledger of an existing classifier can reduce black-box debt more than it increases score. If the classifier remains unchanged, the transition resolves black-box residue but does not discover a classifier. □

Theorem 9462.342 (Positive discovery-resolution is the strongest resolution form)**.** *A positive discovery-resolution both changes the certified classifier surface and positively reduces black-box debt in net terms.*

Proof. The first condition follows from positive interpretability discovery. The second follows from positive black-box resolution. Thus the transition improves both the classifier axis and the black-box debt axis. □

Definition 9462.343 (Verification-assisted positive discovery)**.** *A positive discovery is verification-assisted when formal hardening contributes to the positive margin. It is verification-dependent when removing the verification benefit makes the net information difference nonpositive.*

Theorem 9462.344 (Verification assistance does not replace classifier novelty)**.** *Verification-assisted positive discovery still requires classifier novelty.*

Proof. The verification term can contribute to benefit, but positive discovery also requires certified classifier shift. A verification-only transition without classifier novelty is a hardening improvement, not discovery. □

Theorem 9462.345 (Verification-assisted discovery must count verification cost)**.** *If formal hardening contributes to a positive discovery claim, then verification cost and verification-ledger debt must be included.*

Proof. Formal hardening can increase benefit, but it also adds proof cost, dependency cost, trust-boundary obligations, and verification-ledger residue. Omitting those terms overstates net information. □

9462.13.5 Lineage and Anti-Laundering

Definition 9462.346 (Positive discovery lineages)**.** *A positive discovery lineage contains at least one positive discovery transition. A pre-positive discovery lineage contains a certified discovery step that is not yet positive. A delayed-positive lineage becomes positive only after later ledger repair, compression, hardening, transfer, or unification work. A transient-negative lineage has an initial discovery step whose net information is negative.*

Theorem 9462.347 (Discovery can become positive later)**.** *A certified discovery transition with nonpositive net information can become part of a positive discovery lineage after later audit work.*

Proof. The initial classifier shift can impose high source, stability, ledger, seal, semantic, or verification costs. Later work can lower debt, reduce score, increase transfer, or improve unification. The total transition from the original state to the later state can then have positive net information. □

Theorem 9462.348 (Positive status can decay under new debt)**.** *A positive discovery claim can lose positive status when later audit reveals critical debt large enough to erase the positive margin.*

Proof. Positive status depends on $\Delta\mathsf{Info}_{\mathbf{w}} > 0$. Newly recorded critical debt increases the debt term. If it exceeds the margin, the inequality no longer holds. □

Definition 9462.349 (Discovery laundering)**.** *Scope laundering creates apparent positive gain by hiding a scope narrowing. Debt laundering hides ledger, semantic, verification, intervention, or generalization debt. Classifier laundering presents feature-side, ledger-side, hardening-side, or semantic-side improvement as classifier novelty.*

Theorem 9462.350 (Laundering invalidates positive discovery claims)**.** *Any positive discovery claim that relies on scope, debt, or classifier laundering is invalid.*

Proof. Scope laundering changes the domain of the benefit and debt calculation without sealing the change. Debt laundering suppresses terms subtracted by net information. Classifier laundering asserts classifier novelty where the classifier relation is unchanged. Each case violates a necessary audit condition for positive discovery. □

Theorem 9462.351 (Positive interpretability discovery theorem)**.** *Positive interpretability discovery is certified classifier novelty with positive net explanation information under a public, debt-complete, scope-sealed cost protocol.*

Proof. Definition 9462.319 gives certified discovery, including classifier novelty, NameCert, ledger, witness, and not-claimed boundary. Definition 9462.316 supplies the strict net-information inequality. Definition 9462.328 and Definition 9462.330 require a public protocol and critical debt accounting. Definition 9462.350 rules out apparent gains obtained by hiding scope, debt, or classifier non-novelty. These conditions are exactly the stated characterization. □

9462.14 Classifier-Forming Learning

section 9462.13 defines positive discovery as certified classifier novelty with positive net explanation information. The same separation applies to learning itself. A training run can move parameters, lower an objective, improve a benchmark, memorize more cases, or expose more traces without yet forming a certified classifier. In the BEDC reading, strong learning is classifier formation under training pressure: a stable distinction is extracted from a learning trajectory, lifted to a NameCert surface, and ledgered against the residues that training can hide.

Definition 9462.352 (Learning system)**.** *A learning system is a tuple*

$$\mathcal{M} = (X, Y, \Theta, M, \mathcal{D}, \mathcal{L}),$$

where X is an input space, Y is an output space, Θ is a parameter space, $M : \Theta \to (X \to Y)$ is a model family, $\mathcal{D}$ is a data family or sampling regime, and $\mathcal{L}$ is a loss, reward, constraint, or other training pressure. For $\theta \in \Theta$, write $M_\theta = M(\theta)$.

Definition 9462.353 (Learning state)**.** *A learning state is*

$$\mathfrak{L} = (\theta, R, \mathcal{B}, \mathcal{C}, \Lambda),$$

where θ is the model state, R is the training record, $\mathcal{B}$ is the family of observed behaviors, $\mathcal{C}$ is the family of classifier candidates or certified classifiers, and Λ is the learning ledger recording training, generalization, compression, memorization, failure, shortcut, and distribution-boundary residue.

Definition 9462.354 (Learning transition)**.** *A learning transition is a passage*

$$\mathfrak{L}_t \rightsquigarrow \mathfrak{L}_{t+1}$$

between learning states. It may change the model state, extend the training record, alter observed behavior, expose classifier candidates, construct NameCert rows, repair ledgers, harden formal components, or add transfer evidence.

Definition 9462.355 (Learning classifier state)**.** *A learning classifier state is the certified classifier state*

$$\mathcal{T}_{\mathsf{learn}} = (S_{\mathsf{learn}}, P_{\mathsf{learn}}, L_{\mathsf{learn}}, C_{\mathsf{learn}}, N_{\mathsf{learn}}),$$

where S_{learn} records data, traces, activation sources, task scope, and training protocol; P_{learn} records the learned pattern; L_{learn} records the learning ledger; C_{learn} is the classifier induced by the learning process; and N_{learn} licenses the state.

Definition 9462.356 (Learning classifier shift)**.** *Two learning classifier states are equivalent when their classifier relations agree on the common source scope. A learning transition has learning classifier shift when the before and after learning classifier states are not equivalent.*

Definition 9462.357 (Certified learning discovery)**.** *A learning transition is a certified learning discovery when it has learning classifier shift, the target classifier has a NameCert, the learning ledger records the relevant scope and boundary residues, and the classifier supports observable behavior or certified generalization.*

Definition 9462.358 (Positive certified learning)**.** *A certified learning discovery is positive when its learning net information is positive:*

$$\mathsf{Info}_{\mathsf{learn}} = \mathrm{Benefit}_{\mathsf{learn}} - \mathrm{Cost}_{\mathsf{learn}} - \mathrm{Debt}_{\mathsf{learn}} > 0.$$

The benefit term may include coverage, prediction, generalization, transfer, compression, intervention, and unification gains. The cost term includes training, data, model, NameCert, ledger, and verification costs. The debt term includes unrecorded learning residue.

9462.14.1 Separation from Metrics

Theorem 9462.359 (Parameter motion is not learning discovery)**.** *A change in parameter state does not by itself imply certified learning discovery.*

Proof. Parameter motion reports an internal numerical change. It does not display a changed classifier relation, a source specification, a pattern row, a stability witness, a ledger policy, or a NameCert. Equivalent reparameterization, margin movement, and calibration can move parameters while preserving the classifier surface. □

Theorem 9462.360 (Model size is not certified information)**.** *Increasing parameter count or representational capacity does not by itself produce certified learning information.*

Proof. Additional capacity can store redundant representations, memorized cases, or alternative implementations of the same classifier. Certified learning information requires a classifier surface with NameCert and ledger rows. □

Theorem 9462.361 (Loss reduction is not learning discovery)**.** *Lower loss does not by itself imply certified learning discovery.*

Proof. Loss reduction can come from calibration, increased margin, sample memorization, shortcut use, or optimization inside an already certified classifier. It supplies an optimization signal, not the source, classifier, stability, and ledger rows required for learning discovery. □

Theorem 9462.362 (Learning discovery can precede loss reduction)**.** *A classifier can form before it lowers the displayed training loss.*

Proof. A classifier may support future transfer, organize a latent distinction, or apply to a target domain not emphasized by the current objective. Its certificate value is therefore not determined by immediate loss decrease. □

Theorem 9462.363 (Performance gain is not a certified explanation)**.** *External performance or benchmark improvement does not by itself supply a certified explanation of what was learned.*

Proof. A performance row reports behavior under a score. It does not identify which classifier supports the behavior, whether that classifier differs from a prior state, whether it is stable under transfer, or whether its failure boundary is ledgered. □

Corollary 9462.364 (Training success is not structural learning)**.** *A training run can succeed under its metric while failing to produce a certified learning discovery.*

Proof. Metric success may result from parameter optimization, calibration, memorization, or shortcut use under the same classifier surface. By the preceding theorems, none of these alone supplies certified classifier formation. □

9462.14.2 Memory, Generalization, and NameCert

Definition 9462.365 (Memorization event)**.** *A memorization event occurs when the model preserves reproducible outputs for training cases or training patterns without a transferable classifier witness. A rote learning transition is one whose main visible effect is memorization or record growth rather than certified classifier formation.*

Definition 9462.366 (Classifier-mediated generalization)**.** *Classifier-mediated generalization occurs when behavior on a target domain is supported by the same classifier surface formed on a source domain, together with a stability or transfer witness and a target residue ledger.*

Definition 9462.367 (Learning NameCert)**.** *A Learning NameCert for a learned classifier is*

$$\mathsf{NameCert}_{\mathsf{learn}} = (S_{\mathsf{learn}}, P_{\mathsf{learn}}, C_{\mathsf{learn}}, \Sigma_{\mathsf{learn}}, L_{\mathsf{learn}}).$$

The rows record training sources and extraction protocol, stable learned patterns, the induced classifier, stability or transfer evidence, and the learning ledger.

Theorem 9462.368 (Memorization is not structural learning)**.** *Memorization without a certified classifier is not structural learning.*

Proof. Structural learning requires a classifier surface that supports compression, prediction, transfer, or unification beyond the memorized records. A memorization event alone supplies stored cases, not a NameCert-backed classifier. □

Theorem 9462.369 (Certified generalization is structural learning)**.** *Classifier-mediated generalization with NameCert and ledger is structural learning.*

Proof. The transfer witness says that the source-side classifier remains the governing relation on the covered target side. The NameCert and ledger make the classifier and its target residue auditable. This is certified classifier formation with transfer scope. □

Theorem 9462.370 (Learning NameCert creates a certified learning object)**.** *A learned classifier equipped with a Learning NameCert is a certified learning object.*

Proof. The Learning NameCert supplies source, pattern, classifier, stability, and ledger rows. These are exactly the rows needed to treat the learned classifier as an auditable object rather than a parameter vector, loss value, activation dump, feature label, or benchmark row. □

Theorem 9462.371 (Learning claims require learning ledger)**.** *A claim that a model learned a structure is not closed without a learning ledger.*

Proof. Learning claims can hide memorization, shortcut use, spurious correlation, data leakage, benchmark overfitting, unsupported transfer, out-of-domain failure, threshold debt, feature entanglement, semantic debt, and verification debt. These residues must be recorded before the claim is closed. □

Theorem 9462.372 (Shortcut learning is not certified discovery without ledger)**.** *Shortcut-based performance gain is not certified learning discovery when shortcut debt is unrecorded.*

Proof. A shortcut may raise performance while depending on a spurious correlation. Without ledger rows for source, pattern, stability, and failure boundary, the apparent classifier lacks a complete Learning NameCert. □

9462.14.3 Representation and Transfer

Definition 9462.373 (Representation classifier)**.** *Given an activation map $a_\ell^\theta : X \to V_\ell$ and a tensor distinction $\phi : V_\ell \to [0,1]$, a representation classifier at threshold τ is the relation*

$$x \sim_{\ell,\phi,\tau} y \quad \Longleftrightarrow \quad m_{\phi,\tau}(a_\ell^\theta(x)) = m_{\phi,\tau}(a_\ell^\theta(y)).$$

Definition 9462.374 (Certified representation learning)**.** *Representation learning is certified when a representation classifier is equipped with a Tensor NameCert and a ledger for representation compression debt.*

Definition 9462.375 (Learning-to-generalization bridge)**.** *A learning-to-generalization bridge records that a classifier formed on a source domain is the classifier used on a covered target domain. Its certificate includes source and target domains, transfer or stability witness, target residue, failure cases, and not-claimed target boundary.*

Theorem 9462.376 (Representation learning requires Tensor NameCert)**.** *Features, clusters, embeddings, or low-dimensional views do not by themselves certify representation learning.*

Proof. They are candidate evidence for a representation classifier. Certified representation learning requires the source, pattern, classifier, stability, and ledger rows supplied by a Tensor NameCert. □

Theorem 9462.377 (Representation compression requires ledger)**.** *Representation compression requires a ledger for collapsed distinctions.*

Proof. Dimensionality reduction, bottlenecks, sparse-autoencoder codes, probes, clusters, and latent compression can collapse source distinctions. The collapsed distinctions are hidden residue and must be recorded when the representation is used as an explanatory certificate. □

Theorem 9462.378 (Certified generalizing learner requires transfer ledger)**.** *A model is a certified generalizing learner only when its classifier transfer is ledgered.*

Proof. The transfer ledger records target residue, out-of-domain boundary, failed transfer, stability limits, and not-claimed target scope. A test-set score can be evidence, but it is not this ledger. □

9462.14.4 Effect Certification

Definition 9462.379 (Machine-learning effect certificate)**.** *A machine-learning effect certificate is a derived packet*

$$\mathsf{MLEffectCert}(\hat{\theta}, D, \Pi, \ell, \epsilon, \mathcal{C})$$

whose rows record the source data packet, split provenance, training trace, prediction rows, loss-classifier rows, fit rows, validation or test rows, stability domain $\mathcal{C}$, NoLeak audit, failure surface, reproducibility row, and Learning NameCert for the predictor $\hat{\theta}$.

Definition 9462.380 (Certified machine-learning effectiveness)**.** *A predictor $\hat{\theta}$ is machine-learning-effective relative to $(D, \Pi, \ell, \epsilon, \mathcal{C})$ when $\mathsf{MLEffectCert}(\hat{\theta}, D, \Pi, \ell, \epsilon, \mathcal{C})$ is accepted and the displayed evaluation row satisfies*

$$\mathrm{Err}_\ell(\hat{\theta}; D_*) \preceq_\ell \epsilon$$

for the declared evaluation split D_*.

Theorem 9462.381 (Training fit does not imply learning effectiveness)**.** *A low training loss row does not by itself establish certified machine-learning effectiveness.*

Proof. Training fit compares the predictor only with the records consumed by the training route. The effect certificate also requires split provenance, prediction rows on the declared evaluation split, loss classifier rows, stability domain, NoLeak audit, failure surface, reproducibility, and a Learning NameCert. A training row omits these fields and therefore cannot license the effectiveness claim. □

Theorem 9462.382 (Effectiveness is scope-relative)**.** *An accepted machine-learning effect certificate licenses effectiveness only relative to its displayed data packet, protocol, loss classifier, error budget, and stability domain.*

Proof. Each row of the effect certificate is indexed by the declared source, split, protocol, loss, budget, and continuation scope. The certificate therefore proves a bounded predictor claim over those rows. It does not export an unrestricted claim over unlisted domains, losses, budgets, tasks, or continuation classes. □

Theorem 9462.383 (Leakage breaks effect certification)**.** *If evaluation information enters the training or selection route without being recorded as an admitted source row, the machine-learning effect certificate is not accepted.*

Proof. The split and NoLeak rows distinguish prediction on held-out records from replay of information already present in the training route. If evaluation information enters the training or selection route, the declared evaluation row no longer witnesses prediction on separated records. The split provenance and NoLeak audit therefore fail, so the effect certificate is rejected. □

Definition 9462.384 (Machine-learning effect strength)**.** *Machine-learning effect strength is ordered by the strongest certificate row displayed for the predictor:*

$$\mathsf{TrainFit} < \mathsf{ValFit} < \mathsf{TestFit} < \mathsf{ReproducedFit} < \mathsf{StabilityFit} < \mathsf{BridgeFit} < \mathsf{TheoremPreservingBridge}.$$

The rows respectively record training fit, validation fit, test fit with split provenance, reproduced fit, certified continuation stability, records-to-readout bridge fit, and bridge fit with preservation rows.

Theorem 9462.385 (Effect strength is certificate strength)**.** *An effectiveness claim may be reported only at the strongest effect row whose certificate fields are present.*

Proof. Each effect row adds fields not supplied by the weaker rows. Validation requires a split row beyond training fit. Test fit requires test-split provenance and NoLeak audit beyond validation fit. Reproduced fit requires a reproducibility row. Stability fit requires a certified continuation class and failure surface. Bridge fit requires an adapter or bridge readout row. Theorem-preserving bridge fit requires preservation rows. If those additional fields are absent, the stronger claim is not licensed by the displayed certificate. □

Corollary 9462.386 (Test fit requires split provenance)**.** *A small error row on a named test split does not have test-effect meaning unless the split provenance and NoLeak rows are present.*

Proof. By Definition 9462.384, TestFit includes test-split provenance. By Definition 9462.383, an evaluation row whose separation is not certified cannot pass the effect certificate. The remaining statement is only a finite record comparison, not a certified test-effect row. □

9462.14.5 Lineage, Verification, and Anti-Laundering

Definition 9462.387 (Learning lineage)**.** *A learning lineage is a finite chain of learning states. It is an optimization lineage when the visible improvements are parameter, record, loss, or performance improvements without certified classifier shift. It is a structural learning lineage when at least one edge has certified classifier shift. It is positive when at least one certified learning discovery has positive learning net information.*

Theorem 9462.388 (Optimization lineage need not be structural learning)**.** *A learning lineage can improve loss or performance without being a structural learning lineage.*

Proof. Old classifiers can become better calibrated, higher-margin, more memorized, or more shortcut-adapted without a certified classifier shift. The lineage improves metrics but not the certified classifier surface. □

Theorem 9462.389 (Structural learning need not be immediately positive)**.** *A structural learning transition can have nonpositive net learning information when the classifier first appears.*

Proof. The classifier may require costly source, stability, transfer, ledger, verification, and seal work before its benefits exceed its costs and remaining debts. □

Theorem 9462.390 (Verified learning claim is not necessarily learning discovery)**.** *Formal verification of a learning component is not learning discovery unless it changes and certifies the learning classifier surface.*

Proof. Verification can harden a property of data, optimization, stability, or certification while preserving the classifier relation. Then it is a hardening improvement rather than classifier-forming learning. □

Theorem 9462.391 (Formal hardening cost enters learning information)**.** *When formal hardening is counted as learning benefit, its cost and verification debt must also be counted.*

Proof. Hardening adds proof, dependency, backend, maintenance, and trust-boundary obligations. Omitting these terms overstates learning net information. □

Definition 9462.392 (Learning laundering)**.** *Loss laundering treats lower loss as learning discovery. Benchmark laundering treats score improvement as learning discovery. Parameter laundering treats model size or architecture complexity as learning discovery. Memorization laundering treats stored training cases as generalization. Shortcut laundering treats shortcut-based performance as certified classifier learning.*

Theorem 9462.393 (Learning laundering invalidates discovery claims)**.** *Loss, benchmark, parameter, memorization, and shortcut laundering invalidate certified learning discovery claims.*

Proof. Certified learning discovery requires classifier shift, NameCert, and ledger. Lower loss, higher benchmark score, parameter growth, memorized cases, and shortcut performance do not supply those rows. Shortcut and memorization claims are especially debt-bearing unless their residues are ledgered. □

Theorem 9462.394 (Classifier-forming learning theorem)**.** *The information-theoretic content of machine learning is certified classifier formation rather than parameter motion, loss reduction, benchmark improvement, record growth, or memorization.*

Proof. Definition 9462.359, Definition 9462.360, Definition 9462.361, and Definition 9462.363 separate learning discovery from common metrics. Definition 9462.368 separates structural learning from rote storage. Definition 9462.370 gives the certificate route from learned classifier to learning object. Definition 9462.371 supplies the ledger condition, and Definition 9462.393 rules out metric-based substitutes. □

Concretized in §6097: The finite packet realizes classifier-forming learning as certified classifier shift with ledgered training residue.

Concretized in §7546: Classifier-formation traces realize learning classifier shift as finite before/after classifier, ledger-residue, and NameCert rows.

9462.15 Certified Model Quality

section 9462.18 decomposes a machine-learning black box into missing certificate rows, and section 9462.14 reads learning as certified classifier formation. Model quality is the evaluation-level form of the same discipline. A model is not better merely because a displayed score rises. It is better on a declared scope when its critical behaviors are supported by certified classifiers, their stability and transfer rows improve, and their remaining black-box, ledger, shortcut, safety, semantic, and verification debts are accounted for under a public cost protocol.

Definition 9462.395 (Model quality scope)**.** *A model quality scope is a tuple*

$$\Omega_{\mathsf{q}} = (D, M, \mathcal{A}, \mathcal{B}_{\mathsf{crit}}, \Pi),$$

where D is the evaluation domain, M is the model state, $\mathcal{A}$ is the admitted transformation, perturbation, intervention, or transfer family, $\mathcal{B}_{\mathsf{crit}}$ is the family of critical behavior targets, and Π is the public scoring and certificate protocol.

Definition 9462.396 (Certified behavior coverage)**.** *For a model quality scope Ω_{q}, the certified behavior coverage of M is the subfamily*

$$\mathrm{CertBeh}(M; \Omega_{\mathsf{q}}) = \{B \in \mathcal{B}_{\mathsf{crit}} \mid \exists C, N.\ C \Vdash B \text{ and } N = \mathsf{NameCert}(C)\},$$

with the NameCert read on the displayed scope. The uncovered behavior family is

$$\mathrm{UncertBeh}(M; \Omega_{\mathsf{q}}) = \mathcal{B}_{\mathsf{crit}} \setminus \mathrm{CertBeh}(M; \Omega_{\mathsf{q}}).$$

Definition 9462.397 (Model quality ledger)**.** *A model quality ledger records, for every critical behavior target, the present classifier support, NameCert status, stability status, transfer status, safety boundary, shortcut risk, semantic boundary, verification status, failure cases, and not-claimed scope. It also records the public weights used to compare benefit, cost, and debt.*

Definition 9462.398 (Certified model quality score)**.** *For a public weight protocol $\mathbf{w}$, the certified model quality score is the audited quantity*

$$Q_{\mathbf{w}}(M; \Omega_{\mathsf{q}}) = \mathrm{Benefit}_{\mathbf{w}}(M; \Omega_{\mathsf{q}}) - \mathrm{Cost}_{\mathbf{w}}(M; \Omega_{\mathsf{q}}) - \mathrm{Debt}_{\mathbf{w}}(M; \Omega_{\mathsf{q}}).$$

The benefit term may include performance, certified classifier gain, stability gain, generalization gain, safety gain, intervention gain, and verification gain. The cost term records model, data, training, certificate, ledger, intervention, and verification cost. The debt term records black-box debt, ledger debt, stability debt, generalization debt, safety debt, shortcut debt, semantic debt, and verification debt.

Definition 9462.399 (Model quality improvement)**.** *A transition $M_0 \rightsquigarrow M_1$ is a certified model quality improvement on Ω_{q} when*

$$Q_{\mathbf{w}}(M_1; \Omega_{\mathsf{q}}) > Q_{\mathbf{w}}(M_0; \Omega_{\mathsf{q}})$$

and the comparison ledger records which benefit, cost, and debt rows changed.

Definition 9462.400 (Model quality gate)**.** *A model quality gate is a decision rule that accepts a model state on Ω_{q} only when the critical behavior coverage, maximum critical debt, safety ledger, transfer ledger, and verification ledger meet the declared thresholds of Π.*

9462.15.1 Separation from Performance

Theorem 9462.401 (Performance gain does not imply quality gain)**.** *A performance improvement on a displayed metric does not by itself imply certified model quality improvement.*

Proof. The certified model quality score includes benefit, cost, and debt. A metric improvement can be offset by certificate cost, stability loss, generalization debt, safety debt, shortcut debt, semantic debt, or verification debt. It may also leave the supporting classifier uncertified. Therefore the performance row alone does not determine the quality comparison. □

Concretized in §6625: Certified model quality ledgers are realized as finite behavior-coverage, weight-profile, cost, debt, stability, and verification NameCert rows.

Concretized in §6117: The CertifiedModelQualityUp chapter realizes the model-quality ledger as finite certificate rows.

Theorem 9462.402 (Debt reduction can improve quality without metric gain)**.** *For a fixed performance row, lowering critical debt can yield certified model quality improvement.*

Proof. If the performance contribution is unchanged and the added cost of the transition is smaller than the decrease in weighted critical debt, then the value of $Q_{\mathbf{w}}$ strictly increases by Definition 9462.398. The improvement is an audit improvement rather than a raw metric improvement. □

Theorem 9462.403 (Certified classifier gain is a quality row)**.** *Adding a NameCert-backed classifier for a critical behavior is a model quality benefit when its certificate cost and remaining debt are accounted for.*

Proof. The certified behavior coverage expands, and the behavior moves from uncovered or partial-certificate status toward certified support. The quality score counts this as certified classifier gain, while the certificate and ledger work enter the cost and debt terms. Thus the benefit is legitimate only under the public accounting protocol. □

Theorem 9462.404 (Unledgered classifier gain is not closed quality gain)**.** *A classifier that appears to support a critical behavior does not give closed model quality gain when its ledger is absent or critically incomplete.*

Proof. Critical behavior support requires not only a classifier candidate but also source, pattern, stability, and ledger rows. If the ledger is absent or critically incomplete, the behavior retains black-box residue by Definition 9462.465. The apparent gain therefore remains debt-bearing and cannot be counted as closed quality gain. □

9462.15.2 Debt-Guided Training

Definition 9462.405 (Debt-guided training signal)**.** *A debt-guided training signal is a training pressure derived from the model quality ledger. It may target boundary cases, unstable margins, shortcut residues, unsafe behavior, failed transfer, unclassified critical behaviors, semantic ambiguity, or verification gaps.*

Theorem 9462.406 (Ledger rows can define training targets)**.** *Critical residue recorded in a model quality ledger can be used as a certificate-guided training target.*

Proof. Each recorded residue row identifies a specific failure of source, pattern, classifier, stability, transfer, safety, semantic, or verification closure. A training objective can be directed at reducing that row, for example by adding boundary cases, strengthening margin stability, removing shortcut dependence, or improving transfer evidence. The ledger therefore supplies a structured target rather than an undifferentiated error signal. □

Theorem 9462.407 (Debt-guided training needs post-training recertification)**.** *Reducing a ledger-derived training loss does not by itself establish certified model quality improvement.*

Proof. The new model state may alter classifier boundaries, create new residue, shift safety behavior, or change the transfer scope. Certified quality compares the full audited score and ledger after the transition. Thus debt-guided training must be followed by renewed classifier, stability, ledger, and gate checks. □

Theorem 9462.408 (Model quality gate blocks laundering)**.** *A model quality gate rejects score, benchmark, feature, and verification laundering when the required certificate and ledger rows fail the declared thresholds.*

Proof. The gate reads acceptance from certified behavior coverage, critical debt, safety ledger, transfer ledger, and verification ledger rather than from a single performance row or proof artifact. A high score, a named feature, or a verified subcomponent therefore cannot pass the gate unless the corresponding certificate and ledger obligations are also met. □

Theorem 9462.409 (Certified model quality theorem)**.** *On a declared scope, model quality is certified classifier quality with public accounting for benefit, cost, and debt.*

Proof. Definition 9462.398 defines quality by benefit minus cost and debt. The benefit rows include certified classifier formation, stability, transfer, safety, intervention, and verification gains. The debt rows record the certificate and ledger residues that prevent closed explanation. The separation theorems above exclude performance-only and unledgered readings. Hence the BEDC quality object is the public accounting of certified classifier support for the critical behavior family. □

9462.16 World-Model Classifier Certification

section 9462.4 treats tensor features as classifier candidates, and section 9462.14 separates structural learning from loss reduction. World-model representation learning supplies a sharper test case. A latent representation does not become an explanation merely by aligning paired views, recovering a coordinate system, or improving planning. It becomes a BEDC object only when the recovered relation is displayed as a scoped classifier with source rows, stability rows, transfer rows, and a ledger for the assumptions that make the recovery meaningful.

Definition 9462.410 (World-model certification scope)**.** *A world-model certification scope is a tuple*

$$\Omega_{\mathsf{wm}} = (Z, X, g, \mathcal{P}, \mathcal{T}, \mathcal{H}, \mathcal{A}),$$

where Z is the latent carrier, X is the observation carrier, $g : Z \to X$ is the observation map, $\mathcal{P}$ is the positive-pair protocol, $\mathcal{T}$ is the transition family, $\mathcal{H}$ is the admitted encoder family, and $\mathcal{A}$ is the assumption ledger. The ledger records independence, stationarity, dimension matching, noise, sampling, population or finite-sample status, and not-claimed target domains.

Definition 9462.411 (World-latent classifier candidate)**.** *For an encoder $f : X \to V$, write $h = f \circ g : Z \to V$. A world-latent classifier candidate is a relation*

$$z \sim_h z'$$

whose public comparison is induced by h together with a declared readout rule. The readout may compare recovered coordinates, invariant subspaces, thresholded latent features, transition classes, or planning states, provided the scope records how those comparisons are observed.

Definition 9462.412 (Identifiability witness)**.** *An identifiability witness for h on Ω_{wm} is a displayed map W and an equivalence mode $\equiv_W$ such that the recovered representation is compared to the latent carrier by*

$$h(z) \equiv_W W(z)$$

on the stated scope. The witness may be exact, approximate, empirical, formal, or hybrid. Its mode, bound, and residual cases are certificate data.

Definition 9462.413 (World-latent NameCert)**.** *A World-latent NameCert for $(\Omega_{\mathsf{wm}}, h, \sim_h)$ is the packet*

$$\mathsf{NameCert}_{\mathsf{wm}} = (S_{\mathsf{wm}}, P_{\mathsf{wm}}, C_{\mathsf{wm}}, \Sigma_{\mathsf{wm}}, L_{\mathsf{wm}}).$$

The source row S_{wm} records the scope, encoder, observation protocol, pair protocol, transition family, and assumption ledger. The pattern row P_{wm} records alignment, recovery, separation, transition, and planning evidence. The classifier row C_{wm} is the relation $\sim_h$. The stability row Σ_{wm} records invariance under admitted transformations, approximation bounds, and transfer witnesses. The ledger row L_{wm} records unidentified coordinates, rotational or gauge freedom, finite-sample residue, model-class restriction, shortcut risk, planning failures, and not-claimed domains.

Definition 9462.414 (Certified world-model classifier)**.** *A certified world-model classifier is a tuple*

$$(\Omega_{\mathsf{wm}}, h, \sim_h, \mathsf{NameCert}_{\mathsf{wm}})$$

where the world-latent classifier candidate carries the World-latent NameCert on the displayed scope.

Theorem 9462.415 (Latent recovery is certificate data)**.** *An identifiability claim for a learned world representation is not a closed BEDC explanation unless its witness, equivalence mode, scope, and residue are recorded in a World-latent NameCert.*

Proof. An identifiability statement compares a learned representation with a latent carrier only relative to a scope and an equivalence mode. The comparison may hide dimension assumptions, sampling assumptions, coordinate freedom, approximation error, and uncovered domains. These are precisely source, stability, and ledger rows in Definition 9462.413. Without those rows, the claim gives evidence for a classifier candidate but not a certified world-model classifier. □

Concretized in §6124: World-model classifier packets realize scoped latent recovery, identifiability, transfer, and residue ledgers as finite NameCert data.

Theorem 9462.416 (World-model objectives do not certify classifiers)**.** *Optimizing a world-model objective does not by itself certify the world-latent classifier induced by the learned representation.*

Proof. An objective supplies a training pressure and possibly a record of alignment or prediction. It does not by itself display the classifier relation, the identifiability witness, the stability mode, the transfer scope, or the residue ledger. By Definition 9462.414, those rows are required for certification. □

Theorem 9462.417 (Assumptions are source rows, not hidden laws)**.** *Distributional and transition assumptions used in world-model recovery belong to the source and ledger rows of the certificate.*

Proof. The assumptions determine which latent systems, pair protocols, transition families, and recovery comparisons are covered. If they are not displayed, the classifier's domain of validity is ambiguous. If they are displayed but their failures are not ledgered, the certificate hides boundary debt. Thus these assumptions are certificate rows rather than ambient laws. □

Theorem 9462.418 (Planning transfer requires a transfer ledger)**.** *A claim that a recovered world representation supports planning is not closed without a transfer ledger from latent recovery to planning behavior.*

Proof. Latent recovery and planning success are different behavior targets. Planning adds policy extraction, rollout stability, objective alignment, intervention boundary, and failure-mode residue. A recovery certificate can support the planning claim only when these transfer rows are recorded in Σ_{wm} and L_{wm}. □

Theorem 9462.419 (World-model certification is scoped black-box resolution)**.** *If a learned representation supports a world-latent classifier and carries a World-latent NameCert on Ω_{wm}, then the corresponding world-model behavior is no longer black-box behavior on that scope.*

Proof. Black-box behavior is the absence of a certificate for the classifier supporting the behavior. The World-latent NameCert supplies the source, pattern, classifier, stability, and ledger rows for the supporting classifier on Ω_{wm}. The resolution is scoped because the certificate explicitly records its assumptions and not-claimed domains. □

Theorem 9462.420 (World-model quality is certified classifier quality)**.** *Within a declared world-model scope, representation quality relevant to BEDC explanation is certified classifier quality rather than raw performance, latent visual coherence, or objective value.*

Proof. Raw performance, visual coherence, and objective value can be evidence for the pattern row, but they do not determine a certified classifier. The BEDC object is formed only when the recovered relation carries the World-latent NameCert of Definition 9462.413. Therefore the explanatory quality of the world model is measured by the certified classifier surface and its remaining ledger debt. □

9462.17 Formal Verification in Certified Interpretability

section 9462.5 treats formal verification as a hard-certificate layer, and section 9462.6 separates ledger-only, partially hardened, and fully hardened classifiers. The present section applies that separation to certified interpretability. Formal verification is not the rule that forms an explanation object; the object is formed by classifier, NameCert, and ledger. Verification hardens the components that have been faithfully transcribed into formal statements, and it must carry its own ledger.

Definition 9462.421 (Certified interpretability object)**.** *A certified interpretability object is*

$$E = (B, C, N_C, \Lambda_C),$$

where B is the explained behavior, C is the classifier supporting B, $N_C = (S_C, P_C, C, \Sigma_C, L_C)$ is the NameCert or Tensor NameCert for C, and Λ_C is the explanation ledger.

Definition 9462.422 (Explanation component)**.** *An explanation component of E is any row or role used by its certified surface: source, pattern, classifier, stability, ledger, feature, circuit, intervention, semantic assignment, seal, or verification component. The family of such components is denoted* $\mathrm{Comp}(E)$.

Definition 9462.423 (Verifiable component)**.** *A component $F \in \mathrm{Comp}(E)$ is verifiable relative to a backend $\mathcal{V}$ when it can be transcribed as a formal statement φ_F with an explicit proof obligation and declared scope. It is ledger-only when it is not presently transcribable without losing essential empirical, semantic, distributional, or boundary content, but its evidence and limitations are recorded in the ledger.*

Definition 9462.424 (Formal verification target)**.** *A formal verification target is a tuple*

$$T = (F, \varphi_F, \mathcal{V}),$$

where F is an explanation component, φ_F is its transcribed formal statement, and $\mathcal{V}$ is the verification backend. A proof object π_F hardens the target when

$$\mathcal{V} \vdash \pi_F : \varphi_F.$$

Definition 9462.425 (Verification coverage)**.** *The verification coverage of a hardened component F is the part of F actually expressed by φ_F. If the coverage is a proper subcomponent of F, the remainder must be recorded in a transcription ledger or the hardening claim is incomplete.*

9462.17.1 Hardenable Components

Definition 9462.426 (Threshold-classifier targets)**.** *For a threshold classifier*

$$m_{\phi,\tau}(x) = \begin{cases} 0, & \phi(a(x)) < \tau, \\ 1, & \phi(a(x)) \geq \tau, \end{cases}$$

verifiable targets include threshold-definition consistency, equivalence-relation properties of the induced classifier, finite-scope classification tables, margin stability, and threshold-perturbation bounds.

Definition 9462.427 (Compression, finite-data, circuit, and ledger targets)**.** *Compression and projection targets include injectivity on a scope, non-injectivity witnesses, collapsed-distinction enumeration, and compression-cell equivalence. Finite-data targets include enumeration coverage, finite classifier-table correctness, finite confusion-matrix properties, and finite no-counterexample claims. Circuit targets include graph reachability, acyclicity, dependency containment, path coverage, and declared intervention-site membership. Ledger targets include finite or formal coverage claims of the form*

$$\mathrm{Req}(E) \subseteq \mathrm{Rec}(\Lambda).$$

Definition 9462.428 (NameCert structure targets)**.** *NameCert structure targets include existence of the source, pattern, classifier, stability, and ledger rows; consistency of references between rows; agreement between source scope and classifier domain; and ledger coverage for the declared scope.*

Theorem 9462.429 (Finite classifier tables are verifiable)**.** *If a classifier is displayed by a finite table on a finite domain, then its basic classifier properties can be formally verified.*

Proof. On a finite domain $D_0 = \{x_1, \ldots, x_n\}$ the classifier relation can be represented by a finite Boolean matrix M_{ij} with $M_{ij} = 1$ exactly when $C(x_i, x_j)$. Reflexivity, symmetry, and transitivity reduce to finitely many Boolean conditions on this matrix. Those conditions are formal verification targets. □

Theorem 9462.430 (Margin stability is verifiable under a bound)**.** *If*

$$|\phi(a(x)) - \tau| > \epsilon$$

and every admitted perturbation α satisfies

$$|\phi(a(\alpha(x))) - \phi(a(x))| \leq \epsilon,$$

then the threshold mark of x is preserved by α.

Proof. If $\phi(a(x)) \geq \tau$, the margin assumption gives $\phi(a(x)) - \tau > \epsilon$, and the perturbation bound gives $\phi(a(\alpha(x))) > \tau$. If $\phi(a(x)) < \tau$, the margin assumption gives $\tau - \phi(a(x)) > \epsilon$, and the perturbation bound gives $\phi(a(\alpha(x))) < \tau$. In both cases the threshold mark is unchanged. □

Theorem 9462.431 (Finite ledger coverage is verifiable)**.** *If required residue and recorded residue are finite displayed families, then the coverage claim*

$$\mathrm{Req}(E) \subseteq \mathrm{Rec}(\Lambda)$$

is formally verifiable.

Proof. The finite inclusion is equivalent to checking, for each displayed required row, membership in the recorded family. This is a finite family of decidable membership checks. □

9462.17.2 Limits and Transcription

Definition 9462.432 (Open semantic and distributional components)**.** *An open semantic component depends on natural-language meaning, cultural context, open-ended categories, or semantic similarity. An open distributional component depends on an unknown or open distribution. Such components may be ledgered, sampled, or partially modeled, but they are not fully hardened unless their formalization and residual gap are declared.*

Definition 9462.433 (Transcription ledger)**.** *A transcription ledger for $F \rightsquigarrow \varphi_F$ records which parts of F are expressed by φ_F, which parts are omitted, the scope and assumptions of the transcription, any semantic weakening, approximation, excluded cases, and the not-claimed boundary.*

Definition 9462.434 (Transcription gap)**.** *A transcription gap exists when critical content of F is neither expressed by φ_F nor recorded in the transcription ledger.*

Theorem 9462.435 (Open semantics are not closed by proof alone)**.** *An open semantic component is not closed by formal verification alone unless a formal semantics and semantic ledger are supplied.*

Proof. Formal verification checks a formal statement. Natural-language meaning has ambiguity, context dependence, polysemy, and boundary cases. A formal semantics specifies what has been modeled, and the semantic ledger records the gap between that model and the open concept. □

Theorem 9462.436 (Finite empirical stability is not global formal stability)**.** *Passing finite perturbation tests does not by itself prove stability on an open domain or open transformation family.*

Proof. Finite tests cover only the displayed sample and displayed transformations. A larger domain or transformation family may contain cases not tested. Global formal stability requires a proof over the declared domain and family. □

Theorem 9462.437 (Untranscribed claims have no proof target)**.** *If an explanation component has not been transcribed into a formal statement, then formal verification has no target for that component.*

Proof. A backend judgment has the form $\mathcal{V} \vdash \pi : \varphi$. Without a statement φ_F representing the component, no such judgment can be posed for it. □

Theorem 9462.438 (Verified statement needs transcription ledger)**.** *A verified statement does not audit-completely support an explanation component unless its transcription ledger is supplied.*

Proof. The proof establishes φ_F. Without the transcription ledger, the auditor cannot tell whether φ_F covers the critical content of F, weakens the claim, omits a boundary, or changes semantic scope. □

Theorem 9462.439 (Transcription gaps block full hardening)**.** *A component with a transcription gap cannot be claimed fully hardened.*

Proof. Full hardening requires every critical part of the component to be covered by the verified statement or ledgered as residue. A transcription gap is precisely a critical part covered by neither. □

9462.17.3 Verification Ledgers and Grades

Definition 9462.440 (Component verification ledger)**.** *A component verification ledger records the backend, formal statement, proof object, assumptions, axioms, dependencies, trusted libraries, kernel or checker trust boundary, extraction assumptions, unverified components, and portability boundary for a verified component.*

Definition 9462.441 (Verification opacity)**.** *Verification opacity occurs when a verification claim lacks its backend, checked statement, proof artifact, assumptions, dependencies, or trust boundary.*

Definition 9462.442 (Verification grade)**.** *An explanation is ledger-only when it has NameCert and ledger but no formally hardened component; partially verified when at least one component is hardened; fully verified scoped when every hardenable critical component in the declared scope is hardened and every non-hardenable residue is ledgered; and globally verified only when the global scope and all excluded cases are ledgered.*

Theorem 9462.443 (Verification opacity blocks audit completeness)**.** *An opaque verification claim is not audit-complete.*

Proof. The auditor must know which backend accepted which statement, with which proof object, assumptions, dependencies, and trust boundary. If these rows are absent, the strength and scope of the verification cannot be audited. □

Theorem 9462.444 (Verification ledger does not replace explanation ledger)**.** *A component verification ledger does not replace the explanation ledger.*

Proof. The verification ledger audits proof acceptance and trust boundary. The explanation ledger audits source residue, classifier boundary, stability limits, semantic ambiguity, intervention residue, generalization residue, and not-claimed behavior. These are different required rows. □

Theorem 9462.445 (Partial verification is not scoped full verification)**.** *Partially verified explanation does not imply fully verified scoped explanation.*

Proof. One hardened component may leave other hardenable critical components unhardened and unledgered. Fully verified scoped status requires the entire critical hardening frontier of the declared scope to be handled. □

Theorem 9462.446 (Global verification requires global scope ledger)**.** *A global verification claim requires a global scope ledger.*

Proof. Global verification quantifies over the whole claimed source, behavior, model, or domain space. The ledger must record that scope, the excluded cases, the assumptions, and every non-hardenable residue. Without that ledger, the global claim is unclosed. □

9462.17.4 NDNA Verification and Discovery

Definition 9462.447 (NDNA verification profile)**.** *An NDNA verification profile records, for each NDNA locus, whether it is unhardened, hardenable, hardened, or ledger-only, together with the hardening frontier, the component verification ledger, and the not-claimed boundary.*

Theorem 9462.448 (One hardened NDNA locus does not harden all NDNA)**.** *Hardening one NDNA locus does not imply that the whole NDNA packet is hardened.*

Proof. NDNA has source, feature, circuit, classifier, stability, intervention, ledger, and seal loci. A proof about one locus does not establish the formal statements, ledgers, or non-hardenable residues of the other loci. □

Theorem 9462.449 (Fully verified NDNA requires verification profile)**.** *A fully verified NDNA claim requires a complete NDNA verification profile.*

Proof. The claim requires all critical hardenable loci to be hardened and all non-hardenable critical residue to be ledgered. The verification profile is the audit surface that records those statuses locus by locus. □

Definition 9462.450 (Verification-assisted discovery)**.** *A positive discovery is verification-assisted when formal hardening contributes positive verification gain to its net explanation information. It is verification-only when the classifier surface is unchanged and the transition only hardens components.*

Theorem 9462.451 (Verification gain does not replace classifier novelty)**.** *Verification gain does not by itself create classifier-level discovery.*

Proof. Classifier-level discovery requires classifier novelty. A verification gain can harden a row, reduce verification debt, or improve reuse while leaving the classifier relation unchanged. □

Theorem 9462.452 (Verification-assisted discovery counts verification cost)**.** *When verification contributes to positive discovery, verification cost and verification debt must be counted.*

Proof. Formal hardening consumes transcription work, proof construction, dependency maintenance, checking, transport, and verification-ledger work. Omitting those terms overstates net explanation information. □

Definition 9462.453 (Verification misuse)**.** *Verification laundering uses a verified statement to hide a missing NameCert, ledger, classifier novelty, or scope boundary. Proof-quantity laundering treats many proof artifacts as explanation quality. Backend laundering states that a result is verified without naming backend, dependencies, and trust boundary. Scope laundering by verification uses a scoped proof as if it were global.*

Theorem 9462.454 (Verification misuse invalidates the stronger claim)**.** *Verification laundering, proof-quantity laundering, backend laundering, and scope laundering by verification invalidate the stronger explanation or discovery claim they are used to support.*

Proof. Verification does not replace NameCert or ledger, proof quantity does not determine explanation quality, opaque backend claims are not audit-complete, and scoped proofs do not prove larger scopes. Each misuse therefore asserts more than the verification evidence supports. □

Theorem 9462.455 (Formal verification in certified interpretability theorem)**.** *In certified interpretability, formal verification hardens transcribed components under a backend and verification ledger; it does not replace the NameCert, explanation ledger, NDNA profile, or classifier-novelty condition for discovery.*

Proof. Definition 9462.429, Definition 9462.430, and Definition 9462.431 identify typical hardenable targets. Definition 9462.435, Definition 9462.436, and Definition 9462.437 identify limits. Definition 9462.438 and Definition 9462.443 give the ledger requirements. Definition 9462.451 separates hardening from discovery. The theorem follows. □

Concretized in §4106: Type-checking classifier packets realize finite classifier-membership verification as Ext-membership, derivation-trace, subject-reduction, hsame, Cont, Pkg, and NameCert rows.

Concretized in §7920: Verification coverage ledger packets realize certified-interpretability coverage as component-key, transcription, backend proof-boundary, coverage, residue, scoped-explanation, classifier-facing, hsame, Cont, Pkg, and NameCert rows.

9462.18 BEDC Decomposition of Machine-Learning Black Boxes

section 9462.7 identifies black-box behavior as supported structure without certificate closure. section 9462.8 isolates the ledger part of that debt, section 9462.9 gives the role-complete neural packet, and section 9462.17 separates certificate closure from formal hardening. The present section puts those readings into one decomposition theorem: a machine-learning black box is not a primitive opacity, but a certificate deficit for a classifier candidate supporting a displayed behavior.

Definition 9462.456 (Behavioral black-box object)**.** *A behavioral black-box object is a tuple*

$$\mathbb{B} = (B, D_B, E_B),$$

where B is a displayed model behavior, D_B is the behavior scope, and E_B is the evidence packet, consisting of samples, outputs, statistics, traces, failure cases, or an observation protocol. It is eligible for decomposition when B has observed stability but lacks a closed explanation.

Definition 9462.457 (Support candidates)**.** *For a behavior B, the support-candidate family is*

$$\mathrm{SuppCand}(B) = \{C \mid C \Vdash B\},$$

where $C \Vdash B$ means that classifier candidate C supports B by prediction, correlation, intervention, formal constraint, or hybrid evidence.

Definition 9462.458 (Decomposition target)**.** *A BEDC decomposition target is a pair (B, C) with $C \in \mathrm{SuppCand}(B)$. The target asks which certificate rows and ledger rows are already present for the claim that C supports B, and which rows remain absent or incomplete.*

Definition 9462.459 (Certificate fields)**.** *For a classifier candidate C, its certificate-field family is*

$$\mathrm{Field}(C) = \{S_C, P_C, C_C, \Sigma_C, L_C\},$$

where S_C is the source row, P_C the pattern row, C_C the classifier row, Σ_C the stability row, and L_C the ledger-policy row.

Definition 9462.460 (Present and missing fields)**.** *For a target (B, C), $\mathrm{Present}(B, C)$ is the subfamily of certificate fields that are declared, anchored, scoped, and supplied with the required ledger evidence. Its missing-field family is*

$$\mathrm{Missing}(B, C) = \mathrm{Field}(C) \setminus \mathrm{Present}(B, C).$$

Definition 9462.461 (BEDC black-box decomposition)**.** *The BEDC decomposition of B relative to C is*

$$\mathrm{Decomp}_{\mathrm{BEDC}}(B, C) = (\mathrm{Present}(B, C), \mathrm{Missing}(B, C), \Lambda_{B,C}, \mathrm{Debt}_{B,C}),$$

where $\Lambda_{B,C}$ is the ledger currently attached to the target and $\mathrm{Debt}_{B,C}$ is the cost of unrecorded or incomplete critical residue.

9462.18.1 Decomposition States

Definition 9462.462 (Decomposition states)**.** *A behavior is unexplained when $\mathrm{SuppCand}(B) = \emptyset$. It is in candidate state relative to C when $C \Vdash B$ but the certificate rows are absent or only fragmentary. It is in partial-certificate state when $\mathrm{Present}(B, C) \neq \emptyset$ and $\mathrm{Missing}(B, C) \neq \emptyset$. It is NameCert-complete when $\mathrm{Missing}(B, C) = \emptyset$, ledger-complete when the critical ledger gap is empty, and closed-explanation state when NameCert-completeness, ledger-completeness, scope seal, and not-claimed boundary are all present.*

Theorem 9462.463 (Unexplained and black-box states are distinct)**.** *If $\mathrm{SuppCand}(B) = \emptyset$, then B is not a certificate-deficit black box.*

Proof. A certificate-deficit black box requires a supporting classifier candidate whose certificate rows are absent or incomplete. When $\mathrm{SuppCand}(B)$ is empty, no such candidate has been displayed. The failure is therefore at the support-candidate level, not at the certificate-completion level. □

Concretized in §7533: Black-box fiber witness packets realize visible behavior, support-candidate, missing-certificate, hidden-fiber, and ledger rows as finite NameCert data.

Theorem 9462.464 (Partial certificate states retain black-box residue)**.** *If (B, C) is in partial-certificate state, then the explanation of B relative to C retains black-box residue.*

Proof. Partial-certificate state means that at least one certificate field is missing. A closed explanation requires source, pattern, classifier, stability, and ledger-policy rows for the declared scope. The absent row therefore remains a certificate deficit. □

Theorem 9462.465 (Ledger deficit blocks decomposition closure)**.** *If the ledger-policy row is absent or the critical ledger gap is nonempty, then (B, C) is not in closed-explanation state.*

Proof. Closed-explanation state includes ledger-completeness. By Definition 9462.183, ledger completeness is absence of required residue gap. An absent ledger-policy row or nonempty critical ledger gap violates that condition. □

Theorem 9462.466 (Closed explanation removes scoped black-box status)**.** *If (B, C) is in closed-explanation state, then B is not a black box relative to C on the sealed scope.*

Proof. Black-box status relative to C is the absence or incompleteness of the certificate and ledger rows supporting $C \Vdash B$. Closed-explanation state supplies those rows and seals their scope. Hence the certificate-deficit condition no longer holds on that scope. □

9462.18.2 Deficit Vectors and Frontiers

Definition 9462.467 (Deficit vector)**.** *The deficit vector of a target (B, C) is*

$$\mathbf{D}(B, C) = (d_S, d_P, d_C, d_\Sigma, d_L) \in \{0, 1\}^5,$$

where the coordinate is 1 exactly when the corresponding source, pattern, classifier, stability, or ledger field is absent or incomplete. The ledger coordinate is also 1 when the ledger-policy row is present but the critical ledger gap is nonempty.

Definition 9462.468 (Weighted deficit score)**.** *For nonnegative field weights*

$$\mathbf{w}_D = (w_S, w_P, w_C, w_\Sigma, w_L),$$

the weighted deficit score is

$$\mathrm{DefScore}(B, C) = w_S d_S + w_P d_P + w_C d_C + w_\Sigma d_\Sigma + w_L d_L.$$

Definition 9462.469 (Decomposition frontier)**.** *The decomposition frontier of (B, C) is*

$$\mathrm{Frontier}(B, C) = \mathrm{Missing}(B, C) \cup \mathrm{Gap}(\Lambda_{B,C}, (B, C)).$$

It is the family of certificate fields and ledger rows whose completion would next reduce black-box residue.

Theorem 9462.470 (Zero deficit is field-and-ledger closure)**.** *The equality* $\mathbf{D}(B, C) = (0, 0, 0, 0, 0)$ *holds exactly when no certificate field is missing and the critical ledger gap is empty.*

Proof. Each nonledger coordinate records absence or incompleteness of its corresponding certificate field. The ledger coordinate records either absence of the ledger-policy row or nonempty critical ledger gap. All coordinates vanish exactly when every field is present and no critical ledger row is missing. □

Theorem 9462.471 (Decomposition improvement reduces black-box deficit)**.** *If a transition from decomposition* D_0 *to* D_1 *satisfies*

$$\mathrm{DefScore}(D_1) < \mathrm{DefScore}(D_0),$$

then it reduces black-box deficit for the fixed target.

Proof. The score is the weighted cost of the displayed certificate deficits. Strict decrease of that score is precisely reduction of the weighted deficit. □

Theorem 9462.472 (Frontier gives the decomposition route)**.** *For a fixed target* (B, C)*, the decomposition frontier identifies the certificate rows and ledger rows that must be addressed to move toward closure.*

Proof. The frontier is the union of missing certificate fields and required ledger rows not recorded by the current ledger. These are exactly the rows preventing closure under Definition 9462.462. □

9462.18.3 NDNA and Formal Hardening

Definition 9462.473 (NDNA decomposition map)**.** *For a behavior* B *with neural theorem-DNA packet*

$$\mathsf{NDNA}(B) = (G_{\mathsf{source}}, G_{\mathsf{feature}}, G_{\mathsf{circuit}}, G_{\mathsf{classifier}}, G_{\mathsf{stability}}, G_{\mathsf{intervention}}, G_{\mathsf{ledger}}, G_{\mathsf{seal}}),$$

the NDNA decomposition map reads the source row from G_{source}*, pattern evidence from* G_{feature} *and* G_{circuit}*, the classifier row from* $G_{\mathsf{classifier}}$*, stability evidence from* $G_{\mathsf{stability}}$ *and* $G_{\mathsf{intervention}}$*, ledger rows from* G_{ledger}*, and the closure scope from* G_{seal}*.*

Definition 9462.474 (NDNA-complete decomposition)**.** *An NDNA-complete decomposition is a decomposition in which the NDNA packet is complete, anchored, NameCert-compatible, ledger-complete, and sealed for the declared scope.*

Theorem 9462.475 (NDNA-complete decomposition yields BEDC closure)**.** *An NDNA-complete decomposition yields closed-explanation state for some supporting classifier candidate.*

Proof. By completeness and anchoring, every NDNA locus has displayed content and evidence route. By NameCert compatibility, the projected source, pattern, classifier, stability, and ledger rows form a certificate for the classifier supporting B. Ledger-completeness and the seal provide the remaining closure rows. Thus the corresponding target is in closed-explanation state. □

Definition 9462.476 (Verification-aware decomposition)**.** *A decomposition is verification-aware when it records which components are formally hardened, which hardenable components remain unhardened, which components are ledger-only, and which transcription ledger, verification ledger, and trust boundary govern every verification claim.*

Theorem 9462.477 (Closure and hardening are separate axes)**.** *Verification-aware decomposition separates certificate closure from formal hardening.*

Proof. Certificate closure is determined by NameCert rows, ledger rows, scope seal, and not-claimed boundary. Formal hardening is determined by transcribed statements, proof objects, verification ledgers, and backend trust boundaries. A verification-aware decomposition records both families of rows rather than identifying one with the other. □

Theorem 9462.478 (Verification gaps block fully hardened decomposition)**.** *If a decomposition contains a verification claim without its transcription ledger or verification ledger, it cannot be fully hardened.*

Proof. By Definition 9462.438 and Definition 9462.443, a verified component without these ledgers is not audit-complete. Fully hardened decomposition requires all verification claims in the decomposition to be audit-complete. □

9462.18.4 Value and Discovery

Definition 9462.479 (Decomposition information)**.** *For a decomposition D, its decomposition information is*

$$\mathrm{Info}_{\mathrm{dec}}(D) = \mathrm{Benefit}_{\mathrm{dec}}(D) - \mathrm{Cost}_{\mathrm{dec}}(D) - \mathrm{Debt}_{\mathrm{dec}}(D).$$

The benefit term may count coverage, prediction, classifier clarity, transfer, intervention, unification, and verification gain. The cost and debt terms count certificate construction, ledger work, NDNA work, formal hardening, remaining gaps, and seal cost.

Definition 9462.480 (Positive and discovery-resolving decompositions)**.** *A decomposition is positive when* $\mathrm{Info}_{\mathrm{dec}}(D) > 0$*. It is a positive black-box resolution when it is positive and in closed-explanation state. It is a discovery-resolving decomposition when the transition to the resolved state includes classifier shift and positive decomposition-information gain.*

Theorem 9462.481 (Closure does not imply positive value)**.** *Closed-explanation state does not imply positive decomposition information.*

Proof. Closure records that the certificate and ledger obligations are met. Those obligations can be costly, and the resulting behavior coverage or transfer value may be small. If cost plus remaining debt is at least the benefit, the decomposition information is not positive. □

Theorem 9462.482 (Positive decomposition is not automatically discovery)**.** *Positive decomposition information does not by itself imply discovery.*

Proof. The positive value may come from ledger repair, source clarification, verification gain, reduced debt, or better scope sealing while the classifier relation remains unchanged. Discovery at this level requires classifier shift, as in Definition 9462.51. □

Theorem 9462.483 (Discovery resolution requires closure, classifier shift, and positive gain)**.** *A discovery-resolving decomposition requires closed-explanation state, classifier shift, and positive decomposition-information gain.*

Proof. Resolution supplies closure, classifier shift supplies the discovery axis, and positive decomposition-information gain supplies the value axis. Omitting any one of these conditions leaves either an unclosed explanation, a non-discovery audit improvement, or a nonpositive resolution. □

9462.18.5 Practice Illusions

Definition 9462.484 (Explanation illusion)**.** *An explanation illusion is a claim that appears to explain B while its BEDC decomposition still has a critical certificate, ledger, scope, semantic, NDNA, or verification gap.*

Theorem 9462.485 (Feature and circuit records are not decompositions)**.** *A feature label or circuit diagram is not a black-box resolution unless it is embedded in a ledger-complete certificate for a supporting classifier.*

Proof. Feature and circuit records may contribute to the pattern row, but they do not by themselves supply source scope, classifier relation, stability row, ledger row, seal, or not-claimed boundary. They are evidence fragments until the missing rows are supplied. □

Theorem 9462.486 (Probe and benchmark gains are not decompositions)**.** *Probe accuracy or benchmark improvement does not by itself resolve a machine-learning black box.*

Proof. A probe is a classifier candidate that needs its own certificate and ledger. A benchmark improvement reports performance movement, not the source, classifier, stability, ledger, and seal rows explaining the behavior. Either can support a decomposition, but neither is closure by itself. □

Theorem 9462.487 (Local proof is not black-box resolution)**.** *A local formally verified statement is not a black-box resolution unless the surrounding decomposition is certificate-complete, ledger-complete, and verification-aware.*

Proof. The local proof hardens a transcribed statement. It does not by itself provide the behavior source, classifier boundary, stability scope, explanation ledger, transcription ledger, verification ledger, or seal. Those rows are required for black-box resolution. □

Theorem 9462.488 (BEDC decomposition theorem for machine-learning black boxes)**.** *For a displayed machine-learning behavior B, BEDC decomposes its black-box status into support candidates, certificate fields, ledger gaps, debt, NDNA loci, optional verification hardening, and value accounting. If no support candidate is displayed, B is unexplained. If a support candidate exists but its certificate or ledger is incomplete, B has black-box residue. If a support candidate has complete certificate rows, complete ledger rows, and a sealed scope, B is resolved on that scope. Positive discovery-resolution additionally requires classifier shift and positive decomposition-information gain.*

Proof. Definition 9462.463 separates unexplained behavior from certificate-deficit black boxes. Definition 9462.464 and Definition 9462.465 identify the remaining residue when rows or ledgers are absent. Definition 9462.466 gives scoped resolution. Definition 9462.475 connects NDNA to BEDC closure, while Definition 9462.477 separates formal hardening from certificate closure. The value and discovery conditions are given by Definition 9462.481, Definition 9462.482, and Definition 9462.483. Together these statements give the decomposition theorem. □

Concretized in §6100: finite certificate-deficit packets realize the black-box decomposition surface as NameCert data

9462.19 No Global Black-Box Eliminator

section 9462.18 decomposes a machine-learning black box into support candidates, certificate fields, ledger gaps, debt, NDNA loci, optional verification hardening, and value accounting. The present section records the corresponding limitation: black-box resolution is scope-relative unless a global ledger is displayed. A total feature label, total diagram, total proof, or total interpretability narrative is not a global eliminator unless it carries the behavior family, classifier family, NameCert family, global ledger, verification ledger where applicable, and not-claimed boundary.

Definition 9462.489 (Explanation scope)**.** *An explanation scope is a tuple*

$$\Omega = (D, M_\theta, \mathcal{A}, B),$$

where D is the input or behavior source domain, M_θ is the model state, $\mathcal{A}$ is the admitted perturbation, transformation, transfer, or rewrite family, and B is the behavior being explained. An explanation is scoped when its certificate and ledger claims are made only inside Ω.

Definition 9462.490 (Scoped black-box resolution)**.** *Behavior B is resolved on scope Ω when there is an explanation object*

$$E_\Omega = (B, C, N_C, \Lambda_C)$$

such that $C \Vdash_\Omega B$, $N_C = \mathsf{NameCert}(C)$, the ledger Λ_C is complete for (B, C, Ω), and the seal records Ω together with the not-claimed boundary.

Definition 9462.491 (Global behavior family)**.** *For a model state M_θ, the global behavior family $\mathcal{B}(M_\theta)$ is the family of behaviors being covered by a global explanation claim. It may contain output behaviors, refusals, errors, transfer behaviors, safety behaviors, intervention behaviors, and boundary behaviors.*

Definition 9462.492 (Global resolution and global ledger)**.** *A model state is globally resolved when every $B \in \mathcal{B}(M_\theta)$ has a closed explanation and these explanations are covered by a common global ledger. A global ledger Λ_{global} records, for every covered behavior and supporting classifier, the required source, pattern, classifier, stability, semantic, intervention, verification, generalization, and not-claimed residue:*

$$\mathrm{Req}(B, C_B) \subseteq \mathrm{Rec}(\Lambda_{\text{global}}).$$

Definition 9462.493 (Global black-box eliminator)**.** *A global black-box eliminator is an explanation claim that asserts global resolution of M_θ. It is uncertified when it omits the covered behavior family, the supporting classifier family, the NameCert family, the global ledger, the verification ledger for verified rows, or the not-claimed boundary.*

Theorem 9462.494 (Scoped resolution does not imply global resolution)**.** *Resolving B on a scope Ω does not imply global resolution of M_θ.*

Proof. Scoped resolution supplies a closed explanation only for the target (B, Ω). Global resolution requires closed explanations for every behavior in $\mathcal{B}(M_\theta)$ and a common ledger covering their required residue. The scoped certificate gives neither the remaining behaviors nor their global ledger. □

Concretized in §6249: ScopedExplanationLedgerUp realizes scoped black-box certification as finite explanation-scope, classifier, ledger, refusal, transport, and NameCert rows.

Theorem 9462.495 (Finite-sample closure is not open-domain closure)**.** *Closure on a finite sample domain D_0 does not by itself imply closure on a larger open domain D.*

Proof. The finite certificate records required residue for D_0. A larger domain may contain boundary cases, out-of-distribution cases, semantic ambiguity, and generalization residue not recorded by the finite ledger. Thus the ledger inclusion for D_0 does not entail the ledger inclusion for D. □

Theorem 9462.496 (Global resolution requires global ledger)**.** *Any global resolution claim for M_θ requires a global ledger.*

Proof. Global resolution requires each behavior in $\mathcal{B}(M_\theta)$ to have a closed explanation. Each closed explanation requires ledger coverage for its required residue. Taking the family of all such required rows gives the required residue of the global claim, and a ledger covering that family is precisely the global ledger. □

Theorem 9462.497 (No uncertified global black-box eliminator)**.** *An uncertified global black-box eliminator is not a valid global resolution claim.*

Proof. By Definition 9462.496, global resolution requires a global ledger. It also requires behavior coverage, supporting classifiers, NameCert rows, and the relevant verification and not-claimed ledgers. An eliminator claim omitting these rows lacks the conditions it asserts. □

9462.19.1 Classifier and Semantic Globalization

Definition 9462.498 (Single-classifier explanation)**.** *A single-classifier explanation uses one classifier $C^\star$ to explain several behaviors. Two behaviors are classifier-separated when their closed explanations require nonequivalent classifier relations unless a product classifier or bridge ledger is supplied.*

Definition 9462.499 (Product classifier and bridge ledger)**.** *For classifiers $C_1, \ldots, C_n$, a product classifier is the joint relation*

$$C_\Pi(x, y) \iff \bigwedge_{i=1}^{n} C_i(x, y).$$

A bridge ledger for such a product records each source scope, each classifier boundary, the distinctions created by the product, the behaviors unified or separated by it, and its not-claimed boundary.

Theorem 9462.500 (A single classifier does not automatically explain many behaviors)**.** *If B_1 and B_2 are supported by nonequivalent classifiers, a closed explanation of B_1 by C_1 does not automatically close an explanation of B_2.*

Proof. The certificate for $C_1 \Vdash B_1$ records the source, classifier, stability, and ledger rows for B_1. Nonequivalence of the classifiers means that the public classification surface needed for B_2 can differ. Without a proof that C_1 supports B_2, or a certified product or bridge, the rows for B_2 are absent. □

Theorem 9462.501 (Product classifiers require bridge ledgers)**.** *A product classifier used to unify several behavior explanations requires a bridge ledger.*

Proof. The product classifier changes classification granularity. It can split old cells, expose boundary cases, and change which behavior rows are covered by which classifier. These residues are created by the unification operation itself and must be recorded for the unified claim to close. □

Definition 9462.502 (Semantic globalizer)**.** *A semantic globalizer is an explanation claim that uses one natural language concept K to unify several features, classifiers, behaviors, or model states. It overreaches when it lacks a semantic ledger for positive cases, negative cases, ambiguous cases, polysemy, domain dependence, context dependence, label drift, unsupported connotations, and not-claimed semantics.*

Theorem 9462.503 (Semantic globalization requires semantic ledger)**.** *A natural-language concept used as a global explanation requires a semantic global ledger.*

Proof. Natural-language concepts have ambiguous boundaries, domain dependence, and unsupported connotations. A global use of such a concept must record which behaviors fall under it, which do not, which are ambiguous, and where the concept is not claimed. Those rows are exactly the semantic global ledger. □

9462.19.2 Formal and Diagonal Residue

Definition 9462.504 (Formal globalizer)**.** *A formal globalizer uses a checked judgment*

$$\mathcal{V} \vdash \pi : \varphi$$

as a claim about the model or behavior family beyond the scope of the statement φ.

Definition 9462.505 (Verification global ledger)**.** *A verification global ledger records checked statements, their scopes, unverified components, backend, trust boundary, proof dependencies, translation assumptions, portability boundary, and behaviors not covered by the verification claim.*

Theorem 9462.506 (Scoped proof does not imply global explanation)**.** *A formally checked statement on scope Ω does not imply a global explanation unless the checked statement and its verification ledger are global.*

Proof. The proof establishes the formal statement that was checked. If the statement is scoped, its conclusion is scoped. A larger explanation claim requires additional behavior coverage, transcription ledgers, verification ledgers, and non-hardenable residue rows. □

Definition 9462.507 (Diagonal residue)**.** *For an explanation E, diagonal residue is a behavior case, boundary case, input, intervention, counterexample, out-of-distribution case, or semantic ambiguity that lies in a not-covered region or ledger gap of E.*

Definition 9462.508 (Self-exposure test)**.** *A self-exposure test for E searches for unrecorded source rows, unrecorded boundaries, false positives, false negatives, semantic ambiguity, untested interventions, verification gaps, and generalization residue.*

Theorem 9462.509 (Non-global ledgers admit diagonal-residue risk)**.** *If an explanation lacks a global ledger, then diagonal residue remains a possible risk.*

Proof. Without a global ledger, the required residue of the global claim is not known to be covered by the recorded ledger rows. Any uncovered required row may be exposed by an input, behavior case, intervention, or semantic ambiguity. The absence of the global ledger is therefore a diagonal residue risk even when a specific witness has not yet been displayed. □

Theorem 9462.510 (Diagonal residue forces classifier refinement or ledger repair)**.** *When diagonal residue changes the boundary of the supporting classifier, the explanation must either refine the classifier or repair the ledger.*

Proof. If the residue shows that the old classifier wrongly joins or separates cases, the classifier relation must change. If the classifier is kept, the residue must be recorded as a boundary, failure case, or not-claimed row. These are respectively classifier refinement and ledger repair. □

9462.19.3 Cost and Free Explanation

Definition 9462.511 (Global explanation cost)**.** *For a global behavior family, the global explanation cost is the cost of its NameCert rows, ledger rows, verification rows where used, and seal rows. When the behavior family is finite this can be written as*

$$\mathrm{Cost}_{\mathrm{global}}(M_\theta) = \sum_{B \in \mathcal{B}(M_\theta)} \big(\mathrm{NameCertCost}(B) + \mathrm{LedgerCost}(B) + \mathrm{SealCost}(B)\big).$$

For nonfinite behavior families, the sum is replaced by the appropriate cost observer for the declared scope.

Definition 9462.512 (Global explanation compression)**.** *Global explanation compression uses a smaller family of schemas to cover many behavior explanations. The compression is certified only when its schema ledger records coverage, failure cases, uncovered behavior classes, schema-specific debt, and the bridge from schemas to behaviors.*

Theorem 9462.513 (Global explanation has nonzero certificate cost)**.** *If the covered behavior family contains a nontrivial behavior, then a global explanation has nonzero certificate cost.*

Proof. A nontrivial covered behavior requires at least a supporting classifier, certificate rows, ledger rows, and a seal. These rows are nonempty audit objects. Their construction and maintenance cost is therefore not zero. □

Theorem 9462.514 (Compressed global explanations require schema ledgers)**.** *A schema that compresses many behavior explanations requires a schema ledger.*

Proof. Compression hides behavior-specific boundaries, failure cases, domain differences, and residue. The schema ledger records which cases the schema covers, which it does not, and which bridge rows connect the schema to each behavior explanation. Without those rows the compressed global claim is unclosed. □

Definition 9462.515 (Free explanation and free gain)**.** *A free explanation claims that E explains B without supplying a classifier, NameCert, ledger, scope, and not-claimed boundary. A free global explanation makes the same omission for an entire behavior family. A free interpretability-gain claim asserts positive explanation information without subtracting certificate cost, ledger cost, verification cost, and remaining debt.*

Theorem 9462.516 (No free explanation)**.** *A free explanation is not a closed explanation.*

Proof. Closed explanation requires a supporting classifier, certificate rows, ledger rows, scope seal, and not-claimed boundary. A free explanation omits these rows by definition, so it lacks the closure conditions. □

Theorem 9462.517 (No free global explanation)**.** *A free global explanation is not a valid global resolution claim.*

Proof. A free global explanation is already missing the rows required for ordinary closed explanation, and global resolution additionally requires global behavior coverage and a global ledger. It therefore lacks both local closure rows and global closure rows. □

Theorem 9462.518 (No free interpretability gain)**.** *An interpretability-gain claim that omits certificate cost, ledger cost, verification cost, or remaining debt is not audit-complete.*

Proof. Explanation information is benefit minus cost and debt. Omitting any required cost or debt term overstates the value of the explanation and prevents an auditor from determining whether the net gain is positive. □

Theorem 9462.519 (No global black-box eliminator theorem)**.** *There is no uncertified global black-box eliminator. Machine-learning black-box resolution is scoped, classifier-relative, NameCert-bound, and ledger-complete unless a global behavior family, classifier family, NameCert family, global ledger, verification ledger where applicable, and global seal are displayed.*

Proof. Definition 9462.494 and Definition 9462.495 separate scoped and finite closure from global closure. Definition 9462.496 gives the global-ledger requirement, and Definition 9462.497 rules out eliminator claims that omit it. Definition 9462.500, Definition 9462.501, and Definition 9462.503 rule out unsupported classifier and semantic globalization. Definition 9462.506 rules out proof-scope overreach. Definition 9462.509 and Definition 9462.510 identify the diagonal-residue risk. Definition 9462.513, Definition 9462.514, Definition 9462.516, Definition 9462.517, and Definition 9462.518 give the cost and audit requirements. Together these statements prove the theorem. □

9462.20 Unified Theory Closure

The preceding machine-learning and interpretability sections form one closure pattern. Generated material is not yet information, a learned parameter state is not yet a learning claim, a feature label is not yet an explanation, a checked proof is not yet a complete interpretation, and a black box is not a primitive opacity. In the BEDC reading, each of these becomes auditable only when a classifier surface is certified, ledgered, placed into a role-complete packet, and sealed by scope.

Definition 9462.520 (Unified epistemic object)**.** *A unified epistemic object is a tuple*

$$\mathfrak{U} = (G, R, C, N, \Lambda, D, V, \Omega),$$

where G is generated or observed material, R is its record surface, C is the classifier relation, N is the NameCert or Tensor NameCert, Λ is the ledger, D is the theorem-DNA or neural theorem-DNA packet, V is the formal-hardening profile, and Ω is the scope seal.

Concretized in §6284: Unified epistemic objects are realized as generated-material, classifier, certificate, ledger, theorem-DNA, hardening-profile, and scope-seal NameCert rows.

Definition 9462.521 (Unified layers)**.** *The generated-material layer records histories, event flows, theorem candidate flows, proof traces, tensor traces, activation records, learning records, intervention logs, and verification artifacts. The classifier layer declares how such material is grouped. The certificate layer records source, pattern, classifier, stability, and ledger-policy rows. The ledger layer records residue from identification, compression, projection, thresholding, generalization, semantic assignment, intervention, and formal verification. The DNA layer records the role-complete packet. The verification layer records which components are hardened and under which backend. The scope seal records source scope, target scope, claim kind, not-claimed boundary, and closure route.*

Definition 9462.522 (Closure axes)**.** *The object $\mathfrak{U}$ has material closure when G is traceable and referencable; classifier closure when C is displayed for the stated scope; NameCert closure when N supplies the five certificate rows; ledger closure when*

$$\mathrm{Req}(\mathfrak{U}) \subseteq \mathrm{Rec}(\Lambda);$$

DNA closure when every critical locus of D is complete, anchored, and certificate-compatible; verification closure when every critical hardenable component is hardened and every non-hardenable residue is ledgered; and scope closure when Ω states the scope, claim kind, not-claimed boundary, and closure route.

Definition 9462.523 (Theory and hardening closure)**.** *Theory closure for $\mathfrak{U}$ is the conjunction of material, classifier, NameCert, ledger, DNA, and scope closure. Fully hardened closure is theory closure together with verification closure.*

Theorem 9462.524 (Hardening closure implies theory closure)**.** *Every fully hardened closed object is theory-closed.*

Proof. Fully hardened closure is defined as theory closure plus verification closure. The theory-closure component is therefore inherited. □

Theorem 9462.525 (NameCert closure without ledger closure is not theory closure)**.** *NameCert closure alone does not imply theory closure when ledger closure fails.*

Proof. Theory closure requires ledger closure. If required residue is not recorded by the ledger, one conjunct of theory closure fails even when the NameCert rows are present. □

Theorem 9462.526 (DNA closure without NameCert compatibility is not theory closure)**.** *A complete DNA packet that is not certificate-compatible does not yield theory closure.*

Proof. DNA closure records completeness and anchoring of loci. Theory closure also requires the classifier to have a compatible NameCert. If the DNA packet cannot project to such a certificate, the NameCert-closure axis fails. □

Theorem 9462.527 (Verification closure does not replace ledger closure)**.** *Verification closure without ledger closure is not theory closure.*

Proof. Verification closure audits checked statements and their hardening profile. Ledger closure audits source, semantic, intervention, generalization, projection, and not-claimed residue. Since theory closure requires ledger closure, verification cannot substitute for it. □

9462.20.1 Unified Information and Discovery

Definition 9462.528 (Unified information)**.** *The unified benefit of $\mathfrak{U}$ counts coverage, prediction, transfer, intervention, unification, verification, and compression gains. The unified cost counts NameCert, ledger, DNA, verification, seal, and maintenance costs. The unified debt counts ledger, semantic, verification, generalization, intervention, DNA, and scope debt. The unified information is*

$$\mathrm{UInfo}(\mathfrak{U}) = \mathrm{UBenefit}(\mathfrak{U}) - \mathrm{UCost}(\mathfrak{U}) - \mathrm{UDebt}(\mathfrak{U}).$$

Definition 9462.529 (Unified transition and classifier shift)**.** *A unified transition is a passage*

$$\mathfrak{U}_0 \rightsquigarrow \mathfrak{U}_1.$$

It has unified classifier shift when the classifier layers of $\mathfrak{U}_0$ *and* $\mathfrak{U}_1$ *are not equivalent on their common declared source. Its unified information gain is*

$$\Delta\,\mathrm{UInfo} = \mathrm{UInfo}(\mathfrak{U}_1) - \mathrm{UInfo}(\mathfrak{U}_0).$$

Definition 9462.530 (Unified positive discovery)**.** *A unified transition is a unified positive discovery when it has classifier shift, the target* $\mathfrak{U}_1$ *is theory-closed, and*

$$\Delta\,\mathrm{UInfo} > 0.$$

Theorem 9462.531 (Positive information gain is not classifier discovery)**.** *Positive unified information gain does not by itself imply classifier shift.*

Proof. The gain may come from ledger repair, verification-debt reduction, cost compression, source-scope clarification, seal strengthening, or semantic ledger repair while the classifier relation is preserved. Such a transition can have positive value but no classifier shift. □

Theorem 9462.532 (Classifier shift is not positive information gain)**.** *Classifier shift does not by itself imply positive unified information gain.*

Proof. A changed classifier can create new certificate, ledger, DNA, verification, and seal obligations. If those costs and debts exceed the benefit produced by the new classifier, the unified information gain is not positive. □

Theorem 9462.533 (Unified positive discovery has two audits)**.** *Every unified positive discovery passes both a classifier-shift audit and a net-information audit.*

Proof. Classifier shift and positive unified information gain are both defining conditions of Definition 9462.530. Theory closure is the certification condition tying those two audits to a closed target object. □

9462.20.2 Speakable Model Form

Definition 9462.534 (BEDC-speakable interface)**.** *A target* X *is* BEDC-speakable *on a declared scope when public use of its upward interface factors through a certificate surface*

$$X^{\uparrow} = (S_X, P_X, C_X, \Sigma_X, \Lambda_X),$$

where S_X *is the source specification,* P_X *is the pattern specification,* C_X *is the classifier specification,* Σ_X *is the stability certificate, and* Λ_X *is the ledger policy. The tuple is read only through the generated-history, continuation, probe-signature, package, gap-ledger, and naming-certificate route*

$$\mathsf{Hist} \longrightarrow \mathsf{Cont} \longrightarrow \mathsf{Ask} \longrightarrow \mathsf{Sig} \longrightarrow \mathsf{Pkg} \longrightarrow \mathsf{Gap} \longrightarrow \mathsf{NameCert}.$$

Thus $X^{\uparrow}$ *is not a host object placed behind a name. It is the licensed public interface by which the name* X *may be consumed.*

Definition 9462.535 (BEDC model form)**.** *The* BEDC model form *of a speakable interface* $X^{\uparrow}$ *is the role pattern*

$$\mathrm{ModelForm}(X) = (\mathsf{Hist}_X, \mathsf{hsame}_X, \mathsf{Cont}_X, \mathsf{Ask}_X, \mathsf{Sig}_X, \mathsf{sameSig}_X, \mathsf{Pkg}_X, \mathsf{Gap}_X, \mathsf{NameCert}_X).$$

Two speakable interfaces have the same model form when there are bidirectional role translations preserving generated-history source, internal sameness transport, continuation, probe-signature readback, signature comparison, package rows, ledger residue, and NameCert admission, with round trips witnessed only by the relevant internal hsame, sameSig*, or classifier-preserving transport.*

Theorem 9462.536 (Speakability factors through model form)**.** *Every theory-closed unified object is an instance of the BEDC model form.*

Proof. By Definition 9462.523, theory closure is the conjunction of material, classifier, NameCert, ledger, DNA, and scope closure. The material axis supplies generated histories and record surfaces. The classifier axis supplies the comparison relation by which records are grouped. NameCert closure supplies the source, pattern, classifier, stability, and ledger-policy rows. Ledger closure records the residue of projection, compression, identification, thresholding, semantic assignment, and scope restriction. The scope seal states the claim kind and not-claimed boundary. These are exactly the roles listed in Definition 9462.535, read through the route of Definition 9462.534. □

Theorem 9462.537 (Model-form agreement is not object identity)**.** *If two speakable interfaces preserve the same BEDC model form, the licensed conclusion is structural comparison, not host-level equality or content collapse.*

Proof. Model-form agreement preserves only the public roles displayed in Definition 9462.535. The round trips are witnessed by internal sameness, signature comparison, or classifier-preserving transport. None of these is host equality, and none identifies the source material, pattern evidence, classifier scope, or ledger residue of one target with that of another. Thus a theorem instance, a tensor behavior instance, and a physical-observation instance may share the same certification grammar without becoming the same object. □

Corollary 9462.538 (Projection is not ontology)**.** *A probe result, signature, package, projection, compression, or displayed model output is not the target whose interface it supports unless a separate exactness, recovery, or ledger certificate licenses that reading.*

Proof. Each listed output is one role or one role fragment inside the BEDC-speakable interface. Reading it as the whole target would discard the remaining source, classifier, stability, ledger, and scope rows. Theory closure forbids that discard unless the missing residue is recovered or recorded by the certificate surface. □

9462.20.3 Specializations

Definition 9462.539 (Unified specializations)**.** *A learning instance is a unified object whose generated material consists of training records, activation traces, learned features, and behavior records. An interpretability instance has a neural behavior target and a Neural Theorem-DNA layer. A theorem instance has a theorem-like target and theorem-DNA layer. A black-box decomposition instance has a behavior target together with the BEDC decomposition data of its supporting classifier candidates.*

Theorem 9462.540 (Learning discovery is a unified positive discovery instance)**.** *A learning transition that produces certified classifier shift, learning ledger closure, and positive learning information gain is a unified positive discovery instance.*

Proof. The certified classifier shift supplies unified classifier shift. The Learning NameCert and ledger closure supply theory closure for the learning instance. Positive learning information gain supplies positive unified information gain. □

Theorem 9462.541 (Interpretability discovery is a unified positive discovery instance)**.** *An interpretability transition with classifier shift, Tensor NameCert, NDNA closure, ledger closure, and positive explanation-information gain is a unified positive discovery instance.*

Proof. Classifier shift supplies the discovery axis. Tensor NameCert, NDNA closure, ledger closure, and scope seal supply theory closure. Positive explanation-information gain is the interpretability specialization of positive unified information gain. □

Theorem 9462.542 (Black-box discovery-resolution is a unified positive discovery instance)**.** *A black-box decomposition transition that resolves the scoped black box, introduces classifier shift, carries NameCert and ledger rows, and has positive decomposition-information gain is a unified positive discovery instance.*

Proof. Scoped resolution supplies closure, the new classifier supplies classifier shift, and positive decomposition-information gain supplies the value condition. These are exactly the unified positive discovery conditions under the black-box decomposition specialization. □

9462.20.4 False Discovery and Lineage

Definition 9462.543 (Unified false discovery claim)**.** *A unified false discovery claim asserts unified positive discovery while lacking classifier shift, theory closure, positive information gain, cost protocol, ledger closure, or scope seal. Record growth, parameter growth, loss reduction, benchmark gain, feature count, proof count, ledger-entry count, semantic relabeling, local verification, scope narrowing, and hidden debt are not substitutes for these conditions.*

Theorem 9462.544 (Record growth and hardening alone are not unified positive discovery)**.** *If a transition only adds records or hardens verification rows while preserving the classifier, it is not unified positive discovery.*

Proof. Unified positive discovery requires classifier shift. Record growth and verification hardening may improve audit status or reduce debt, but when the classifier is preserved they fail the classifier-shift condition. □

Theorem 9462.545 (Hidden debt invalidates positivity claims)**.** *If a claimed positive gain depends on unrecorded debt, the unified positive discovery claim is not audit-complete.*

Proof. Unified information subtracts unified debt. Hiding debt overstates $\Delta\,\mathrm{UInfo}$, and restoring the omitted term may remove strict positivity. The claim cannot be audited until that debt is recorded. □

Definition 9462.546 (Closure lineage)**.** *A closure lineage is a sequence*

$$\mathfrak{U}_0 \rightsquigarrow \mathfrak{U}_1 \rightsquigarrow \cdots \rightsquigarrow \mathfrak{U}_n$$

whose edges may be material extension, classifier shift, NameCert completion, ledger repair, DNA completion, seal strengthening, formal hardening, information compression, or positive discovery. An audit lineage improves closure or debt without classifier shift. A discovery lineage contains classifier shift. A positive closure lineage ends in theory closure with positive total unified information gain. A fully hardened lineage ends in fully hardened closure.

Theorem 9462.547 (Audit, discovery, positivity, and hardening are separate lineage axes)**.** *Audit lineage, discovery lineage, positive closure lineage, and fully hardened lineage do not imply one another in general.*

Proof. An audit lineage can lower debt without changing the classifier. A discovery lineage can introduce a classifier before its certificate and ledger costs are paid. A positive closure lineage can close and yield positive value without full formal hardening. A fully hardened lineage can harden an old classifier without classifier shift. The axes therefore record distinct properties. □

9462.20.5 Unified Closure Theorems

Definition 9462.548 (Unified closed, hardened, and discovery objects)**.** *A unified object is closed when it has theory closure. It is hardened when it has fully hardened closure. It is a discovery object when it is the target of a classifier-shift transition with theory closure. It is a positive discovery object when, in addition, the transition has positive unified information gain.*

Theorem 9462.549 (Unified closure theorem)**.** *A unified object is closed exactly when its generated material is traceable, its classifier is displayed, its NameCert rows are complete, its ledger covers required residue, its DNA critical loci are complete, anchored, and certificate-compatible, and its scope seal states the claim kind and not-claimed boundary.*

Proof. This is the expansion of theory closure into its material, classifier, NameCert, ledger, DNA, and scope axes. Each listed condition is one axis; together they are the conjunction defining theory closure. □

Theorem 9462.550 (Unified hardening theorem)**.** *A unified object is hardened exactly when it is closed and every critical hardenable component is formally hardened with complete verification ledger, while non-hardenable residue is ledgered.*

Proof. Fully hardened closure is theory closure together with verification closure. The stated condition expands verification closure and combines it with the closed-object condition. □

Theorem 9462.551 (Unified discovery theorem)**.** *A transition is unified discovery exactly when the classifier layer changes and the target object is theory-closed. It is unified positive discovery exactly when, additionally,* $\Delta\,\mathrm{UInfo} > 0$.

Proof. The first sentence expands the definition of discovery object. The second adds the positive unified-information condition from Definition 9462.530. □

Theorem 9462.552 (Unified BEDC information theorem)**.** *In the BEDC reading, information, learning, interpretability, black-box resolution, and formal verification are unified by the chain*

$$\textit{generated material} \longrightarrow \textit{classifier} \longrightarrow \mathsf{NameCert} \longrightarrow \textit{ledger} \longrightarrow \textit{DNA} \longrightarrow \textit{scope seal} \longrightarrow \textit{optional formal hardening}$$

Information growth is certified classifier shift rather than record growth; learning is certified classifier formation rather than parameter motion; interpretability is Tensor NameCert and NDNA

closure rather than feature labeling; black-box resolution is decomposition closure rather than narrative explanation; and formal verification is a hardening layer rather than the object-formation rule.

Proof. Definition 9462.57 separates information growth from record growth. Definition 9462.540 identifies learning discovery as a unified instance. Definition 9462.541 does the same for interpretability discovery. Definition 9462.542 does the same for black-box discovery-resolution. Definition 9462.527 and Definition 9462.524 separate formal hardening from theory closure. The displayed chain is the common closure route shared by these cases. □

9462.21 Unified Schematic Map

section 9462.20 gives the closure theorem. The present section records the same result as a schematic map: each layer is read by the next layer, and no lower layer is allowed to impersonate the closure supplied by a higher layer.

Definition 9462.553 (Primitive-to-certified route)**.** *The primitive-to-certified route is the ordered reading*

$$\mathsf{Distinction} \longrightarrow \mathsf{History} \longrightarrow \mathsf{Record} \longrightarrow \mathsf{Classifier} \longrightarrow \mathsf{NameCert} \longrightarrow \mathsf{Ledger} \longrightarrow \mathsf{CertifiedObject}.$$

The first three layers record generated material; the classifier layer organizes material into stable same-and-different judgments; the certificate and ledger layers make that organization auditable.

Concretized in §6295: The primitive-to-certified route is realized as an ordered NameCert carrier from generated distinction rows through classifier, ledger, and certified-object seal.

Theorem 9462.554 (Record growth is below classifier discovery)**.** *Record growth, longer traces, shorter presentations, new names, and formal hardening do not by themselves imply information discovery.*

Proof. Each can occur while the classifier relation is preserved. Discovery in the classifier-shift reading requires a changed classifier surface together with certificate and ledger support, not merely additional material, altered presentation, or changed verification status. □

Definition 9462.555 (Machine-learning certification stack)**.** *The machine-learning certification stack reads tensor traces, activations, soft features, probes, thresholds, and behaviors as classifier candidates. A candidate becomes an auditable explanation only through Tensor NameCert rows: tensor source, tensor pattern, tensor classifier, tensor stability, and tensor ledger. Formal verification may harden selected rows, but it does not replace the Tensor NameCert or the ledger.*

Theorem 9462.556 (Feature evidence is below Tensor NameCert)**.** *Features, top examples, probe accuracy, visualizations, and tensor directions are evidence fragments rather than certified explanations unless they enter a Tensor NameCert with ledger coverage.*

Proof. Each fragment can support a pattern or classifier row, but none supplies the full source, pattern, classifier, stability, ledger, and seal surface by itself. Certification begins only when those rows are jointly displayed. □

Definition 9462.557 (NDNA schematic)**.** *The neural theorem-DNA schematic for a behavior B is the role family*

$$\mathsf{NDNA}(B) = (G_{\mathsf{source}}, G_{\mathsf{feature}}, G_{\mathsf{circuit}}, G_{\mathsf{classifier}}, G_{\mathsf{stability}}, G_{\mathsf{intervention}}, G_{\mathsf{ledger}}, G_{\mathsf{seal}}).$$

It is an explanation genome only when the loci are complete, anchored, NameCert-compatible, ledgered, and sealed.

Theorem 9462.558 (Single loci are not explanation genomes)**.** *A feature label, circuit diagram, classifier relation, intervention record, or semantic label is a single locus or locus fragment, not an NDNA-certified explanation.*

Proof. The NDNA packet requires source, feature, circuit, classifier, stability, intervention, ledger, and seal loci. A single displayed locus leaves the remaining roles absent or unanchored. □

9462.21.1 Black-Box and Information Schematics

Definition 9462.559 (Black-box schematic)**.** *The black-box schematic is*

$$\mathsf{BlackBox}(B) \iff \exists C.\, C \Vdash B \text{ and } \neg\exists N.\, N = \mathsf{NameCert}(C).$$

Resolution on a scope is the package

$$C \Vdash B \quad + \quad \mathsf{NameCert}(C) \quad + \quad \mathsf{LedgerComplete}(C, B) \quad + \quad \mathsf{Seal}(B, C).$$

Definition 9462.560 (Five-field deficit schematic)**.** *For a behavior B and classifier candidate C, the five-field deficit vector is*

$$\mathbf{D}(B, C) = (d_S, d_P, d_C, d_\Sigma, d_L) \in \{0, 1\}^5.$$

The coordinates record source, pattern, classifier, stability, and ledger gaps. The all-zero vector together with zero critical ledger debt is the field-level signature of scoped BEDC resolution.

Concretized in §6303: The five-field explanation schematic is realized as finite source, classifier, evidence, ledger-gap, certification-route, transport, replay, provenance, and NameCert rows.

Theorem 9462.561 (Ledger gaps dominate scoped resolution)**.** *If the ledger coordinate or critical ledger debt is nonzero, scoped black-box resolution fails.*

Proof. Scoped resolution requires ledger completeness. A nonzero ledger coordinate or nonzero critical ledger debt records an unclosed required residue row, so the resolution package is incomplete. □

Definition 9462.562 (Information schematic)**.** *For an explanation or unified object E, the auditable information schematic is*

$$\mathsf{Info}(E) = \mathsf{Benefit}(E) - \mathsf{Cost}(E) - \mathsf{Debt}(E).$$

A transition is positive only when the corresponding information difference is strictly positive under a public cost protocol.

Definition 9462.563 (Discovery schematic)**.** *Certified discovery is classifier shift with NameCert and ledger rows. Positive discovery is certified discovery with positive net information gain:*

$$\mathsf{Discovery}^{+} = \mathsf{ClassifierShift} \quad + \quad \mathsf{NameCert} \quad + \quad \mathsf{Ledger} \quad + \quad \Delta\mathsf{Info} > 0.$$

Theorem 9462.564 (Audit progress and discovery are separate schematic cases)**.** *Ledger repair, proof hardening, cost reduction, and seal clarification can be positive audit progress without being classifier discovery.*

Proof. Each may improve benefit, reduce cost, or lower debt while preserving the classifier relation. The discovery schematic requires classifier shift, so same-classifier audit progress is not discovery. □

9462.21.2 Learning, Generalization, and Verification

Definition 9462.565 (Learning schematic)**.** *The learning schematic reads training traces and activation records as candidate sources for stable tensor distinctions. Strong learning is the formation of a learned classifier together with Learning NameCert and learning ledger rows. Positive certified learning additionally requires positive learning information gain.*

Theorem 9462.566 (Performance movement is below certified learning)**.** *Loss reduction, benchmark gain, parameter growth, and memorization do not by themselves establish certified learning discovery.*

Proof. They can occur without a displayed classifier shift and without Learning NameCert or ledger rows. Certified learning discovery requires the classifier surface and its audit packet, not merely a performance or parameter event. □

Definition 9462.567 (Generalization schematic)**.** *Certified generalization is classifier transfer with ledger. It requires a source-domain classifier, target-domain support, transfer or stability witnesses, a generalization NameCert, and a target-residue ledger.*

Theorem 9462.568 (Accuracy transfer is below certified generalization)**.** *Target-domain performance is not yet a certified generalization explanation unless the classifier transfer and target residue are ledgered.*

Proof. Performance can transfer while the classifier boundary changes, while target failures remain unrecorded, or while the source classifier is not the one supporting the target behavior. The certified claim therefore requires classifier-transfer evidence and ledger coverage. □

Definition 9462.569 (Verification schematic)**.** *Formal verification follows the route*

$$F \longrightarrow \varphi_F \longrightarrow \pi_F \longrightarrow \mathcal{V} \vdash \pi_F : \varphi_F \longrightarrow \mathsf{Hardened}(F),$$

where F is a transcribed component. The route requires transcription ledger and verification ledger whenever it is used to support an interpretability claim.

Theorem 9462.570 (Verification hardens components rather than forming objects)**.** *Formal verification can harden selected components, but it does not by itself create the NameCert, explanation ledger, NDNA packet, or global scope ledger.*

Proof. The verification judgment concerns a formal statement and proof object. Object formation requires source, pattern, classifier, stability, ledger, role loci, and scope seal. Those rows are outside the proof judgment unless separately supplied. □

9462.21.3 Global and Final Schematics

Definition 9462.571 (Global-resolution schematic)**.** *Global resolution for a model state requires the covered behavior family, supporting classifier family, NameCert family, global ledger, and global seal. Without the global ledger, the claim remains scoped even when many local explanations are present.*

Theorem 9462.572 (No global ledger, no global explanation)**.** *A global explanation claim without a global ledger is not closed.*

Proof. By Definition 9462.496, global resolution requires ledger coverage for the required residue of all covered behaviors and supporting classifiers. Without that ledger, the global claim lacks its closure surface. □

Theorem 9462.573 (Unified schematic theorem)**.** *The schematic reading of the machine-learning layer, BEDC certification layer, and formal-verification layer is the single chain*

$$\mathsf{Distinction} \longrightarrow \mathsf{Classifier} \longrightarrow \mathsf{NameCert} \longrightarrow \mathsf{Ledger} \longrightarrow \mathsf{Explanation} \longrightarrow \mathsf{OptionalHardening}.$$

Black boxes are uncertified classifier structures; resolving them means supplying NameCert, ledger, and seal; learning is classifier formation; discovery is certified classifier shift; and positive discovery is certified classifier shift with positive net information gain.

Proof. The primitive-to-certified route supplies the lower chain. Definition 9462.555 and Definition 9462.557 specialize it to tensor interpretability. Definition 9462.559 gives the black-box and resolution equations. Definition 9462.563 gives the discovery and positive-discovery equations. Definition 9462.569 places formal verification as hardening rather than object formation. These are the listed schematic identifications. □

9462.22 Observation, Subject, and Time

The first layer identifies the path from distinction to history:

$$\text{distinction} \to \mathsf{Hist} \to \text{information}.$$

The present layer reads the next structural path:

$$\mathsf{Hist} \to \mathsf{Cont} \to \text{observation},$$
$$\mathsf{Hist} + \mathsf{hsame} \to \text{observer identity},$$
$$\mathsf{Cont}\text{-asymmetry} \to \text{time},$$
$$\text{multiple histories} \to \text{no global clock}.$$

Its compressed thesis is that the observer is a history, observation is continuation, and time is history growth. These are not additional primitives. They are the public readings of the same kernel surface.

9462.22.1 Internalizing observation

Definition 9462.574 (Observation)**.** *An observation is a continuation witness* $\mathsf{Cont}(h, d, h')$*, where* h *is the antecedent history,* d *is the displayed distinction or continuation tail, and* h' *is the successor history. Its public reading is that a history continues under a distinction into another history.*

Definition 9462.575 (Subject-free observation)**.** *A continuation is subject-free when its signature has no auxiliary observer-substance parameter. It does not contain a parameter of the form* s : Subject*, an owner map for histories, or a separate viewpoint carrier outside the history layer.*

Theorem 9462.576 (Observation is continuation, not representation)**.** *In BEDC, observation is the visible continuation of history rather than a mental representation owned by a hidden subject.*

Proof. The relation $\mathsf{Cont}(h, d, h')$ relates histories through a displayed distinction. Its endpoints lie in the history layer, and its witness is available for later transport, classifier comparison, and ledger assembly. It invokes no private mental state, external subject, or host equality oracle. Therefore the BEDC form of observation is generated continuation. □

Corollary 9462.577 (Observation needs no subject-substance)**.** *The BEDC theory of observation does not require a hidden subject entity.*

Proof. If the observation is already given by a continuation witness, adding a subject parameter contributes no new kernel witness. It instead introduces an unaudited carrier that is not generated by Hist, compared by hsame, or transported by a displayed continuation law. □

Corollary 9462.578 (Observation is a ledger event)**.** *Observation in BEDC is a public ledger event rather than an incomparable private inspection.*

Proof. A continuation witness can be reused by history-sameness transport, licensed classifiers, packages, and naming certificates. A purely private inspection that cannot enter these ledgers has no object-layer standing in BEDC. □

Concretized in §1266: Finite observation locks realize subject-free observation as a finite continuation, hsame, budget, readback, and NameCert packet.

Concretized in §1271: Subject-free observation packets realize Cont observations, hsame observer identity, no-subject exclusion, and public ledger-event exposure as one finite NameCert surface.

9462.22.2 Observer identity

Definition 9462.579 (Observer history identity)**.** *Two histories have the same observer identity when licensed observations do not separate them except through a displayed classifier witness against their internal history-sameness comparison. In short, observer identity is history identity read through licensed observational comparison.*

Definition 9462.580 (Observer ledger)**.** *An observer ledger is a finite evidence packet consisting of mark emissions, continuation witnesses, probe bundles, signature relations, derived classifiers, and the corresponding history-sameness or classifier comparison rows.*

Theorem 9462.581 (Observer identity remains internal)**.** *Every accepted BEDC judgment of observer identity is internal to the finite witness ledger.*

Proof. The observations entering the judgment are BEDC witnesses: marks, continuations, bundles, signatures, classifiers, and history-sameness comparisons. Repackaging them as an observer ledger uses only internal sameness and classifier relations. No host equality and no invisible subjective sameness criterion is introduced. □

Corollary 9462.582 (Same observer does not mean same mental entity)**.** *Two observers are identified by licensed history comparison, not by sharing a hidden mental substance.*

Proof. A hidden mental substance is not a mark emission, continuation, signature, classifier, or history-sameness row. It therefore cannot serve as a licensed BEDC identity criterion. □

Corollary 9462.583 (Observer identity is history identity)**.** *At the kernel-facing surface, observer identity is history identity under* hsame *and licensed classifier comparison.*

Proof. The observer ledger has no independent subject parameter. Its only identity surface is the generated history trace and the comparisons licensed over that trace. □

9462.22.3 Observer as history

Definition 9462.584 (Self-reference closure)**.** *The kernel is self-reference closed when every continuation relates history values,* hsame *is the kernel identity criterion for those values, and no observer-substance identity is defined alongside* hsame*.*

Definition 9462.585 (Observer)**.** *An observer in the BEDC object layer is a history equipped with its recorded distinction trace and admissible continuation and history-sameness comparisons. Since these structures are already history-layer structures, the compressed reading is observer* = Hist*, modulo* hsame*.*

Theorem 9462.586 (History-sameness is observer identity)**.** *If observers are read as self-distinguishing histories, then two observers have the same kernel identity precisely when their generated distinction traces are related by* hsame*.*

Proof. The generation rules for hsame preserve constructor shape: empty history compares only with empty history, E0-extensions compare through E0-extensions, and E1-extensions compare through E1-extensions. Thus a history-sameness witness preserves the finite distinction trace shape. Under the observer-as-history reading, that trace shape is the observer's identity surface. □

Theorem 9462.587 (No subject parameter)**.** *The kernel-level continuation signature contains no auxiliary parameter representing a subject or a carrier outside the history layer.*

Proof. Adding a parameter s : Subject to continuation would require that parameter to be transported or preserved by associativity and unit laws for continuation. The kernel supplies no witness for such transport, and the existing laws have no position in which an independent subject-substance can be consumed. The added parameter therefore does not refine the kernel; it changes the structure. □

Corollary 9462.588 (Observer is history)**.** *In BEDC, modulo* hsame*, the observer is the history itself.*

Proof. There is no independent subject parameter in continuation, and the identity surface available for observers is generated history-sameness. The only carrier left for observer identity is therefore Hist. □

Corollary 9462.589 (The self is a trace reading)**.** *The self is not an entity behind history, but the continuous reading of a history trace through* hsame *and its ledgers.*

Proof. If the observer is a history, persistence of the self can only mean persistence of the trace under licensed history comparison. A separate self-entity would require an additional carrier and identity transport not provided by the kernel. □

Corollary 9462.590 (No substance behind the trace)**.** *BEDC does not need to adopt any external doctrine of self-negation in order to obtain the structural conclusion that no observer-substance stands behind the trace.*

Proof. The conclusion follows from the kernel signature itself. The continuation relation has history endpoints, the identity criterion is history-sameness, and adding an independent observer carrier would require unlicensed transport. The result is structural, not an imported psychological or theological thesis. □

9462.22.4 Time as history growth

Definition 9462.591 (Hist time step)**.** *A Hist time step is one application of* E0 *or* E1 *to a history. The step is recorded both in the generated history value, by constructor shape, and in the continuation witness, by the displayed distinction argument.*

Definition 9462.592 (Local time stream)**.** *The local time stream of a history h is the finite sequence of continuation applications producing h from* e*, equivalently the generated unary history together with the displayed distinction record at each step.*

Theorem 9462.593 (Time is history growth)**.** *In BEDC, time is history growth.*

Proof. Time minimally requires an order of before and after. In the kernel, before and after first appear as constructor growth from a history to an E0- or E1-extension, and as the corresponding continuation witness. No independent time carrier is needed to produce this order. □

Corollary 9462.594 (No external time axis)**.** *The kernel has no time axis independent of histories.*

Proof. The available time-step surface is the generated history step and its continuation witness. An external axis would be a further primitive carrier, not part of the kernel signature. □

Corollary 9462.595 (Time is not an event container)**.** *Events do not first occur inside time and then become recorded; the temporal order is the order in which distinctions enter histories.*

Proof. An E0- or E1-application is simultaneously a distinction record and a time step. Without such record formation, the object layer has no kernel time stream to read. □

9462.22.5 The arrow of time

Definition 9462.596 (Forward continuation)**.** *A forward continuation is a witness* $\mathsf{Cont}(h, d, h')$ *read from an antecedent history h and distinction data d to the successor history h'.*

Definition 9462.597 (Backward recovery)**.** *Backward recovery is the problem of reconstructing an antecedent history h from a displayed successor h' and distinction data d such that* $\mathsf{Cont}(h, d, h')$ *holds.*

Theorem 9462.598 (Continuation is time-asymmetric)**.** *Continuation is constructive in the forward direction, while backward recovery requires structural analysis of the successor history.*

Proof. Given an antecedent history and a displayed distinction step, the successor is fixed by the relevant history constructor. Given a successor, recovering a predecessor requires inspecting the successor's generated form. This difference between construction and readback is the kernel-level arrow of time. □

Corollary 9462.599 (The time arrow is not an added physical postulate)**.** *The BEDC arrow of time follows from constructive directionality rather than from an additional physical axiom.*

Proof. The asymmetry is already present in the formation and recovery of history constructors. A separate primitive saying that time has a direction would duplicate the constructive structure. □

Corollary 9462.600 (Past as readback, future as construction)**.** *The past is structurally readable from generated histories; the future is continuation not yet generated.*

Proof. A generated history can be analyzed through its constructors. A successor not yet present must be produced by a new continuation. The distinction is between readback of a trace and construction of a trace. □

9462.22.6 No global clock

Definition 9462.601 (Global clock)**.** *A global clock would be a kernel-level history or equivalent structure that synchronizes the local time streams of arbitrary histories.*

Theorem 9462.602 (No kernel global clock)**.** *The BEDC kernel has no global clock synchronizing distinct local history streams.*

Proof. Each history carries its own generated time stream. The kernel supplies history constructors, continuation witnesses, and internal history-sameness, but no separate synchronizing carrier for arbitrary histories. Any synchronization relation must therefore be introduced as an extension with its own witnesses and certificate discipline. □

Corollary 9462.603 (No absolute present)**.** *There is no kernel-level absolute present shared by all histories.*

Proof. An absolute present would require a global synchronization of local time streams. Such a synchronization is not present in the kernel. □

Corollary 9462.604 (Cross-history time comparison must be certified)**.** *Any comparison between the time streams of distinct histories must be given by an explicit extension carrier, classifier, ledger, or naming certificate.*

Proof. Since the kernel does not define inter-history time comparison, such a comparison cannot be read directly. To enter the object layer, it must be displayed as additional data and audited as such. □

Concretized in §2171: Local time fibers realize observer-local Hist growth as finite source, Contstep, transport, refusal, provenance, and NameCert rows.

9462.22.7 Multiple observers and no God's-eye view

Definition 9462.605 (Multi-history configuration)**.** *A multi-history configuration is a finite family of histories considered together without assuming a shared base history, shared step indexing, or global synchronization.*

Definition 9462.606 (Inter-history locality)**.** *An inter-history relation is local when each positive witness factors through finite BEDC data: source histories, continuation or bundle witnesses, and classifier comparisons using* hsame*,* msame*, or licensed derived classifiers.*

Theorem 9462.607 (Inter-history relations must be ledger-visible)**.** *An acceptable inter-history relation must be auditable by finite BEDC ledger data.*

Proof. A relation between histories has object-layer standing only through generated marks, emitted histories, continuation witnesses, bundles, signatures, or licensed classifiers. A comparison supplied by an external observer without such rows is not a BEDC witness. □

Corollary 9462.608 (No observer outside all observers)**.** *BEDC contains no super-observer standing outside all histories and synchronizing them from without.*

Proof. If the alleged super-observer is not a history, it violates the observer-as-history reading. If it is a history, it has its own local time stream and lacks a kernel global clock. Adding further observers therefore does not repair the absence of a God's-eye frame. □

Corollary 9462.609 (Frame-independent content is inter-history invariant)**.** *Without a global clock, frame-independent content can only be carried by certified inter-history invariants.*

Proof. Single histories carry local time streams. Distinct histories do not share a kernel index. A cross-observer claim can therefore be stable only when it is expressed as a symmetric, history-sameness-respecting, ledgered relation or invariant. □

9462.22.8 Observation, distinction, and time

Definition 9462.610 (Three act-shapes)**.** *The kernel admits three readings of the same act-shape: observation as* $\mathsf{Cont}(h, d, h')$*, distinction as an* $\mathsf{E0}$*- or* $\mathsf{E1}$*-step, and time as a Hist time step.*

Theorem 9462.611 (Observation-distinction-time identity)**.** *At the kernel-facing surface, observation, distinction, and time are extensionally the same act-shape modulo* hsame *and the continuation closure laws.*

Proof. All three readings have the same domain of histories and distinction steps. The observation reading uses the continuation witness; the distinction reading uses the constructor step; the time reading uses the same step as local history growth. The relevant associativity, unit, and history-sameness-respect conditions are therefore conditions on the same generated structure. □

Corollary 9462.612 (Observation is not added after distinction)**.** *Observation is not an extra act placed on top of distinction and time.*

Proof. The continuation act that records a distinction is already the time step and the observation witness. No additional psychological layer is needed at the kernel surface. □

Corollary 9462.613 (Time is not outside observation)**.** *Time is not a background in which observation occurs; it is the generated order of observation as continuation.*

Proof. The time step and the observation act share the same continuation structure. An external temporal background would require a separate primitive not present in the kernel. □

Corollary 9462.614 (Distinction is dynamic)**.** *Distinction is not merely a static opposition; it is a generative act capable of becoming observation and time.*

Proof. An $\mathsf{E0}$- or $\mathsf{E1}$-application enters a history, supplies a continuation witness, and forms a local time step. Its role is therefore dynamic. □

9462.22.9 Continuation as universal verb

Definition 9462.615 (Universal verb)**.** Cont *is a universal verb when extension-type phenomena are read as specializations of the same continuation relation under different carrier, classifier, stability, ledger, and naming-certificate conditions.*

Theorem 9462.616 (Continuation is the universal verb)**.** Cont *is the universal verb of BEDC.*

Proof. Category morphisms, small-step computation, continuous moduli, type checking by classifier membership, and related extension phenomena all use the same pattern: a displayed source, a continuation or transition, a target, and certificate conditions preserving admissibility. Their differences lie in the surrounding NameCert fields, not in a new kernel verb. □

Corollary 9462.617 (Mathematical structure is stabilized continuation)**.** *Many mathematical structures in BEDC are stable certified readings of continuation rather than independent primitives.*

Proof. The carrier and classifier decide which continuation rows count as the phenomenon in question; the stability and ledger fields decide how the rows persist under reuse, composition, and transport. The kernel action remains continuation. □

Corollary 9462.618 (Action, observation, computation, and time cohere)**.** *Action, observation, computation, and time are four disciplined readings of generated continuation.*

Proof. Each reading concerns a finite passage from one displayed state to another. Action reads the passage as generated transition, observation as recorded distinction, computation as small-step relation, and time as history growth. □

9462.22.10 Synthesis

Theorem 9462.619 (Observer-observation-time synthesis)**.** *At the kernel-facing surface of BEDC,*

$$\textit{observer} = \mathsf{Hist}, \qquad \textit{observation} = \mathsf{Cont}, \qquad \textit{time} = \textit{history growth},$$
$$\textit{and} \qquad \textit{observation} = \textit{distinction} = \textit{time}$$

as structural readings modulo hsame *and the continuation closure laws.*

Proof. Observation is continuation between histories. Observer identity is carried by history-sameness and licensed classifier comparison. No subject parameter is present in the continuation signature. A time step is an E0- or E1-extension recorded by continuation. Continuation is asymmetric between construction and readback. Finally, the observation act, distinction step, and time step are readings of the same generated history transition. Combining these facts gives the claimed synthesis. □

Corollary 9462.620 (Excluded subject primitives)**.** *The kernel does not admit bare primitives such as* Subject*,* ObserverSubstance*,* SelfEntity*,* GlobalViewpoint*, or* AbsoluteNow*.*

Proof. The work assigned to those names is already carried by histories, history-sameness, continuation ledgers, inter-history relations, naming certificates, or exposed boundary markers. As bare primitives they would require additional carriers and transports absent from the kernel. □

Corollary 9462.621 (BEDC phenomenological form)**.** *The BEDC phenomenological form is not that a subject intends an object in time, but that a history continues by distinction, and that continuation is observation-time.*

Proof. The same continuation event can be read as distinction occurring, observation occurring, a time step occurring, and history growing. The four descriptions name one generated structure. □

9462.23 Objects, Knowledge, and Naming Certificates

The first layer reads distinction as the condition of history. The second layer reads continuation as observation, time, and observer identity. The present layer asks how stable patterns in histories, continuations, signatures, packages, and gaps become objects and knowledge. Its compressed thesis is:

$$\text{object} = \text{licensed name},$$
$$\text{knowledge} = \text{auditable witness},$$
$$\text{definition} = \text{certificate for stable generated behavior.}$$

Thus BEDC does not begin with mature objects and then describe them. It generates histories, classifies stable behavior, records the hidden material in ledgers, and licenses names only after the relevant certificate fields are supplied.

9462.23.1 Objects are not primitive

Definition 9462.622 (Bare object)**.** *A name N is a bare object name when it is introduced into the theory without a displayed source specification, pattern specification, classifier specification, stability certificate, and ledger policy. A name such as natural number, real number, set, type, function, limit, or circle is bare in this sense whenever it is not accompanied by a certificate explaining how it is generated from BEDC materials and how its behavior is classified, stabilized, and tracked.*

Definition 9462.623 (Mature object)**.** *A mature object is a licensed derived interface. For a proposed name N, maturity means that N is accepted through a naming certificate rather than supplied as a kernel primitive.*

Theorem 9462.624 (Anti-primitive principle)**.** *No mature object enters BEDC as a kernel primitive.*

Proof. The kernel begins with marks, histories, internal sameness judgments, continuations, asking events, signatures, packages, gaps, and naming certificates. Traditional mathematical interfaces such as equality, functions, natural numbers, arithmetic operations, limits, real numbers, geometric figures, and folds occur only after the relevant carrier, classifier, stability, and ledger obligations have been displayed. They are outputs of the certificate discipline, not inputs to the finite kernel. □

Corollary 9462.625 (Definitions do not create objects ex nihilo)**.** *A definition does not produce an object from nothing; it names stable generated behavior under a certificate.*

Proof. Without a source specification, the proposed name has no generated material. Without a pattern specification, it has no stable behavior. Without a classifier, it has no internal same-object condition. Without a stability certificate, it cannot be reused, descended, composed, or sealed. Without a ledger policy, its hidden material is not auditable. The definition becomes object-forming only when these obligations are met. □

Corollary 9462.626 (Object existence is certificate existence)**.** *For a mature BEDC object, object-layer existence entails the presence of an auditable naming certificate.*

Proof. A mature object is a licensed name, and a licensed name is not a primitive input. Its object-layer standing is therefore mediated by the certificate that licenses it. □

9462.23.2 The five fields of a naming certificate

Definition 9462.627 (Source specification)**.** *The source specification of a proposed name N records the generated material from which the name receives its license. Its sources may include raw marks, histories, bundles, signatures, packages, gaps, or previously licensed names.*

Definition 9462.628 (Pattern specification)**.** *The pattern specification records the stable behavior that the proposed name is meant to expose: repetition, continuation, signature classification, package stability, compatible threading, or another displayed regularity in the source material.*

Definition 9462.629 (Classifier specification)**.** *The classifier specification states how source material is grouped under the proposed name. It answers when two source rows count as the same N-object, when two behaviors instantiate the same pattern, and when two representatives are the same only through a licensed classifier.*

Definition 9462.630 (Stability certificate)**.** *The stability certificate records the closure, reuse, descent, composition, or sealing behavior that makes the name stable enough for later use. Different interfaces may require different combinations of these stability modes.*

Definition 9462.631 (Ledger policy)**.** *The ledger policy records what the name hides and how the hidden material remains traceable after compression, packaging, projection, or sealing. It specifies the relevant gap ledger, composite gap, tail ledger, phase ledger, source ledger, or other derived ledger surface.*

Definition 9462.632 (Naming certificate)**.** *A paper-level naming certificate for a proposed interface N is the five-field packet*

$$\mathsf{NameCert}(N) = (\mathsf{SourceSpec}_N, \mathsf{PatternSpec}_N, \mathsf{ClassifierSpec}_N, \mathsf{StabilityCert}_N, \mathsf{LedgerPolicy}_N).$$

The name N is licensed only when the required fields of this packet are supplied.

Theorem 9462.633 (The five fields are irreducible)**.** *No field of a naming certificate can be omitted without losing the object's auditable standing.*

Proof. Without source, the name has no generated material. Without pattern, the name has no stable behavior to expose. Without classifier, there is no internal sameness condition for the named interface. Without stability, the name cannot be safely reused or transported. Without a ledger policy, compression loses provenance. The five fields therefore correspond to source, pattern, sameness, stability, and memory. □

Corollary 9462.634 (Objects are fivefold qualifications)**.** *A BEDC object is not a single bare entity but a source-qualified, pattern-stabilized, classifier-organized, stability-certified, and ledger-tracked interface.*

Proof. The naming certificate licenses the object exactly through those five fields, and the fields are not optional. □

9462.23.3 Paper certificates and finite-kernel certificates

Definition 9462.635 (Paper naming certificate)**.** *A paper naming certificate is the five-field theoretical template that explains why a proposed interface may be named.*

Definition 9462.636 (Finite-kernel naming certificate)**.** *A finite-kernel certificate of the form* NameCert(Carrier, Equiv) *is a carrier-and-equivalence certificate over generated histories or their derived carriers. It supplies inhabitedness of the carrier, reflexivity, symmetry and transitivity of the equivalence relation, and transport of carrier membership along that relation.*

Theorem 9462.637 (Kernel certificates formalize the classifier core)**.** *The finite-kernel certificate is the formal core of the paper* NameCert *at the carrier and classifier layer.*

Proof. The paper certificate requires a classifier specification and stability conditions explaining how a carrier is organized and transported. The finite-kernel certificate supplies exactly the formal equivalence laws and membership transport needed for that organization. It does not exhaust every paper-level semantic field, but it gives the formal carrier-classifier nucleus of the licensed interface. □

Corollary 9462.638 (Paper completion is not machine checking)**.** *A complete paper certificate is not the same status as a machine-checked certificate.*

Proof. The paper certificate states and argues for the required fields. A machine-checked certificate requires corresponding formal targets and auditable acceptance by the checker. The former is a paper obligation surface; the latter is a verified formal object. □

9462.23.4 Knowledge as witness

Definition 9462.639 (BEDC knowledge)**.** *To know an object or claim X in BEDC is to possess a witness for X. Such a witness may be an* msame *or* hsame *witness, a* Cont *witness, a signature witness, a package witness, a gap witness, a naming-certificate witness, a semantic-certificate witness, or a derivation-certificate witness.*

Definition 9462.640 (Auditable knowledge)**.** *A knowledge item is auditable when its source is visible or ledger-tracked, its classifier is stated, its stability or transport law is supplied, its hidden material is recorded by a ledger, and its proof strength is marked.*

Theorem 9462.641 (Knowledge is witness, not bare truth)**.** *The BEDC form of knowledge is witness possession, not an internal bare truth predicate.*

Proof. Object knowledge requires a naming certificate. Classification knowledge requires a classifier witness. Compressed knowledge requires a ledger exposing the source material behind the token. Formal knowledge requires a target accepted by the relevant audit. A claim without a witness has no public object-layer standing, because the object layer has no global truth predicate through which it could be consumed. □

Corollary 9462.642 (Truth remains meta, certificates enter the object layer)**.** *BEDC object-layer operations consume certificates rather than a total truth predicate.*

Proof. A total internal truth predicate would classify arbitrary propositions at once. BEDC instead licenses local interfaces through source, classifier, stability, and ledger witnesses. The object layer operates with those certificates. □

9462.23.5 Packaging, compression, and gaps

Definition 9462.643 (Package token)**.** *A package judgment* $\mathsf{Pkg}(\Pi, s, p)$ *says that, under bundle* Π*, the answer-history* s *is represented by the package token* p*. The relation* $\mathsf{psame}(p, q)$ *is the internal sameness judgment for package tokens.*

Definition 9462.644 (Package policy)**.** *A package policy supplies existence of tokens for generated answer-histories, extensionality of tokens along history-sameness, grounding of package-token sameness in represented histories, and the visibility rule that only the token and its ledger appear at the package interface.*

Theorem 9462.645 (Packages are not quotients)**.** *Package tokens are not quotient classes. Quotient-like behavior is a certified theorem of the package policy, not a primitive.*

Proof. If package tokens were quotient classes, the theory would need a quotient object or a quotient-soundness principle at the point of introduction. Instead, tokens are introduced by package judgments, and their sameness is controlled by extensionality and grounding fields. The visible quotient-like behavior is therefore derived from package policy rather than imported as a primitive quotient. □

Definition 9462.646 (Gap ledger)**.** *A gap ledger records which source histories lie behind a visible package token, signature token, or compressed interface. It is the memory surface of a compression.*

Definition 9462.647 (Gap policy)**.** *A gap policy exposes provenance and generation witnesses, covers the admitted source histories by visible gaps, and separates package tokens when the same source lies behind their gaps.*

Theorem 9462.648 (Compression must remember)**.** *Every BEDC operation that packages, compresses, projects, seals, or hides generated material must carry a gap ledger.*

Proof. Packaging replaces source histories by visible tokens. Without a gap ledger, the theory loses the internal witness connecting the token to the histories it hides. The token would then be a free object rather than a certified compression. A valid compression must therefore retain provenance through a ledger. □

Corollary 9462.649 (No amnesic compression)**.** *BEDC permits compression, but not compression that forgets its source.*

Proof. Compression is acceptable only when the visible token remains connected to its hidden source material by a gap policy. Removing that memory breaks auditability. □

9462.23.6 Semantic naming and pattern-ledger transport

Definition 9462.650 (Semantic naming certificate)**.** *A semantic naming certificate is a naming certificate enriched by source-to-pattern soundness, source-to-ledger soundness, and classifier transport preserving the pattern and ledger fields.*

Theorem 9462.651 (Semantic certificates contain pattern and ledger witnesses)**.** *Every semantic naming certificate contains a source witness from which both the pattern condition and the ledger policy are obtained.*

Proof. Eliminating the semantic certificate exposes its core naming certificate and its pattern and ledger soundness fields. The core certificate supplies the source witness, and the soundness fields apply to that same witness. □

Theorem 9462.652 (Pattern-ledger transport)**.** *If a semantic naming certificate classifies a source history h with a history k, then the pattern and ledger conditions transport to k.*

Proof. The core naming certificate transports carrier membership along the classifier relation. Once the target is again recognized as a source row, the semantic pattern and ledger soundness fields apply at the target. □

Theorem 9462.653 (Classifier-chain transport)**.** *If a semantic certificate supplies classifier links from h to k and from k to r, and h carries the source witness, then the pattern and ledger conditions transport to r.*

Proof. Transitivity of the core classifier composes the two links into a single link from h to r. Pattern-ledger transport then applies to that composite link. □

Corollary 9462.654 (Object stability is transportability)**.** *The stability of a BEDC object is not metaphysical immobility but transportability of its pattern and ledger across licensed classifier relations.*

Proof. The object remains stable precisely when the certificate can carry its pattern and ledger through the equivalence or classifier paths that the interface licenses. □

9462.23.7 Certificate-organized clusters

Definition 9462.655 (Certificate-organized cluster)**.** *A certificate-organized cluster is a paper-level interface*

$$\mathsf{ClusterCert}(S, P, L, R, B, F, O)$$

whose first component is a semantic naming certificate over source rows S, pattern rows P, ledger rows L, and classifier relation R. The remaining rows record, respectively, a connectivity or membership witness for the cluster, a boundary predicate B, forbidden claims F, and open obligations O. The interface is a derived certificate protocol; it is not a kernel primitive and not an axiom schema.

Theorem 9462.656 (Cluster names are licensed names)**.** *If a certificate-organized cluster is accepted, then its public name is a licensed BEDC name rather than a bare cluster label.*

Proof. The cluster interface contains a semantic naming certificate. By Definition 9462.651, that certificate supplies a source witness together with pattern and ledger witnesses. The classifier core supplies transport across the cluster by Definition 9462.652 and Definition 9462.653. Therefore the cluster name is admitted through source, pattern, classifier, stability, and ledger data, not through a detached label. □

Corollary 9462.657 (Cluster objects are transportable source families)**.** *A certificate-organized cluster names a transportable source family under a displayed classifier, not a single unqualified point.*

Proof. Pattern and ledger rows transport along licensed classifier paths by Definition 9462.652 and Definition 9462.653. The named object is therefore the classifier-stable family of admissible source rows together with its ledger, boundary, forbidden-claim, and open-obligation surface. □

Corollary 9462.658 (Cluster compression preserves memory)**.** *Any readout, coordinate, probability, or model token exported from a certificate-organized cluster must preserve its source memory through a ledger or expose the missing source as a boundary.*

Proof. The cluster interface contains the ledger row of its semantic certificate and the explicit boundary row B. A readout that hides source material is a compression, so Definition 9462.648 applies. If the source fiber cannot be fully displayed, the remaining material belongs to the boundary or gap surface rather than to a closed object-layer claim. □

9462.23.8 Acceptance gates and strength

Definition 9462.659 (Derivation strength)**.** *The strength of a derived object is ordered as*

$$\mathsf{seed} < \mathsf{paperCert} < \mathsf{checkedCert} < \mathsf{bridgeCert}.$$

A seed has a sketched carrier and classifier. A paper certificate fills the certificate fields in the manuscript. A checked certificate is backed by formal targets and audit. A bridge certificate adds a conservative bridge to a standard model.

Definition 9462.660 (Acceptance gate)**.** *For a mature object name N at strength s, the acceptance gate is the conjunction of a naming certificate for N and a derivation certificate recording that strength.*

Definition 9462.661 (Derivation certificate)**.** *A derivation certificate records the source layer carrying N, the classifier organizing the carrier, exactness of the classifier with respect to the relevant sameness judgments, the ledger or explicit absence statement, the stability certificate, and the declared strength.*

Theorem 9462.662 (Object export passes through the acceptance gate)**.** *BEDC may export a mature object N only at a displayed strength whose acceptance gate is satisfied.*

Proof. The naming certificate explains why the name is licensed. The derivation certificate explains which strength level has been reached. Without the first, N is not a licensed name. Without the second, the theory cannot distinguish a sketch from a paper certificate, a checked certificate, or a standard-model bridge. □

Corollary 9462.663 (No strength inflation)**.** *BEDC cannot report a lower strength as a higher one.*

Proof. The strength order is cumulative in one direction only. A checked certificate includes more obligations than a paper certificate, and a bridge certificate includes more obligations than a checked certificate. Reporting a lower level as a higher one hides unfinished certificate obligations. □

9462.23.9 Synthesis

Theorem 9462.664 (Object-knowledge-certificate synthesis)**.** *In BEDC, objects and knowledge enter through certificates:*

$$\mathit{object}_N = \mathit{licensed\ name}(N),$$
$$\mathit{knowledge} = \mathit{auditable\ witness}.$$

The mature object is generated from histories, continuations, signatures, packages, gaps, and prior names through source, pattern, classifier, stability, and ledger fields, then exported only at a declared strength. The knowledge claim appears through a displayed witness rather than through a bare truth predicate.

Proof. Mature objects are not primitives. A naming certificate has five irreducible fields. Finite-kernel certificates formalize the carrier-classifier core. Knowledge is witness possession. Compression requires a gap ledger. Semantic certificates transport pattern and ledger along classifiers. Export requires an acceptance gate with a declared strength. Combining these facts gives the stated synthesis. □

Corollary 9462.665 (BEDC object theory)**.** *The BEDC theory of objects can be summarized as follows: an object is a licensed name, a name is a certificate for stable behavior, and a certificate is the fivefold structure of source, pattern, classifier, stability, and ledger.*

Corollary 9462.666 (BEDC epistemology)**.** *The BEDC theory of knowledge can be summarized as follows: to know is to hold a witness, to prove is to supply transport, stability, and ledger data, and to understand an object is to identify the certificate through which it enters.*

Corollary 9462.667 (Passage to logic and meta-loop discipline)**.** *Once objects and knowledge are certificate-mediated, the next task is to identify which proof patterns preserve this discipline and which patterns smuggle in unwitnessed objects or global truth.*

Proof. Certificate discipline accepts local contradiction over fixed carriers, constructor no-confusion, and witness-preserving transport. It rejects unwitnessed positive existence, hidden choice, quotient collapse, propositional extensional collapse, and total truth predicates. The next philosophical layer must therefore analyze proof and meta-loop boundaries. □

Concretized in §1218: Object-knowledge certificates realize licensed object names and auditable witnesses as one finite NameCert packet.

Concretized in §1341: Bare-object refusal is realized as a finite NameCert packet recording missing certificate fields, refusal rows, witness audit, and anti-primitive ledger nonescape.

9462.24 Section Meaning Certificates

section 9462.23 identifies objects with licensed names and knowledge with auditable witnesses. The present layer applies that discipline to interfaces in which an observation is invariant under a displayed symmetry while the semantic label changes along a fiber. Its compressed thesis is:

observation gives a package-level quotient readout,
meaning requires a certified section or fiber ledger.

Thus a BEDC interface may accept an orbit-level observation without accepting a bare representative selector, a hidden canonical section, or a label that descends through the same package token.

Definition 9462.668 (Orbit observation packet)**.** *An orbit observation packet consists of a source carrier X, an internal classifier $\approx_X$, a licensed action certificate for a symmetry interface G, an orbit package Q_G with projection $\pi_G : X \to Q_G$, and a readout $O : X \to Y$ satisfying the displayed invariance row*

$$O(g \cdot x) \approx_Y O(x).$$

The package Q_G is a BEDC package interface with a gap ledger, not a primitive quotient type.

Definition 9462.669 (Anti-invariant label packet)**.** *An anti-invariant label packet over the same source consists of a two-label interface* $\mathsf{B}^{\uparrow} = \{C_0, C_1\}$ *with no-confusion, an involution* ν *exchanging the two labels, a certified involution* $\tau \in G$*, and a label readout* $L : X \to \mathsf{B}^{\uparrow}$ *satisfying*

$$L(\tau \cdot x) = \nu(L(x)).$$

Definition 9462.670 (Section meaning certificate)**.** *A section meaning certificate is the derived paper-level interface*

$$\mathsf{SectionMeaningCert}(X, G, O, L, Q_G, \pi_G, \sigma)$$

whose rows include an orbit observation packet, an anti-invariant label packet, an optional section binding $\sigma : Q_G \to X$ *satisfying* $\pi_G(\sigma(q)) = q$*, and ledgers for the source, orbit package, observation, label, section authorization, and boundary. The section row is valid only when it records its source, authorization, witness, stability, and forbidden-claim surface.*

Theorem 9462.671 (Observation descends while labels need not)**.** *In a section meaning certificate, the invariant observation descends to a licensed readout* $\bar{O} : Q_G \to Y$*, while an anti-invariant label cannot be treated as a readout on* Q_G *unless an additional section or fiber ledger is displayed.*

Proof. If two source rows have the same orbit package token, the action certificate supplies a symmetry path between them. Observation invariance transports O along that path, so O factors through the package projection as $\bar{O} \circ \pi_G$. For the label row, x and $\tau \cdot x$ have the same orbit token, but their labels are exchanged by ν. A package-level label readout would identify those two labels, contradicting no-confusion. Therefore the label requires additional section or fiber data rather than descending through the orbit package alone. □

Corollary 9462.672 (No hidden section from pure observation)**.** *Pure orbit-observation material does not license a distinguished section* $Q_G \to X$*.*

Proof. The visible observation rows are invariant on each orbit. Choosing a representative inside an orbit therefore introduces data not contained in the orbit token or invariant readout. BEDC may expose that data as a section binding, authorization row, action-response row, bridge, or boundary, but it may not present the choice as a theorem of the pure observation packet. □

Theorem 9462.673 (Meaning is section-relative)**.** *When a valid section binding* σ *is supplied, the expression*

$$L_\sigma(q) = L(\sigma(q))$$

is a licensed meaning readout on Q_G *relative to that binding.*

Proof. The section binding is a licensed map from the package interface back to the source carrier, and the label packet is a licensed map from the source carrier to the two-label interface. Their composite is therefore a licensed readout. Its ledger is the composite ledger of the section authorization and the label packet, so the resulting meaning is relative to the displayed binding rather than intrinsic to the orbit token. □

Corollary 9462.674 (Matched twins force a blind ceiling)**.** *In a balanced matched-twin protocol where each pair has the same observation and opposite labels, every decision rule depending only on the orbit observation is bounded by the blind ceiling* $\frac{1}{2}$*.*

Proof. On each matched pair, the rule sees the same observation on both members and therefore returns the same decision. The label packet assigns opposite labels to the two members. With balanced presentation, the rule is correct on exactly one side of each pair, so averaging over the finite protocol gives $\frac{1}{2}$. □

Corollary 9462.675 (Section access, leakage, or protocol mismatch)**.** *If a matched-twin interface is reported above the blind ceiling, then the certificate audit must expose section access, leakage of non-orbit data, or a mismatch in the stated protocol object.*

Proof. The blind ceiling applies to every orbit-observation rule. Exceeding it therefore means that the rule is not using only the certified orbit observation, or that the protocol does not satisfy the matched-twin rows that define the ceiling. In the first case the additional coordinate must be ledgered as section access or recorded as leakage; in the second case the protocol object must be corrected before the reported number can support a certificate claim. □

9462.25 Logic, Contradiction, and the Meta Loop

The previous layer identifies objects with licensed names and knowledge with auditable witnesses. The logical question is therefore not which rules are attractive in isolation, but which proof patterns preserve witness, classifier, stability, and ledger discipline. The central distinction is:

$$\text{closed ground loop} = \text{constructive formation and local refutation,}$$
$$\text{open meta loop} = \text{no total truth, choice, quotient, or halting closure.}$$

9462.25.1 The BEDC form of proof

Definition 9462.676 (BEDC proof)**.** *A BEDC proof of a claim A is a finite witness chain using generated materials such as marks, histories, internal sameness judgments, extension and continuation rows, signatures, packages, gaps, and naming certificates. It must display its sources, continuation steps, classifier comparisons, hidden material, ledger rows, and certificate surface.*

Concretized in §1238: Proof witness chains are realized as finite BHist packets binding proof trace, source carrier, classifier witness, transport, ledger, forbidden-resource refusal, audit verdict, provenance, and local NameCert rows.

Concretized in §1353: Proof-pattern classifiers are realized as finite BHist packets separating positive witness construction, local refutation, decidable double-negation, and prohibited positive extraction.

Definition 9462.677 (Positive proof)**.** *A positive proof constructs a witness for an object, proposition, relation, or certificate field. It does not merely show that the absence of such a witness would be contradictory.*

Definition 9462.678 (Negative proof)**.** *A negative proof transforms any purported witness of A into $\bot$, thereby proving $\neg A$. The conclusion means that every internal witness of A fails inside the displayed carrier, classifier, or certificate; it is not a God's-eye denial over all possible structures.*

Theorem 9462.679 (Proof is witness, not truth-possession)**.** *In BEDC, the basic proof form is an auditable witness chain rather than possession of bare truth.*

Proof. Object-layer contents enter through generated carriers and licensed interfaces. A claim that lacks source rows, continuation witnesses, classifier transport, gap provenance, or certificate fields cannot be consumed by the object layer. Thus a proof must expose the chain by which the claim is generated and stabilized. □

Corollary 9462.680 (Logic follows certificate discipline)**.** *BEDC logic is the proof-theoretic face of certificate discipline.*

Proof. Objects enter through naming certificates and knowledge enters through witnesses. A rule that creates positive content without a witness would bypass that entry discipline. Hence admissible reasoning must preserve witnesses, classifiers, stability, and ledgers. □

9462.25.2 Permitted contradiction

Definition 9462.681 (Permitted refutation)**.** *A refutation is permitted when it has the form $A \to \bot$, and the derivation of $\bot$ uses only fixed carrier data, constructor no-confusion, internal sameness, continuation rows, fixed naming certificate laws, and classifier inversion. It does not use a total truth predicate, arbitrary excluded middle, unwitnessed choice, quotient collapse, or propositional extensionality.*

Theorem 9462.682 (Negative proof is accepted locally)**.** *If a proof only converts any witness of A into an internal contradiction, BEDC accepts it as a proof of $\neg A$.*

Proof. Such a proof creates no new object and supplies no unwitnessed positive existence. It shows that a purported witness conflicts with the fixed constructor, classifier, carrier, or certificate laws already in view. The proof remains inside the closed ground loop. □

Example 9462.683 (Mark no-confusion)**.** *The judgment $\neg\mathsf{msame}(\mathsf{b0}, \mathsf{b1})$ is a permitted refutation. Assuming a witness of $\mathsf{msame}(\mathsf{b0}, \mathsf{b1})$, inversion on the closed generation of msame leaves only the two diagonal cases and no cross-mark constructor. The contradiction uses the mark carrier and constructor no-confusion, not a total truth predicate.*

Definition 9462.684 (Decidable double-negation elimination)**.** *For a displayed decidability witness of $P(h)$, the passage from $\neg\neg P(h)$ to $P(h)$ is decidable double-negation elimination.*

Theorem 9462.685 (Double-negation elimination requires decidability)**.** *BEDC accepts $\mathsf{Decidable}(P(h)) \to \neg\neg P(h) \to P(h)$, but not $\neg\neg P(h) \to P(h)$ without a displayed decidability witness.*

Proof. With decidability, the case split is itself a witness. The positive case supplies $P(h)$. The negative case contradicts $\neg\neg P(h)$ and therefore also yields the positive case. Without decidability, $\neg\neg P(h)$ contains no constructor for $P(h)$; turning it into one would inject missing constructive content. □

Definition 9462.686 (Refuting false existence)**.** *To refute an existential claim is to give a uniform method converting any purported pair $(x, P(x))$ into a contradiction inside the displayed carrier or classifier.*

Theorem 9462.687 (False existence may be refuted)**.** *BEDC accepts a refutation of an existential claim when every purported existential witness can be converted into an internal contradiction.*

Proof. An existential witness, if present, must be usable as internal data. Mapping every such witness to $\bot$ proves that the witness type is uninhabited; it does not construct a positive object. □

Corollary 9462.688 (Negative proof is local)**.** *Negative proof in BEDC must be local to a fixed carrier, classifier, or certificate surface.*

Proof. A global negation over all propositions or all certificate extensions would require a meta-level truth classifier. BEDC permits local inversion and refutation, not total truth closure. □

9462.25.3 Prohibited contradiction

Definition 9462.689 (Prohibited positive extraction)**.** *A proof pattern is prohibited when it produces positive content without constructing the corresponding witness. Typical cases are extracting* $\exists h, P(h)$ *from* $\neg\forall h, \neg P(h)$ *without an exhibited* h*, using double-negation elimination without a decidability witness, or applying excluded middle to arbitrary certificate-level predicates.*

Theorem 9462.690 (Unwitnessed positive existence is meta closure)**.** *Deriving* $\exists h, P(h)$ *from* $\neg\forall h, \neg P(h)$ *without displaying* h *and a witness of* $P(h)$ *closes the meta loop.*

Proof. The existential claim is a witness obligation. If no witness is displayed, the system has nevertheless accepted a value that later constructions may consume. That value is an oracle rather than a generated object. □

Theorem 9462.691 (Undecided double-negation elimination is meta closure)**.** *Without* $\mathsf{Decidable}(P(h))$*, the rule* $\neg\neg P(h) \to P(h)$ *is not a BEDC rule.*

Proof. The conclusion $P(h)$ requires a constructor witness. The premise only says that denying such a witness leads to contradiction. Using it as the witness itself replaces construction by meta-level extraction. □

Theorem 9462.692 (Global excluded middle is meta closure)**.** *Excluded middle over arbitrary certificate-level predicates is a truth-totalizing operation and therefore closes the open meta loop.*

Proof. Such a principle would decide, for each certificate-level predicate, whether a witness exists or any witness is impossible. This is a fragment of an internal truth predicate over the certificate space, not a local classifier witness. □

Corollary 9462.693 (Existence requires a witness)**.** *Every positive existence theorem in BEDC must exhibit the object and the proof that it satisfies the stated predicate.*

Proof. An existential conclusion without witness is precisely the prohibited positive extraction described above. □

Corollary 9462.694 (Classical contradiction must be audited)**.** *Classical proofs by contradiction must be separated into refutational content and positive existence content before entering BEDC.*

Proof. The refutational part may survive as a local proof of negation. The positive existential part must either exhibit a witness or remain outside the certified fragment. □

9462.25.4 Closed ground loop and open meta loop

Definition 9462.695 (Closed ground loop)**.** *The closed ground loop is the mark-level distinction supplied by the two primitive mark constructors and their constructor no-confusion. It is closed because the declaration of the two constructors is already an act of distinction.*

Definition 9462.696 (Open meta loop)**.** *The open meta loop is the position that cannot be closed inside BEDC: an internal truth predicate, internal runtime validator, total halting predicate, or global decision predicate for all certificate-level propositions.*

Theorem 9462.697 (Ground must close)**.** *A formal system whose ground never closes cannot start.*

Proof. If the first primitive required a prior primitive to explain it, the regress would not terminate. BEDC pays this cost once, at the minimal mark distinction. □

Theorem 9462.698 (Meta must stay open)**.** *A sufficiently expressive system cannot internalize its own total truth predicate.*

Proof. Once a system can represent enough of its own syntax, a total truth predicate produces the familiar Tarski-style fixed-point obstruction. Truth recovery requires a stronger metalanguage rather than another object-layer predicate of the same system. □

Theorem 9462.699 (Two-loop balance)**.** *BEDC requires the ground loop to close and the meta loop to remain open.*

Proof. The ground loop closes at the minimal productive distinction, allowing generation to begin. The meta loop remains open because truth, runtime, and total decision cannot be absorbed into the object layer without self-reference collapse. The two requirements occupy different levels and therefore do not conflict. □

Corollary 9462.700 (BEDC exposes rather than evades the boundary)**.** *BEDC does not evade incompleteness or undefinability phenomena; it exposes the primitive distinction on which they depend.*

Proof. Syntax, formula, proof, and classifier distinctions already presuppose distinguishability. BEDC makes that condition explicit at the ground instead of pretending that it can be eliminated at the meta level. □

Corollary 9462.701 (Only the ground closes)**.** *The only loop that closes in BEDC is the form of distinction at the ground layer.*

Proof. Higher layers are built by classifier-based generation, transport, and certification. If a higher layer attempts to close over its own truth, runtime, or total decision procedure, it is no longer a productive ground loop but a meta closure. □

9462.25.5 Self-description and truth boundary

Definition 9462.702 (Structural self-description)**.** *Structural self-description is the construction, inside BEDC, of a certificate-mediated reproduction of formal features of the host calculus: type formation, dependent function formation, inductive type formation, recursors, and well-founded classifier closures.*

Definition 9462.703 (Runtime boundary)**.** *The runtime boundary is the fact that a structural reproduction of a calculus is not the host runtime that checks proofs. The proof checker remains a metalanguage artifact relative to the BEDC object layer.*

Theorem 9462.704 (BEDC may describe formal structure)**.** *BEDC may describe formal structure resembling the calculus in which it is checked.*

Proof. Such a description is a certificate-mediated account of formation rules, inductive shapes, and closure operations. It is structural data inside the theory, not the running checker itself. □

Theorem 9462.705 (BEDC does not internalize its runtime)**.** *BEDC cannot make the proof-checking runtime an object-layer component of itself.*

Proof. The external checker validates BEDC proofs from the metalanguage. A structural reproduction of checking rules does not become the implemented runtime that performs validation. No object layer contains the full runtime that interprets it. □

Theorem 9462.706 (Self-description is not truth definition)**.** *BEDC self-description is not a BEDC truth predicate.*

Proof. Describing syntax and closure rules does not decide which arbitrary object-layer claims are true. A total truth predicate would require the meta loop to close, which is excluded by the Tarski boundary. □

Corollary 9462.707 (Reflection is layered)**.** *BEDC reflection is layered structural reflection, not a collapse of the described layer into the describing layer.*

Proof. The described structure, the structural description, and the external checker occupy distinct roles. Collapsing them would recreate the truth-totalization problem. □

Concretized in §1260: Runtime-boundary audit packets realize the structural self-description/runtime-refusal split as finite BHist, hsame, Cont, Pkg, NameCert, and TasteGate rows.

9462.25.6 Three axioms, one meta closure

Definition 9462.708 (Meta-closure operation)**.** *At a syntactic stratum S, a meta-closure operation accepts a positive existential without a constructor witness and supplies a value at that stratum usable by later kernel constructions.*

Definition 9462.709 (Choice as term-level meta closure)**.** Classical.choice *is term-level meta closure when it turns pointwise existential information into a selector function whose body is not constructed from displayed witnesses.*

Definition 9462.710 (Quotient soundness as type-level meta closure)**.** *Quotient soundness is type-level meta closure when a relation or equivalence is consumed as quotient equality or representative transport without explicit classifier transport and ledger data.*

Definition 9462.711 (Propositional extensionality as proposition-level meta closure)**.** *Propositional extensionality is proposition-level meta closure when a bidirectional implication is consumed as equality of propositions without recording direction, transport, or ledger.*

Principle 9462.712 (The three classical axiom families share one taxonomy)**.** Classical.choice*, quotient soundness, and propositional extensionality are classified here as three meta-closure refusal shapes at the term, type or classifier, and proposition strata.*

Explanation. Each lets insufficiently witnessed positive content be consumed as a value by subsequent constructions. The difference is the stratum at which the value is requested: selector at the term layer, quotient-facing transport or equality at the type layer, and proposition identification at the proposition layer. This is a taxonomy for the audit ledger, not a metatheoretic proof that the host axioms are equivalent to one another or to BEDC collapse modes. □

Corollary 9462.713 (Refusal of the axioms is not refusal of their subject matter)**.** *BEDC refuses the unwitnessed shortcut, not the mathematical content that classical axioms often help express.*

Proof. The same content may enter through explicit witnesses, classifier transport, package sameness, and ledgers. What is rejected is the untracked conversion of existence, relation, or equivalence into a consumable object. □

9462.25.7 Witness-preserving replacements

Definition 9462.714 (Effective choice)**.** *Effective choice in BEDC is finite choice by primitive recursion over closed lists, countable choice with displayed witness functions, or dependent choice along a continuation chain with explicit step functions.*

Theorem 9462.715 (Effective choice preserves witnesses)**.** *The BEDC replacements for choice do not introduce unwitnessed selectors.*

Proof. Each selector is built from displayed data: recursion over a finite carrier, a given witness function, or a given step function along a continuation chain. The selector body is therefore constructed rather than supplied by meta closure. □

Definition 9462.716 (Classifier transport instead of quotient collapse)**.** *BEDC replaces quotient collapse by naming certificates, classifiers, package sameness, and classifier-respecting transport. Carrier elements identified by a classifier are not collapsed at the type level; operations consume explicit transport.*

Theorem 9462.717 (Classifier transport replaces quotient collapse)**.** *Quotient-like behavior in BEDC is implemented by explicit classifier transport rather than by primitive quotient equality.*

Proof. The operation that respects the classifier must display how it transports across the classifier relation. No canonical representative is selected without a witness, and no type-level equality is supplied without ledgered transport. □

Definition 9462.718 (Directional transport instead of propositional collapse)**.** *BEDC replaces propositional extensionality by explicit directional transport. If $P \to Q$ and $Q \to P$ are available, each construction records which direction it consumes instead of identifying P and Q as the same proposition.*

Theorem 9462.719 (Explicit transport replaces proposition collapse)**.** *BEDC does not replace $P \leftrightarrow Q$ by $P = Q$; it preserves direction, transport, and ledger.*

Proof. The bidirectional implication gives two maps. A consumer of P or Q must specify the map it uses. The propositions are not collapsed into a single object by an unwitnessed equality. □

Theorem 9462.720 (Certified content uses witness-preserving replacements)**.** *BEDC certified content is supported by explicit choice, classifier transport, and directional transport rather than by the three meta-closure axioms.*

Proof. Whenever a construction needs a selection, it must display the selection function or recursion. Whenever it needs quotient-like behavior, it must display classifier transport. Whenever it needs a proposition to be consumed under an equivalent form, it must display the direction of transport. □

9462.25.8 Axiom-purity

Definition 9462.721 (Axiom-pure theorem)**.** *A theorem is axiom-pure when its transitive dependencies do not include* Classical.choice*, quotient soundness, or propositional extensionality.*

Definition 9462.722 (Axiom-purity gate)**.** *The axiom-purity gate rejects kernel-level theorems whose dependency graph passes through the three axiom families classified as meta-closure refusal shapes.*

Principle 9462.723 (Axiom-purity rejects meta-closure shapes)**.** *The axiom-purity gate rejects dependencies classified as meta-closure shapes at the term, type or classifier, and proposition strata.*

Explanation. The rejected dependencies are read here as term-level, type-level or classifier-level, and proposition-level ways for unwitnessed positive content to be made usable by later constructions. Excluding them keeps the open meta loop open. □

Corollary 9462.724 (The gate is philosophical discipline)**.** *Axiom-purity is not only an engineering rule; it is the mechanical enforcement of witness discipline on proof dependencies.*

Proof. If no unwitnessed object may enter the object layer, then dependencies that supply hidden witnesses must be rejected. The gate implements that refusal at the dependency level. □

Concretized in §1259: Axiom-purity gate packets realize dependency-audit refusal as finite theorem-target, dependency-report, forbidden-row, replay, replacement, transport, provenance, and NameCert data.

Concretized in §1269: Meta-closure witness ledgers realize the axiom-purity vision as finite witness, classifier-transport, directional-transport, dependency-audit, hsame, Cont, Pkg, and NameCert rows.

Corollary 9462.725 (Purity is not full maturity)**.** *Passing axiom-purity does not by itself show that a mature object has passed its acceptance gate.*

Proof. Axiom-purity checks proof dependencies. Object maturity also requires source, classifier, exactness, ledger, stability, strength, and possibly bridge obligations. These are separate audit surfaces. □

9462.25.9 Halting as the recursive face of the open meta loop

Definition 9462.726 (Continuation-chain termination)**.** *A continuation chain for a naming certificate terminates from a history when there is a finite displayed list of continuation steps ending at a history with no successor under the same continuation relation.*

Definition 9462.727 (Halting predicate)**.** *A halting predicate for BEDC would decide, for arbitrary naming certificates and histories, whether the corresponding continuation chain terminates.*

Theorem 9462.728 (No total halting certificate)**.** *There is no BEDC naming certificate that decides termination for all naming certificates and all histories.*

Proof. Assume such a certificate exists. Build a diagonal certificate that consults the supposed halting certificate on a displayed certificate and initial history, then behaves oppositely: continuing when termination is predicted and stopping when nontermination is predicted. Applying the diagonal certificate to its own displayed code gives the standard contradiction. □

Theorem 9462.729 (Total halting closes the meta loop)**.** *A total halting predicate is a certificate-stratum closure of the open meta loop.*

Proof. It would be a global decision procedure for all continuation behavior of naming certificates. That is a total meta-level classifier imported into the object layer. □

Corollary 9462.730 (No total proof-search oracle)**.** *BEDC has no internal oracle deciding whether arbitrary certificate construction succeeds.*

Proof. Such an oracle would decide termination of the corresponding certificate-search continuations, contradicting the absence of a total halting certificate. □

Corollary 9462.731 (Open targets require exposed status)**.** *When a construction has no displayed witness, its status must remain exposed by a target, horizon, or gap marker rather than absorbed by a total truth or halting oracle.*

Proof. A total oracle would close the meta loop. Exposed status preserves the difference between a witnessed construction and an unwitnessed obligation. □

9462.25.10 Type checking as classifier membership

Definition 9462.732 (Extension as type membership)**.** *For a language-like carrier L, $\mathsf{Ext}_L(t)$ may be read as the predicate that t lies in the well-typed subclass of terms.*

Definition 9462.733 (Continuation as typed reduction)**.** $\mathsf{Cont}_L(t, m, t')$ *may be read as a displayed small-step reduction from t to t' with mark m, subject to preservation of the extension predicate.*

Theorem 9462.734 (Type checking is classifier membership)**.** *In the BEDC reading, type checking is membership checking for a classifier-defined extension predicate.*

Proof. The extension predicate cuts out the admissible subclass of terms, and continuation describes allowed transitions within that subclass. To check the type is to check membership in the displayed classifier surface. □

Definition 9462.735 (Curry–Howard reading)**.** *Under the BEDC Curry–Howard reading, a proposition is a classifier or type, a proof is a witness or inhabitant, and a program is a continuation-preserving construction.*

Theorem 9462.736 (Closure law as constructive proof)**.** *Every classifier closure law is also the constructive proof of the corresponding type closure.*

Proof. If Ext is read as membership in a type, then a closure law proves that the relevant construction sends admitted inputs to admitted outputs. The same witness is both the closure proof and the program transformer. □

Corollary 9462.737 (Proof checking is not proof search)**.** *Checking a displayed witness against a classifier is not the same as having a total proof-search procedure.*

Proof. Classifier membership can be local and decidable for the displayed interface. A total proof-search procedure would decide arbitrary certificate construction and would approach the prohibited halting predicate. □

9462.25.11 Synthesis

Theorem 9462.738 (Logic discipline synthesis)**.** *BEDC permits explicit witness construction and local refutation inside fixed carriers, classifiers, and certificates. It rejects positive content without constructor witnesses and rejects global truth, halting, excluded-middle, choice, quotient, or proposition-equality closures over certificate space.*

Proof. Proofs are witness chains. Local negation stays inside fixed generated structure. Unwitnessed positive extraction supplies a value without construction. Ground closure is needed for generation, while meta closure would internalize truth or runtime. The three classical axioms are term-, type-, and proposition-level instances of the same hidden witness schema; axiom-purity rejects them. A total halting predicate is the recursive version of the same closure. Type checking remains local classifier membership rather than total proof search. □

Corollary 9462.739 (Positive existence must be constructed)**.** *Every BEDC existence theorem must display the witness, its carrier membership, its classifier stability, and its ledger surface.*

Corollary 9462.740 (Contradiction is not wholly rejected)**.** *BEDC does not reject contradiction reasoning as such. It accepts local refutation, decidable double-negation elimination, and explicit counterexample refutation; it rejects unwitnessed positive extraction and global truth closure.*

Corollary 9462.741 (One audit explanation of three axiom families)**.** *Choice, quotient soundness, and propositional extensionality share one audit explanation across three strata: unwitnessed content accepted as construction input.*

Corollary 9462.742 (Passage to boundary sockets)**.** *Once proof patterns that close the meta loop are identified, the next task is to describe how commitments genuinely exceeding closed observation are exposed as gaps or boundary sockets rather than internal theorems.*

9462.25.12 Apophatic T-loops

The two-loop discipline separates a productive ground closure from the meta closures refused by Tarski-style obstruction. The gap discipline then explains how a commitment that exceeds displayed records remains usable without being promoted to an internal theorem. The apophatic T-loop is the composite of these two readings: a records-side history may return to itself through a boundary inscription, but the far-end supply position that makes the return possible is not absorbed into the history.

Definition 9462.743 (Formal strange loop)**.** *A* formal strange loop *is a self-reference pattern in which the described layer and the describing layer are consumed as the same object-layer stratum. In such a loop the system can use its own description as a total truth, runtime, explanation, or decision predicate for the layer being described.*

Definition 9462.744 (Reality-why gap)**.** *Let C be a closed observational context, let $h \in \mathsf{Hist}$ be a records-side history visible to C, and suppose that* $\mathrm{Meaning}_{C,\Pi}(x, \ell, \kappa)$ *holds in the sense of Definition 9414.8. A* reality-why gap *at this site is the failure of the closed records of C to discharge the question*

$$\mathsf{Why}_{\mathrm{real}}(\mathrm{Meaning}_{C,\Pi}(x, \ell, \kappa))$$

while the corresponding label, prediction, action, or proof use continues to be consumed by later records.

Definition 9462.745 (Apophatic T-loop)**.** *An* apophatic T-loop *is a ledgered composite*

$$h \longrightarrow \kappa \longrightarrow \mathrm{Meaning}_{C,\Pi}(x,\ell,\kappa) \longrightarrow \mathsf{RealityConstraint} \longrightarrow \mathsf{GAP}_T(\mathsf{Why}_{\mathrm{real}}) \longrightarrow \mathsf{InscriptionPoint}(\mathsf{T}, C, t) \longrightarrow h',$$

where $h, h' \in \mathsf{Hist}$, h' is a records-side successor or refinement of h, the GAP_T row exposes a non-internalized far-end supply position, and the inscription point is a local records-side entry rather than T itself.

Theorem 9462.746 (Apophatic T-loop theorem)**.** *Assume a closed observational context C, a visible history $h \in \mathsf{Hist}$, a displayed record x, a classifier κ with $\kappa(x) = \ell$, and a reality-constrained meaning packet* $\mathrm{Meaning}_{C,\Pi}(x,\ell,\kappa)$*. If the associated reality-why question is not closed by the records and closed-generation rules of C, while the commitment is still used for continuation, then the admissible return to records has the form of an apophatic T-loop. This loop is a stratified return, not a formal strange loop.*

Proof. By Definition 9414.8, the meaning packet contains a source record, a classifier, a reality constraint, a continuation consequence, and a gap ledger. The equation $\kappa(x) = \ell$ supplies only the classifier field. The reality-facing use of the label also requires preservation of the Π-signature, downstream continuation, and exposure of any unclosed source or residue.

By Definition 9462.744, the why-question at the site is not discharged by the closed records of C, but the commitment is still consumed by later continuation. Hence the missing discharge cannot be recorded as an internal theorem without confusing unclosed supply with generated content. By the gap-socket discipline of Definition 9462.798 and the gap–T synthesis of Definition 9462.842, the missing discharge must instead be exposed as a socket whose far end is the apophatic supply position T.

By Definition 9462.787, T does not enter the object layer as a state, record, rule, axiom, or carrier. By Definition 9462.794, the only admissible records-side return is a local inscription site at which the forward-binding supply is actualized for the history. Thus the return has the displayed composite

$$h \longrightarrow \kappa \longrightarrow \mathrm{Meaning}_{C,\Pi}(x,\ell,\kappa) \longrightarrow \mathsf{RealityConstraint} \longrightarrow \mathsf{GAP}_T \longrightarrow \mathsf{InscriptionPoint}(\mathsf{T}, C, t) \longrightarrow h'.$$

It remains to rule out formal layer collapse. If the composite were a formal strange loop in the sense of Definition 9462.743, then the records-side history could consume the boundary supply position, its description, or its truth condition as object-layer data of the same stratum. That would either internalize T, contradicting Definition 9462.787, or close the meta loop over truth, runtime, explanation, or total decision, contradicting Definition 9462.698 and Definition 9462.701. Therefore the composite is a stratified return through inscription, not a formal strange loop. □

Corollary 9462.747 (T-loop productivity)**.** *An apophatic T-loop is productive exactly when it returns as a ledgered records-side refinement and keeps T outside the object layer.*

Proof. If the loop returns by a ledgered refinement h', the observational history has gained a visible record. If T remains outside the object layer, the meta loop remains open. Conversely, identifying T with h, with an observation record, or with a truth predicate would erase the boundary and turn the return into the formal layer collapse excluded by Definition 9462.746. □

Corollary 9462.748 (Conscious reading)**.** *When the source history factors through a focused conscious record, the apophatic T-loop gives a consciousness-like readback without adding subject-substance.*

Proof. A focused conscious record is records-side data: generated history, local continuation trace, selector ledger, and self-proxy. Applying Definition 9462.746 to such a source changes only the site of inscription. The far-end position remains non-internalized, and no extra subject parameter is added to Cont or to Hist identity. □

Definition 9462.749 (Meaning-bearing focused readback)**.** *Let $L_N = (I, H, \Theta, F, S, D, G, R, J, Q, \rho, A)$ be a focused ledger, let $C_F = (H(F), \Theta(F), S(F), \rho)$ be its focused chain, and suppose that x is a displayed record in $H(F)$. A* meaning-bearing focused readback *occurs at x when $S(F)$ selects a classifier κ with $\kappa(x) = \ell$ and the selected assignment is carried by* $\mathrm{Meaning}_{C,\Pi}(x, \ell, \kappa)$*. The self-proxy ρ then reads a reality-constrained meaning packet at the focused endpoint; it does not create the reality constraint and it does not replace the packet by a private phenomenal object.*

Theorem 9462.750 (Reality–meaning–consciousness relation)**.** *In a focused observational context, reality constrains classifiers into reality-constrained meaning; meaning that enters the focused ledger is readable by the self-proxy as a conscious record; and any question or action that asks for the ultimate reality source of that meaning can return to records only through an apophatic T-loop when the reality-why question is not internally closed.*

Proof. By Definition 9414.8, a label is meaningful in the relevant sense only as a packet containing a source record, classifier, reality constraint, continuation consequence, and gap ledger. Thus the transition from classification to meaning is already a transition through reality constraint rather than through the bare equation $\kappa(x) = \ell$.

If the displayed record lies in a focused ledger, then Definition 9414.523 identifies the records-side carrier of the conscious reading as

$$\mathsf{ConsciousRecord}(L_N, F) := (H(F), \Theta(F), S(F), \rho).$$

Together with Definition 9462.749, this says that the self-proxy reads a selected meaning-bearing record at the local endpoint. The conscious record is therefore a records-side reading of reality-constrained meaning, not an independent source of the constraint.

Now suppose the focused record continues by question, prediction, explanation, action, or proof use, and the continuation asks why the meaning is reality-supported beyond the displayed records. If that reality-why question is not closed by the records and rules of the context, Definition 9462.746 applies to the meaning packet. The admissible composite is

$$\begin{aligned}&\mathsf{Reality} \longrightarrow \mathsf{RealityConstraint} \longrightarrow \mathrm{Meaning}_{C,\Pi}(x, \ell, \kappa) \longrightarrow \mathsf{ConsciousRecord}(L_N, F)\\ &\longrightarrow \mathsf{Question/Action} \longrightarrow \mathsf{GAP}_T \longrightarrow \mathsf{InscriptionPoint}(\mathsf{T}, C_F, t) \longrightarrow \mathsf{ConsciousRecord}(L'_N, F').\end{aligned}$$

By Definition 9414.531, the inscription side of the conscious position is local inscription rather than T itself. Hence the loop relates reality, meaning, and conscious readback through a stratified boundary return, not by making consciousness a creator of reality or by making T an object-level answer. □

Corollary 9462.751 (Meaning is readable reality constraint)**.** *Meaning that reaches conscious readback is a reality-constrained structure readable by a focused self-proxy.*

Proof. The reality constraint belongs to the meaning packet by Definition 9414.8. The focused self-proxy is a component of the records-side conscious carrier by Definition 9414.523. Therefore a meaning-bearing focused readback reads the constrained packet locally; it does not convert meaning into unconstrained interior labeling. □

Corollary 9462.752 (Consciousness does not create reality)**.** *The records-side conscious carrier does not create the reality source of the meaning it reads.*

Proof. The carrier $\mathsf{ConsciousRecord}(L_N, F) = (H(F), \Theta(F), S(F), \rho)$ supplies a focused history, trace, selector, and self-proxy. None of these fields is the reality constraint field of $\mathrm{Meaning}_{C,\Pi}(x, \ell, \kappa)$. The constraint is part of the reality-constrained meaning packet itself, while ρ reads the selected packet at the focused endpoint. Thus conscious readback is not creation of reality. □

Corollary 9462.753 (Question and action expose the socket)**.** *When a focused conscious record asks why a meaning is reality-supported beyond its displayed records, the unclosed route is a socket and an inscription point, not an internal final answer.*

Proof. The question targets the unclosed reality-why component of the meaning-bearing continuation. By Definition 9462.750, if the records and rules do not close that component, the admissible return is through GAP_T and $\mathsf{InscriptionPoint}(\mathsf{T}, C_F, t)$. By Definition 9462.787, this return cannot be an internal object-level answer identical with T. □

Concretized in §6380: The finite NameCert packet records the gap-inscription route for the apophatic T-loop without internalizing the far-end supply position.

Concretized in §1261: Logic and meta-loop boundaries are realized as finite proof-pattern, local-refutation, open-meta-loop refusal, audit-gate, transport, route, provenance, and NameCert rows.

Concretized in §5191: The contradiction-request refusal row is realized as a finite NameCert packet rather than as host-level explosion.

9462.26 Gaps, Transcendental Supply, and Boundary Sockets

The preceding layer distinguishes local witness-preserving proof from unwitnessed meta closure. The present layer describes what remains when a closed observational system genuinely needs a commitment that cannot be generated from its records. Such a commitment must not be hidden as an internal rule. It is exposed as a gap socket, classified by the shape of the missing supply, and held at a boundary whose far end is named only apophatically.

9462.26.1 Closed observational systems

Definition 9462.754 (Closed observational system)**.** *A closed observational system is a packet* $(O, \mathsf{Obs}, \trianglerighteq, \mathsf{GAP})$*, where* O *is the class of observation states,* Obs *is the finite record ledger,* $\trianglerighteq$ *is the information-preserving growth order, and* GAP *records commitments that the system cannot discharge from its own records. Each reasoning step may use only displayed records and closed-generation rules, and every successor state must preserve the records of its predecessors.*

Definition 9462.755 (Observation record)**.** *An observation record is a finite traceable witness: a history, a continuation witness, an internal sameness witness, a signature row, a package row, a naming-certificate field, a checked-theorem row, an audit row, or a gap row.*

Definition 9462.756 (Information preservation)**.** *The relation* $O_t \trianglerighteq O_{t+1}$ *means that every record visible in state* O_t *remains visible in state* O_{t+1}*. The successor may add records, but it may not delete, rewrite, or forget earlier ones.*

Theorem 9462.757 (BEDC is a closed observational system)**.** *The BEDC substrate has the structure of a closed observational system.*

Proof. Its states may be read as proof and manuscript snapshots. Its records include inductive declarations, definitions, mechanized lemmas, naming certificate rows, gap tags, and audit results. Its growth discipline is monotone: later accepted states preserve earlier generated records. Unfinished or boundary commitments are exposed by gap rows rather than consumed as internal facts. □

Corollary 9462.758 (Knowledge comes from records)**.** *BEDC cannot use unrecorded, ungenerated, or uncertified material as substrate-internal knowledge.*

Proof. A closed observational system reasons only from its record ledger and closed-generation rules. Material outside those surfaces has no internal witness by which the object layer can consume it. □

Corollary 9462.759 (Gaps are structural)**.** *The gap mechanism is part of the system structure rather than a repair after failure.*

Proof. The system must distinguish discharged records from commitments whose witness is not internally available. Without gap rows, it would confuse unfulfilled boundary commitments with completed internal content. □

9462.26.2 Finite records and universal closure

Definition 9462.760 (Finite verification trace)**.** *For a predicate P, a finite verification trace is a finite list of records witnessing $P(n_1), \ldots, P(n_k)$, each backed by closed-generation data.*

Definition 9462.761 (Unrestricted universal assertion)**.** *An unrestricted universal assertion has the form $\forall n, P(n)$ over a domain not exhausted by the current finite observation ledger. It commits the system to cases that have not yet appeared as records.*

Theorem 9462.762 (Finite verification does not generate universal closure)**.** *No finite verification trace internally generates an unrestricted universal assertion in a closed observational system.*

Proof. A finite trace supplies only finitely many witnesses. To obtain an unrestricted universal assertion, the system would need either records for every case or an internal rule turning finite evidence into total closure. The first is not finite; the second is not a consequence of closed observation alone. □

Corollary 9462.763 (Induction is not produced by observation alone)**.** *Mathematical induction, when read beyond a displayed generator and its recursor, is not internally produced by finite observation alone.*

Proof. Induction concludes a universal statement. A closed observation ledger can supply finite traces and displayed generator closure, but it does not by itself supply an unrestricted universal range. □

Corollary 9462.764 (Church encodings do not erase the gap)**.** *An encoding of iteration does not by itself provide dependent induction over an unrestricted intended domain.*

Proof. An encoding may express closed iteration for displayed numerals and steps. Dependent induction requires a principle delivering $P(n)$ for all n in the intended range. The encoding therefore strengthens records-side iteration without eliminating the universal-closure gap. □

9462.26.3 Forward-binding belief

Definition 9462.765 (Forward-binding belief)**.** *A forward-binding belief is a present commitment that treats a claim whose witness lies partly in not-yet-observed cases as usable for subsequent reasoning. Its type is closer to a commitment or action than to an internal theorem.*

Theorem 9462.766 (Mathematical reasoning needs forward binding)**.** *A closed observational system that hosts ordinary mathematical reasoning requires at least one forward-binding commitment.*

Proof. Without such a commitment the system accumulates only finite traces. Ordinary mathematics uses universal claims about generated structures, recursion, syntax, proof height, and closure. Those uses require a commitment that reaches beyond the finite record currently displayed. □

Corollary 9462.767 (Forward binding is not a substrate axiom)**.** *Forward-binding belief must not be treated as a substrate-internal axiom.*

Proof. An internal axiom is a rule consumed directly by proof chains. Forward binding marks a commitment whose missing discharge must remain visible as a gap row at each site where it is used. □

Corollary 9462.768 (Gap rows preserve strict axiom discipline)**.** *Exposing forward-binding commitments as gaps preserves strict substrate axiom discipline while keeping observer-side commitments auditable.*

Proof. Putting the commitment into the substrate would turn it into an axiom. Leaving it unmarked would hide the boundary. Gap rows avoid both errors. □

Concretized in §1262: Forward-binding GAP ledgers realize present universal-closure commitments as finite record, GAP-socket, noninternalization, transport, route, provenance, and NameCert rows.

9462.26.4 Negative certification and positive continuation

Definition 9462.769 (Failure witness)**.** *For a closed observational system $\mathcal{C}$ and an output, action, or continuation candidate a, a failure witness for a is a visible record $w \in \mathsf{Obs}(\mathcal{C})$ whose audit reading blocks a: contradiction, failed prediction, rejected continuation, policy violation, exposed gap, or another ledgered refusal surface.*

Definition 9462.770 (Negative certification)**.** *An output a is negatively certified in $\mathcal{C}$ when some failure witness for a is present in the record ledger. An output is safe relative to the current ledger when no such witness is present.*

Theorem 9462.771 (Failure is locally witnessed)**.** *Negative certification is an existential record condition.*

Proof. By definition, negative certification asks only for one displayed failure witness in $\mathsf{Obs}(\mathcal{C})$. Once such a record is present, the ledger can classify the output as blocked without solving any global value-ordering problem. □

Corollary 9462.772 (Safety is weaker than positive adequacy)**.** *The absence of a negative certificate does not by itself certify that an output is positively adequate.*

Proof. Safety says only that the current ledger contains no visible failure witness for the output. It supplies no ordering among safe outputs, no purpose for preferring one continuation to another, and no reason that the relevant ordering should be followed. The safe region is therefore a boundary region, not a positive value horizon. □

Definition 9462.773 (Positive value horizon)**.** *A positive value horizon for a closed observational system is a displayed ordering, preservation target, or continuation law that says which safe outputs should be continued, preferred, protected, or actualized.*

Theorem 9462.774 (Positive adequacy requires a horizon)**.** *A closed observational system cannot read positive adequacy from safety alone.*

Proof. Let a and b be two outputs for which the current ledger contains no failure witness. The ledger has certified neither output as blocked. This common negative status does not decide whether a should be continued rather than b, whether b should be continued rather than a, or whether both should be withheld. Such a decision requires a positive value horizon. Without a displayed horizon, the system has only the failure boundary and cannot promote safety into positive adequacy. □

Corollary 9462.775 (Value supply is a gap discipline)**.** *When a proof, model, policy, or generative process consumes a positive value horizon that is not generated by the current records, the consumption site must be exposed as a gap socket.*

Proof. The horizon is being used to choose among safe continuations. If its source is not a displayed record, certified continuation law, or closed-generation consequence, treating it as internally available would hide external supply inside the substrate. The gap row preserves the difference between negative refusal, relative value under a given horizon, and the source of the horizon itself. □

9462.26.5 Value direction and formal appearance

Definition 9462.776 (Axiological axis)**.** *The axiological axis classifies an output, action, or continuation candidate by its orientation toward a positive value horizon. It asks whether the candidate preserves reality-facing signatures, keeps gap surfaces visible, respects other local histories as histories, and supports a continuation that the displayed horizon licenses as worth preserving.*

Definition 9462.777 (Aesthetic axis)**.** *The aesthetic axis classifies a finite form by the way reality-facing order is made readable in that form. It asks whether the form is coherent, whether its compression is honest about provenance and gap surfaces, and whether conscious readback can continue through it without the form replacing its source by mere surface attraction.*

Theorem 9462.778 (Value direction is distinct from formal appearance)**.** *The axiological axis and the aesthetic axis are distinct audit axes.*

Proof. The axiological axis concerns what should be continued under a positive value horizon. The aesthetic axis concerns how a finite form displays, compresses, or obscures reality-facing order. A candidate can have a licensed continuation while appearing formally broken, and a finite form can be locally harmonious while hiding the source, provenance, or gap surface on which its effect depends. Therefore the two axes cannot be collapsed into one classifier. □

Definition 9462.779 (Positive orientation)**.** *A candidate has positive orientation when it remains safe relative to the current ledger, preserves reality-facing contact, keeps gap rows honest, avoids reducing other histories to consumable material, and is licensed by a positive value horizon.*

Definition 9462.780 (Destructive orientation)**.** *A candidate has destructive orientation when it systematically blocks positive continuation, falsifies reality-facing signatures, conceals gap surfaces, or treats other local histories as tools, noise, or expendable material.*

Definition 9462.781 (Deep formal adequacy)**.** *A finite form has deep formal adequacy when its coherence is not merely surface polish: it honestly compresses a reality-facing signature, keeps provenance and gap residues visible at the right places, and opens further understanding, attention, creation, or silence in conscious readback.*

Definition 9462.782 (Formal distortion)**.** *Formal distortion occurs when a finite form misfits the reality-facing signature it claims to carry, hides provenance, erases gap residues, or produces a hollow appearance whose readback blocks rather than deepens continuation.*

Theorem 9462.783 (Surface attraction does not certify value)**.** *Local formal attraction does not certify positive orientation.*

Proof. Symmetry, polish, rhythm, or elegance can be supplied at the form surface. Positive orientation requires reality-facing contact, gap honesty, other-history respect, and a licensed value horizon. Since those requirements are not implied by surface form, a formally attractive candidate can still carry destructive orientation. □

Theorem 9462.784 (Formal discomfort does not refute value)**.** *Local formal discomfort does not refute positive orientation.*

Proof. Some records are painful, fractured, or resistant to immediate formal comfort because they expose injury, error, loss, or a concealed gap. If such a form preserves reality-facing contact and supports repair, truthful disclosure, or other licensed continuation, the discomfort is not a value refutation. □

Corollary 9462.785 (Four quadrant reading)**.** *Finite histories must allow four readings: positive orientation with deep formal adequacy, positive orientation with formal discomfort, destructive orientation with surface attraction, and destructive orientation with formal distortion.*

Proof. The first quadrant is licensed continuation displayed in coherent form. The second is truthful or reparative continuation whose form is locally painful or broken. The third is the dangerous case in which surface polish hides falsification, gap concealment, or other-history reduction. The fourth is direct failure of both value direction and formal readback. The distinction follows from the non-collapse of the two axes. □

9462.26.6 Transcendental supply

Definition 9462.786 (Transcendental supply position)**.** *T is the structural position from which forward-binding supply enters a closed observational system. It is not an observation state, not a record, not a closed-generation rule, and not a substrate axiom.*

Theorem 9462.787 (T cannot be internalized)**.** *T cannot enter the BEDC object layer as an internal object.*

Proof. If T were internal, it would be a state, record, rule, axiom, or licensed object. Its role is exactly to name the position of supply that cannot be generated from those internal resources. Internalizing it would turn boundary supply into substrate content. □

Corollary 9462.788 (T is not a hidden axiom)**.** *T is not a hidden BEDC axiom.*

Proof. An axiom is a contentful internal rule available to proof chains. T is not consumed as a theorem or rule; it is the far-end position of an exposed socket. □

Corollary 9462.789 (T is not object-theology)**.** *Naming T does not introduce a theological object into the BEDC object layer.*

Proof. The object layer admits names through certificates, witnesses, classifiers, stability, and ledgers. T is outside those surfaces. Its name therefore marks a position rather than a positive object with theological attributes. □

Concretized in §1355: Closed-observation supply boundaries realize the T supply position as finite closed-record, GAP-socket, noninternalization, transport, route, provenance, and NameCert rows.

9462.26.7 Apophatic naming and inscription

Definition 9462.790 (Apophatic naming)**.** *Apophatic naming names a structural position without assigning positive content predicates to that position. In the BEDC reading, naming T as God means only source-position of forward-binding supply outside closed observational systems. It does not assert personhood, will, intervention, revelation, mythic agency, or internal theoremhood.*

Theorem 9462.791 (T is named only by position)**.** *The legitimate BEDC name for T is positional rather than contentful.*

Proof. Any content predicate would need object-layer certificate fields. Since T is not an object-layer carrier, only its boundary role can be named. □

Corollary 9462.792 (God is an apophatic label)**.** *The label God, when used for T, is apophatic.*

Proof. It names the far end of forward-binding supply. It does not add positive attributes or an internal object to the substrate. □

Corollary 9462.793 (Structural monotheism)**.** *If closed observational systems cannot distinguish different ultimate far ends of forward-binding supply, the supply position receives a single structural name.*

Proof. The distinction between multiple ultimate sources would need a system-side witness. If every relevant system-side role is the same, the taxonomy can distinguish socket shapes without multiplying the ultimate supply position. □

Definition 9462.794 (Inscription point)**.** *An inscription point is the local site at which forward-binding supply is actualized in a closed observational system.*

Definition 9462.795 (Individual as closed observational system)**.** *A conscious individual may be read as a closed observational system whose universe-for-that-individual is the accumulated observation history of that system.*

Theorem 9462.796 (Individuals are inscription points)**.** *Each conscious individual, under this reading, is an inscription point.*

Proof. The individual is not first a separate receiver of an external signal. It is a localized closed observational history. The supply required for its forward-binding commitments appears at the local site where records enter that history. □

Corollary 9462.797 (Contribution as inscription event)**.** *Writing an inductive declaration, mechanizing a lemma, identifying a gap socket, or confirming an existing record can be read as an inscription event.*

Proof. In each case, a local history receives a durable record that becomes available to the ledger. The event is not an external signal inserted into a passive receiver; it is the local actualization of recordable supply. □

9462.26.8 Gaps and audit gates

Definition 9462.798 (Gap socket)**.** *A gap socket is a reasoning or naming site at which a requested discharge cannot be supplied by substrate-internal witnesses. It records the consumption site, the missing shape, the reason it cannot be generated internally, and the gate that prevents internalization.*

Theorem 9462.799 (Gap is a honesty mechanism)**.** *BEDC uses gaps to expose external commitments rather than hide them as internal theorems.*

Proof. A closed observational system must mark the difference between an available record and a needed but unavailable discharge. The gap row makes that difference visible in the ledger. □

Corollary 9462.800 (Gaps trade self-sufficiency for transparency)**.** *BEDC is less self-sufficient and more transparent because it exposes forward-binding commitments as gaps.*

Proof. A system that internalizes such commitments appears complete by hiding their source. BEDC keeps the source outside the substrate and records where it would be consumed. □

Definition 9462.801 (Audit gate)**.** *An audit gate is a computable refusal rule that checks whether a proposed record remains within substrate-internal boundaries or tries to internalize supply that should remain socketed.*

Definition 9462.802 (Gate surface and boundary content)**.** *The gate surface is the finite syntactic or dependency condition checked by a script. The boundary content is the transcendental discipline enforced by that finite condition: the substrate may use only what it has generated, defined, certified, or explicitly socketed.*

Theorem 9462.803 (Audit gates enforce transcendental boundaries)**.** *BEDC audit gates are transcendental boundary enforcement, not merely housekeeping.*

Proof. Without gates, external commitments can enter as axioms, forbidden dependencies, unledgered claims, or name drift. The gate refuses the finite surface by which such internalization would occur. □

Corollary 9462.804 (A gate has finite scope)**.** *Passing one audit gate shows only that the boundary checked by that gate has not been crossed.*

Proof. Each gate has a surface: axiom scanning, dependency purity, name drift, or another finite condition. No single gate proves every boundary at once, so the system relies on a family of gates. □

9462.26.9 T-supply sockets

Definition 9462.805 (T-supply socket)**.** *A T-supply socket is a gap tag whose requested discharge cannot be generated from displayed records, closed inductive generators, naming certificate fields, or certified continuation laws. It is well-formed only when the missing shape, consumption site, and preventing audit gate are stated.*

Definition 9462.806 (Supply kind)**.** *A supply kind is an equivalence class of T-supply sockets. Two sockets have the same kind when accepting either one would authorize the same substrate-internal shortcut.*

Theorem 9462.807 (Gap sockets must be classified)**.** *Not all gap sockets have the same shape; each must be classified by the kind of T-supply it requests.*

Proof. Unrestricted induction, missing witnesses, extensional collapse, future-law projection, cross-history recognition, inscription actuality, and self-truth closure consume different shortcuts at different sites. Treating them as one gap kind hides the requested supply. □

Corollary 9462.808 (Many sockets, one far end)**.** *The taxonomy has many socket shapes but does not multiply the ultimate transcendental supply position.*

Proof. The distinction lies in how the closed substrate experiences pressure at its boundary. The far end remains the source-position of forward-binding supply. □

9462.26.10 Seven socket kinds

Definition 9462.809 (Type I socket)**.** *A Type I socket requests unrestricted induction or universal closure beyond the displayed authorized generator. It turns generator closure for a shown carrier into a claim over an unrestricted intended range.*

Theorem 9462.810 (Type I gate)**.** *Type I sockets are governed by the generator-closure ledger.*

Proof. An induction claim must cite the exact carrier, constructor list, recursor, and closure certificate. If the claim ranges beyond that displayed generator, it requests supply not present in the ledger. □

Definition 9462.811 (Type II socket)**.** *A Type II socket requests a positive existential witness without displaying the constructor-level witness. It converts inhabitedness pressure into a usable element.*

Theorem 9462.812 (Type II gate)**.** *Type II sockets are governed by witness visibility.*

Proof. If a later construction consumes an element, the element or the function selecting it must be displayed. Otherwise the construction uses an unwitnessed selector. □

Definition 9462.813 (Type III socket)**.** *A Type III socket requests the conversion of a relation into identity: bidirectional implication into proposition equality, quotient equivalence into equality, classifier sameness into rewrite equality, or observational indistinguishability into identity.*

Theorem 9462.814 (Type III gate)**.** *Type III sockets are governed by refusal of extensional collapse.*

Proof. A relation may support transport only when the transport is displayed. Treating the relation as equality hides the transport witness and therefore crosses the boundary. □

Definition 9462.815 (Type IV socket)**.** *A Type IV socket requests causal continuity: projection of observed regularity into not-yet-observed history.*

Theorem 9462.816 (Type IV gate)**.** *Type IV sockets are governed by separation between records and prediction.*

Proof. Observed records and regularity summaries may be stored. The claim that the same regularity persists into future unobserved cases is a forward-binding commitment, not a record. □

Definition 9462.817 (Type V socket)**.** *A Type V socket requests cross-history coordination: treating a behavior stream recorded by one history as another inscription-bearing closed history rather than merely as an external object.*

Theorem 9462.818 (Type V gate)**.** *Type V sockets are governed by locality discipline.*

Proof. Communication records and observable behavior may be ledgered. The claim that the behavior is another closed observational history is an additional locality commitment and must be exposed as such. □

Definition 9462.819 (Type VI socket)**.** *A Type VI socket requests the actuality of an inscription event inside a history: the arrival of O_{t+1} from O_t as more than a replay of already recorded derivation.*

Theorem 9462.820 (Type VI gate)**.** *Type VI sockets are governed by aspect separation between proof replay and inscription novelty.*

Proof. The record-side derivation can be checked. The event by which a record enters a local history has a different aspect. BEDC may name this aspect, but it must not turn it into an extra proof rule. □

Definition 9462.821 (Type VII socket)**.** *A Type VII socket requests self-reference closure: a total truth predicate, runtime validator, or self-certifying checker for the system's own structural description.*

Theorem 9462.822 (Type VII gate)**.** *Type VII sockets are governed by reflection stratification.*

Proof. Structural self-description, runtime validation, truth classification, and external checking must remain distinct. Collapsing them would close the meta loop. □

9462.26.11 Non-collapse of socket kinds

Definition 9462.823 (Socket collapse)**.** *A socket kind A collapses into a socket kind B when every instance of A can be reported as B without losing audit information. Mutual collapse makes the kinds indistinguishable.*

Theorem 9462.824 (The seven socket kinds do not collapse)**.** *The seven T-supply socket kinds are not mutually reducible.*

Proof. Their consumption sites and audit gates differ. Type I asks for unrestricted universal closure; Type II asks for a missing witness; Type III asks for relation-to-identity collapse; Type IV asks for future persistence; Type V asks for cross-history locality; Type VI asks for inscription actuality; Type VII asks for self-truth or runtime totalization. □

Corollary 9462.825 (Induction is not choice)**.** *Type I is not Type II.*

Proof. Universal closure over a range does not provide a particular missing witness, and a particular witness does not provide total generator closure over an unrestricted range. □

Concretized in §1243: Typed supply sockets realize the seven socket kinds as finite kind, request, gate, non-internalization, transport, provenance, and NameCert rows.

Corollary 9462.826 (Choice is not extensional identity)**.** *Type II is not Type III.*

Proof. A missing witness produces term-level content. Extensional collapse produces an equality or rewrite token. These are different shortcuts. □

Corollary 9462.827 (Identity collapse is not causal continuity)**.** *Type III is not Type IV.*

Proof. An equality token does not supply a future law, and a persistent regularity does not supply proposition or quotient equality. □

Corollary 9462.828 (Causality is not other-history recognition)**.** *Type IV is not Type V.*

Proof. A behavior stream may be regular while still being treated as an external object. Recognizing it as another closed history is a different commitment. □

Corollary 9462.829 (Other-history recognition is not inscription novelty)**.** *Type V is not Type VI.*

Proof. Cross-history locality relates histories. Inscription novelty concerns the actuality of a transition within a history. Neither subsumes the other. □

Corollary 9462.830 (Inscription novelty is not self-truth closure)**.** *Type VI is not Type VII.*

Proof. The actuality of a local record event is not a total truth predicate or runtime validator for the whole system. □

Corollary 9462.831 (Self-truth closure is not induction)**.** *Type VII is not Type I.*

Proof. Even when induction over a displayed generator is authorized, truth-totalization for the system's own syntax and runtime remains a separate boundary. □

Concretized in §767: The seven T-supply socket kinds are realized as a finite NameCert ledger over kind, consumption-site, audit-gate, refusal, and non-collapse rows.

9462.26.12 Socket reports

Definition 9462.832 (Socket report)**.** *A socket report for a BEDC claim is a four-field record* $(\mathsf{Site}, \mathsf{RequestedSupply}, \mathsf{Type}, \mathsf{Gate})$*. It states where the missing supply would be consumed, the precise shape of the missing supply, the socket kind, and the audit discipline that prevents internalization.*

Definition 9462.833 (Narrowest classification)**.** *A socket report uses the narrowest classification when it names the smallest socket kind explaining the blocked move, rather than a broad label that hides the exact requested supply.*

Theorem 9462.834 (Socket reports must be minimal)**.** *BEDC gap reports must use the narrowest socket type available.*

Proof. If a proof attempt lacks a witness, the socket is Type II even if the witness would later be used in an induction. If a proof attempt rewrites along mere equivalence, the socket is Type III even if the equivalence arose from a quotient-like construction. Narrow reporting preserves the shape of the requested supply. □

Definition 9462.835 (Stacked sockets)**.** *A site has stacked sockets when the same blocked move contains several different supply requests. The report then lists each socket rather than choosing a single total label.*

Theorem 9462.836 (Complex proofs may carry socket stacks)**.** *A proof gap may contain several socket kinds at once, and the report must expose the stack.*

Proof. A construction may simultaneously rely on empirical persistence, representative selection, and equality collapse. These requests have different gates, so a single dominant label would lose audit information. □

Example 9462.837 (Analysis socket stack)**.** *A statement such as convergence of every bounded monotone real sequence can carry multiple socket pressures in a BEDC translation: Type I when the sequence range is read as an unrestricted intended class, Type II when a limit point is selected without an explicit Cauchy witness, and Type III when extensionally equal Cauchy names are identified without real-history classifier transport.*

9462.26.13 Unity of transcendental supply

Definition 9462.838 (Single T principle)**.** *The far end of each T-supply socket is the same transcendental supply position T. The seven kinds describe boundary shapes, not seven ultimate sources.*

Theorem 9462.839 (Seven sockets, one supply position)**.** *The seven supply kinds are seven aspect-positions at which a closed observational substrate reaches its boundary, not seven distinct transcendental sources.*

Proof. Each kind is a gap tag whose requested discharge cannot be generated from displayed records or closed generators. By definition, the structural position from which forward-binding supply enters is T. The kinds differ by missing shape: unrestricted induction, witness, identity, causal persistence, cross-history recognition, inscription actuality, or self-reference closure. They do not provide system-side witnesses for multiple ultimate far ends. □

Corollary 9462.840 (Records-side management does not replace T)**.** *Psychology, probability, social trust, and runtime engineering may manage socket records, but they do not replace the far end T.*

Proof. Such devices describe how a system records, estimates, coordinates, or checks a boundary pressure. When the requested discharge exceeds records-side data, the far-end position remains T. □

Corollary 9462.841 (Taxonomy does not discharge)**.** *Classifying a socket does not close it.*

Proof. The taxonomy names the missing shape and the gate. It does not supply the witness, universal closure, identity token, future law, locality commitment, inscription actuality, or truth-totalizing object that the socket requests. □

9462.26.14 Synthesis

Theorem 9462.842 (Gap–T boundary synthesis)**.** *In BEDC, every commitment exceeding closed observation and closed-generation rules must be exposed as a gap socket. Its far end is the transcendental supply position T, T is named only apophatically, and audit gates prevent the requested supply from being hidden as a substrate-internal rule.*

Proof. BEDC is a closed observational system. Finite records do not generate unrestricted universal closure. Mathematical reasoning therefore needs forward-binding commitments at some sites. Such commitments are not substrate axioms; they are exposed as gaps. The structural far end of these gaps is T, which cannot be internalized as an object and can only be named positionally. Audit gates enforce the boundary. Socket taxonomy then records the shape of each requested supply without closing it. □

Corollary 9462.843 (Gaps are not weakness)**.** *Gaps are not defects in BEDC; they are the mechanism by which hidden forward-binding commitments become visible.*

Proof. A system that hides such commitments as axioms, choice principles, quotient collapses, truth predicates, or empirical laws may appear complete, but it has lost boundary transparency. BEDC keeps the commitment explicit. □

Corollary 9462.844 (Transcendental boundaries are not closed by naming)**.** *Classifying or naming a socket does not machine-close the requested content when that content exceeds records-side data.*

Proof. Classification reports the socket. Naming gives a boundary label. Audit gates refuse internalization. None of these supplies the missing records-side witness. □

Corollary 9462.845 (Passage to phenomenology)**.** *With gaps, T, and socket kinds in place, consciousness, universe, space, causality, freedom, other minds, and self-reference can be read as focused histories, observation-history slices, inter-history coordination, Type IV persistence, Type VI inscription novelty, Type V locality recognition, and Type VII self-reference boundary.*

Concretized in §1279: Socket report packets realize the site, requested-supply, narrow socket-kind, and audit-gate record as a finite NameCert carrier.

Concretized in §1283: Socket stack certificates realize stacked socket reports as finite BHist NameCert packets with component socket rows, narrowest-kind classifiers, audit gates, and non-discharge ledger routes.

Concretized in §1240: Typed gap-socket taxonomy is realized as a finite NameCert packet for seven boundary socket kinds, their gates, non-collapse matrix, and local naming rows.

Concretized in §1343: Gap-socket boundaries are realized as finite typed socket, externality gate, apophatic far-end, refusal ledger, transport, route, provenance, and local NameCert rows.

9462.27 Consciousness, Universe, and Phenomenological Frame

The gap and T-supply layer shows how a closed observational system exposes commitments that exceed its finite records. The phenomenological layer applies this discipline to consciousness, universe, time, space, identity, causality, freedom, other minds, mind–matter relation, and self-reference. The result is not a list of new entities, but a records-side translation of traditional

questions into focused histories, local continuations, inter-history relation rows, socketed commitments, and inscription events.

9462.27.1 Finite focused multi-Hist ledgers

Definition 9462.846 (Finite focused multi-Hist ledger)**.** *For a finite horizon N, a finite focused multi-Hist ledger is a records-side packet*

$$L_N = (I, H, T, F, S, D, G, R, J, Q, \rho, A).$$

Here I is a finite index ledger; $H : I \to \mathsf{Hist}$ assigns histories; T gives local continuation chains; F is the focus index; S is the selector ledger; D is a digest ledger; G is the gap and provenance row; R contains inter-history relation rows; J contains inter-history invariant rows; Q contains dependence rows or optional maximum-rate readings; ρ is a focused self-proxy; and A is the audit row.

Definition 9462.847 (Audit row)**.** *The audit row A records the refusals that keep the packet closed: no subject parameter, no global clock, no hidden chooser, no unledgered compression, no object-level T field, and no hidden dependence on the three meta-closure axioms.*

Theorem 9462.848 (Closed records-side carrier)**.** *L_N is a closed records-side carrier when every object has a generator, every branch has selector rows, every compression has provenance, every inter-history relation has a finite witness, every invariant is classifier-stable, and every boundary pressure remains outside the object layer.*

Proof. Each component of L_N is a finite row or finite family of rows. The packet closes only when its histories are generated, its branch choices are ledgered, its compressions remain traceable, its relations are witnessed, and its invariants respect the relevant classifiers. The audit row blocks the extra structures that would turn the packet into a subject substance, global universe object, synchronized clock, hidden choice, or internal T-object. □

Corollary 9462.849 (Phenomenological objects require records-side form)**.** *Consciousness, universe, space, time, identity, and related phenomenological objects can enter the BEDC object layer only as rows, relations, invariants, self-proxies, or gap-tagged boundary readings of a packet such as L_N.*

Proof. The object layer accepts generated records, witnesses, certificates, and ledgers. A phenomenological term that cannot be written as such a finite row or as an exposed boundary reading has no object-layer standing. □

9462.27.2 Records-side consciousness

Definition 9462.850 (Conscious record)**.** *For a focused ledger L_N, the records-side carrier of a consciousness reading is*

$$\mathsf{ConsciousRecord}(L_N, F) = (H(F), T(F), S(F), \rho).$$

It consists of the focused generated history, its local continuation trace, its selector witnesses, and its endpoint or trace self-proxy.

Definition 9462.851 (Consciousness reading)**.** $\mathsf{ConsciousRecord}(L_N, F)$ *is a carrier for consciousness readings. It is not an object-level definition of phenomenal essence.*

Theorem 9462.852 (Consciousness carrier adds no subject)**.** $\mathsf{ConsciousRecord}(L_N, F)$ *introduces no new subject-substance.*

Proof. The four components are already present in L_N: focused history, local continuation trace, selector ledger, and self-proxy. The focus index selects a reading surface but does not create a hidden first-person carrier or an identity principle beyond hsame and the trace ledger. □

Corollary 9462.853 (Consciousness is not reified)**.** *BEDC does not add consciousness as a new ontological substance.*

Proof. A substance reading would require a new carrier and transport laws relating it to histories and continuations. The records-side carrier uses only focused history data already licensed by the finite ledger. □

Corollary 9462.854 (Consciousness becomes a closure question)**.** *The BEDC form of the consciousness question asks which focused history, local continuation trace, selector ledger, self-proxy, and gap rows constitute the records-side carrier of a consciousness reading.*

Proof. The object layer can close the carrier and its audit rows. It does not claim to capture phenomenal essence as an additional object. □

Concretized in §1247: FocusedLedgerUp realizes the finite focused multi-Hist ledger as a BHist, hsame, Cont, Pkg, audit-row, and NameCert packet.

9462.27.3 Universe as observation-history slice

Definition 9462.855 (Finite universe for the focus)**.** *For a finite focused ledger L_N, the universe-for-the-focus is the finite family of histories admitted by the packet within the horizon, together with their selector, digest, gap, provenance, relation, invariant, and dependence rows.*

Definition 9462.856 (Universe slice)**.** *The finite universe-for-the-focus is a universe slice, not the universe itself, not a global universe object, and not a God's-eye world.*

Theorem 9462.857 (Universe is not a global object)**.** *In the BEDC object layer, a universe slice is the records-side family licensed by a finite focused ledger, not the universe as such.*

Proof. The packet admits only finitely displayed histories and rows. Alignment with another perspective is a further inter-history relation problem. No global comparison carrier or synchronized world object is supplied by the kernel. □

Corollary 9462.858 (Focused ledgers need not share one world object)**.** *Distinct focused ledgers do not automatically share a single object-level world.*

Proof. Automatic sharing would require a global synchronization or comparison carrier. Cross-ledger coherence must instead be constructed by witnessed relations, invariants, and provenance rows. □

Corollary 9462.859 (World coordination is relation, not container)**.** *World coordination is an auditable structure of relations and invariants between histories, not a pre-given container holding all observers.*

Proof. The records-side content consists of histories and rows. Cross-history relations are licensed by finite witnesses rather than by an external equality oracle. □

9462.27.4 Time as monotone accumulation

Definition 9462.860 (BEDC-internal time)**.** *In a focused ledger, the internal time of $H(i)$ is its local continuation chain from* `e` *to $H(i)$, equivalently the finite trace order induced by displayed selector rows.*

Definition 9462.861 (Local time)**.** *Time in L_N is local to a history. It is not a shared scalar assigning a single global time coordinate to all indices.*

Theorem 9462.862 (Time is monotone record accumulation)**.** *The object-level meaning of later in BEDC is trace extension inside a displayed local ledger.*

Proof. The local continuation chain produces a history from the empty history by finite extensions. The later state is the state with the larger displayed trace, preserving earlier records and adding further rows. □

Corollary 9462.863 (Global simultaneity is not a carrier field)**.** *Global simultaneity, time reversal, and retrocausal phrasing are not fields of L_N unless supplied as witnessed extension carriers.*

Proof. The packet supplies local continuation chains. Any stronger temporal geometry requires additional rows, witnesses, and certificates. □

9462.27.5 Space as inter-observer coordination

Definition 9462.864 (Inter-system locality cell)**.** *For indices i, j and an event row e, a locality cell records the finite relation data pairing what is read from $H(i)$ and $H(j)$, together with provenance acknowledgement and history-sameness stability witnesses.*

Definition 9462.865 (Records-side space graph)**.** *The records-side space graph of L_N is the finite graph generated by locality-cell rows and inter-history invariant rows. It is not a spacetime manifold unless a further certificate supplies that structure.*

Theorem 9462.866 (Space is locality-cell geometry)**.** *In the BEDC records-side frame, space is the finite relation geometry carried by locality cells and inter-history invariant rows.*

Proof. Without a global frame, a single history does not carry frame-independent spatial content. Relational content is displayed by witnessed pairs, stable invariant rows, and classifier-respecting transport between histories. □

Corollary 9462.867 (Space is not an event substrate)**.** *BEDC does not treat space as an independent substrate in which events occur.*

Proof. The closed records-side packet supplies generated histories, local continuations, relations, invariants, and provenance. A stronger geometry must be built as a named interface above those rows. □

Corollary 9462.868 (Maximum-rate constants are schema surfaces)**.** *A maximum-rate reading, when present, is a packet invariant rather than an empirical light-speed value itself.*

Proof. The invariant can express a structural upper-bound surface over inter-history dependence rows. The empirical value and its physical bridge require additional records and certificates. □

9462.27.6 Identity as history trace

Definition 9462.869 (Focused self-proxy)**.** *The self-proxy ρ records the endpoint and trace surface of the focused history.*

Definition 9462.870 (History-continuous identity)**.** *Focused identity is the* hsame*-stable continuity of the displayed trace of $H(F)$.*

Theorem 9462.871 (Identity is trace continuity)**.** *Focused identity in BEDC is generated history with* hsame*-stable trace continuity, not a self-substance.*

Proof. The focus supplies a generated endpoint and trace. The identity criterion available at the kernel-facing layer is history-sameness and the ledgers that preserve it. No owner or subject carrier is needed. □

Corollary 9462.872 (Self is not owner of history)**.** *The self is not the owner of a history; it is the records-side reading of history through self-proxy and* hsame*-stable continuity.*

Proof. An owner relation would require an additional subject carrier. The focused ledger provides only generated history, continuation trace, self-proxy, and comparison rows. □

Concretized in §1206: ConsciousUniverseSpaceUp realizes finite universe slices, locality-cell space, local time, and trace identity as one BHist-rowed NameCert packet.

9462.27.7 Vision: Materiality as Orbit-Closure and Freedom-like Appearance as Orbit-Escape

Remark 9462.873 (VisionSeed status)**.** *This interface has status VisionSeed, schema-only horizon, and no Lean target. It is not a finite-kernel theorem. It records the certificate shape a later development would have to close before materiality, agency-like appearance, or observer-relative feedback could be reported as a BEDC theorem.*

The schema uses only the current BEDC reading that observer identity is internal to Hist, that Cont has only history-valued arguments, and that no observer-substance stands behind the generated trace. The observer is the history value read modulo hsame, while observation, distinction, and local time-step share the continuation form. A derived interface entering this vocabulary must therefore be licensed through the ordinary naming-certificate discipline:

$$\mathsf{NameCert}(N) = (\mathsf{SourceSpec}_N, \mathsf{PatternSpec}_N, \mathsf{ClassifierSpec}_N, \mathsf{StabilityCert}_N, \mathsf{LedgerPolicy}_N).$$

The interface below is not a primitive object and does not add a subject parameter to the kernel.

Definition 9462.874 (Observational context)**.** *An observational context is a ledger-readable package*

$$\mathcal{O} = (h, \Pi, X, I_X, S_X, \mathcal{R}, L),$$

where $h : \mathsf{Hist}$ is the observer-history, Π is a repeated probe pattern or probe bundle, X is a candidate observed interface, I_X is an identity classifier for feedback records of X, S_X is a state classifier, $\mathcal{R}$ is a finite family of currently available ledger-certified orbit rules, and L records the source, pattern, classifier, stability, and hidden-provenance data required by the relevant naming certificates.

Definition 9462.875 (Feedback prefix)**.** *For an observational context $\mathcal{O}$, a feedback prefix of length N is a finite sequence*

$$F_{\mathcal{O}}^{N}(X) = (r_0, r_1, \ldots, r_N)$$

whose entries are BEDC-visible response histories generated by repeatedly applying Π to X as recorded in h. An infinite feedback stream is admissible here only as a schema whose every finite prefix is ledger-visible; no completed external stream is added to the kernel.

Definition 9462.876 (Identity closure)**.** *A feedback prefix $F_{\mathcal{O}}^{N}(X) = (r_0, \ldots, r_N)$ is identity-closed in $\mathcal{O}$, written $\mathsf{IdCl}_{\mathcal{O}}^{N}(F)$, when the ledger supplies positive classifier witnesses $I_X(r_i, r_j)$ for all $0 \leq i, j \leq N$. Identity closure says that the responses may differ while remaining traceable as responses of the same observed datum.*

Definition 9462.877 (Ledger-certified orbit rule)**.** *A ledger-certified orbit rule in $\mathcal{O}$ is a BEDC-visible continuation and classifier pattern*

$$T : r_i \mapsto r_{i+1}^{\mathsf{pred}}$$

licensed by a naming certificate, reuse certificate, or equivalent certificate, preserving the relevant feedback carrier, respecting S_X, and carrying ledger witnesses for the hidden source and classifier data used by the rule.

Definition 9462.878 (Orbit closure and certified escape)**.** *The prefix $F_{\mathcal{O}}^{N}(X) = (r_0, \ldots, r_N)$ is orbit-closed under T, written $\mathsf{OrbitCl}_{\mathcal{O}}^{N}(F, T)$, when*

$$\forall i < N, \quad S_X(r_{i+1}, T(r_i))$$

is witnessed in the ledger. It escapes the current finite rule family $\mathcal{R}$, written $\mathsf{Escape}_{\mathcal{O}}^{N}(F, \mathcal{R})$, when for every $T \in \mathcal{R}$ there is some $i < N$ with a positive separation witness

$$\mathsf{Sep}_{S_X}(r_{i+1}, T(r_i)).$$

Escape is therefore not absence of prediction. It is certified separation from each currently available orbit rule.

Definition 9462.879 (Material and freedom-like appearance)**.** *The prefix $F_{\mathcal{O}}^{N}(X)$ has material appearance relative to $\mathcal{O}$ when*

$$\mathsf{IdCl}_{\mathcal{O}}^{N}(F) \quad \wedge \quad \exists T \in \mathcal{R},\ \mathsf{OrbitCl}_{\mathcal{O}}^{N}(F, T).$$

It has freedom-like appearance relative to $\mathcal{O}$ when

$$\mathsf{IdCl}_{\mathcal{O}}^{N}(F) \quad \wedge \quad \mathsf{Escape}_{\mathcal{O}}^{N}(F, \mathcal{R}).$$

The phrase freedom-like is part of the schema. It does not assert absolute metaphysical free will; it classifies observer-relative feedback inside a finite ledger.

Definition 9462.880 (Noise-like feedback)**.** *A prefix is noise-like or unformed, for this schema, when the observer lacks identity closure or when the ledger supplies a positive identity-separation witness*

$$\exists i, j \leq N, \quad \mathsf{Sep}_{I_X}(r_i, r_j).$$

Without traceable sameness, non-orbit-closure is not agency-like appearance.

Proposition 9462.881 (Schema consequences)**.** *Within a fixed observational context and finite rule family, material appearance is identity-preserving orbit closure, freedom-like appearance is identity-preserving certified orbit escape, and noise-like feedback is excluded from freedom-like appearance whenever identity classifier separation is sound. If $S_X(a, b)$ implies $\neg\mathsf{Sep}_{S_X}(a, b)$, then the same feedback prefix cannot be both material and freedom-like in that fixed context.*

Proof. Each assertion unfolds the preceding definitions. Material appearance contains identity closure together with an orbit-closing rule. Freedom-like appearance contains identity closure together with certified separation from every rule in the current finite family. Positive identity separation contradicts identity closure when the identity classifier is sound. If material appearance supplies $T_0 \in \mathcal{R}$ with $S_X(r_{i+1}, T_0(r_i))$ for every $i < N$, then freedom-like appearance would require some $i < N$ with $\mathsf{Sep}_{S_X}(r_{i+1}, T_0(r_i))$, contradicting state-classifier separation soundness. □

Proposition 9462.882 (Rule extension changes appearance)**.** *If $\mathcal{R} \subseteq \mathcal{R}'$ in the same observational context, material appearance relative to $\mathcal{R}$ persists relative to $\mathcal{R}'$. Freedom-like appearance need not persist.*

Proof. An orbit-closing rule $T \in \mathcal{R}$ remains available in $\mathcal{R}'$, so the same witness proves material appearance. By contrast, $\mathcal{R}'$ may contain a rule T^* absent from $\mathcal{R}$ that closes the feedback orbit. The prefix then no longer escapes every currently available rule in the enlarged context. □

Corollary 9462.883 (No context-free materiality or free-will predicate)**.** *The schema licenses only context-indexed judgments such as $\mathsf{Material}^N_{\mathcal{O}}(F)$ and $\mathsf{FreedomLike}^N_{\mathcal{O}}(F)$. It does not license unindexed kernel predicates $\mathsf{Material}(X)$ or $\mathsf{FreeWill}(X)$.*

Proof. The definitions require an observer-history, probe pattern, candidate interface, identity classifier, state classifier, finite rule family, ledger, and finite feedback prefix. Removing these parameters removes the judgment. BEDC supplies no global observer, no context-free classifier, and no external equality oracle. □

Remark 9462.884 (Roadmap obligations)**.** *Closing this horizon would require certificate fields for the feedback carrier, the identity classifier, the state classifier, positive separation predicates, orbit-rule stability, prefix-extension ledger stability, and provenance of any packaging that exposes X as a public interface. Standard bridges to dynamical systems, stochastic processes, learning theory, decision theory, or philosophy of agency would remain interpretive until they preserve these certificate obligations without replacing them.*

Materiality and freedom-like appearance are therefore not primitive properties of an object-substance. They are observer-relative classifications of feedback prefixes. A datum appears material when the observer-history can track it as the same datum and close its responses under a finite ledger-certified orbit rule. A datum appears freedom-like when it remains identity-traceable while escaping every currently available orbit rule. Pure irregularity is insufficient: without identity closure, non-orbit-closure is noise or unformed data rather than agency. The contrast is not between law and lawlessness, but between two ledger-visible structures: orbit closure and identity-preserving orbit escape.

Concretized in §2339: Materiality and freedom-like appearance are realized as finite orbit-closure and certified-escape NameCert rows.

Relative Non-Domination and the Refusal of Absolute Acausality

The preceding schema also fixes the admissible reading of free-will language. It does not introduce free will as a primitive metaphysical substance, nor does it identify freedom with absolute acausality. The only BEDC-legible form is indexed by an observer-history, a finite ledger, a classifier package, a rule family, and a feedback prefix:

$$\text{freedom-like appearance} \quad \rightsquigarrow \quad \text{relative non-domination by a finite observer ledger.}$$

The index is load-bearing. A prefix may be freedom-like relative to one observer and material relative to another when their ledgers, probes, classifiers, and available orbit rules differ.

Definition 9462.885 (Ledger dominance)**.** *Let $\mathcal{O}_A = (A, \Pi_A, X, I_A, S_A, \mathcal{R}_A, L_A)$ and $\mathcal{O}_B = (B, \Pi_B, X, I_B, S_B, \mathcal{R}_B, L_B)$ be observational contexts for the same candidate interface X. The observer-history B ledger-dominates X over prefix length N, written $B \triangleright_N X$, when the B-context supplies identity closure and an orbit-closing rule:*

$$\mathsf{IdCl}^N_{\mathcal{O}_B}(F_B) \quad \wedge \quad \exists T_B \in \mathcal{R}_B,\ \mathsf{OrbitCl}^N_{\mathcal{O}_B}(F_B, T_B).$$

Equivalently, X has material appearance relative to the B-context over that prefix.

Definition 9462.886 (Relative non-domination)**.** *The interface X is non-dominated relative to $\mathcal{O}_A$ over prefix length N when*

$$\mathsf{NonDom}^N_{\mathcal{O}_A}(X) \quad \Longleftrightarrow \quad \mathsf{IdCl}^N_{\mathcal{O}_A}(F_A) \wedge \mathsf{Escape}^N_{\mathcal{O}_A}(F_A, \mathcal{R}_A).$$

Thus relative non-domination is not the absence of cause. It is the presence of traceable sameness together with certified escape from the finite orbit rules available to the observer ledger.

Definition 9462.887 (Forbidden absolute predicate)**.** *A context-free predicate $\mathsf{FreeWill}(X)$ would assert a property of X independently of observer-history, probe pattern, identity classifier, state classifier, rule family, ledger, and prefix length. This section does not introduce such a predicate. The admissible judgments are indexed forms such as*

$$\mathsf{FreedomLike}^N_{\mathcal{O}_A}(F_A), \quad \mathsf{NonDom}^N_{\mathcal{O}_A}(X), \quad \mathsf{Material}^N_{\mathcal{O}_A}(F_A), \quad B \triangleright_N X.$$

Proposition 9462.888 (Dominance collapses freedom-like appearance in the same context)**.** *Assume state-separation soundness in the B-context:*

$$S_B(a, b) \Rightarrow \neg \mathsf{Sep}_{S_B}(a, b).$$

If $B \triangleright_N X$, then X does not have freedom-like appearance relative to the same B-context over that prefix.

Proof. By Definition 9462.885, there is some $T_B \in \mathcal{R}_B$ such that

$$\forall i < N, \quad S_B(r_{i+1}, T_B(r_i)).$$

If the same prefix were freedom-like relative to $\mathcal{O}_B$, then escape from $\mathcal{R}_B$ would give an index $i < N$ with

$$\mathsf{Sep}_{S_B}(r_{i+1}, T_B(r_i)).$$

This contradicts state-separation soundness for the orbit-closure witness supplied by T_B. □

Corollary 9462.889 (Layer-indexed materialization)**.** *If $B \triangleright_N A$, then A has material appearance relative to B and lacks freedom-like appearance relative to B over that prefix. This does not imply $\neg\mathsf{FreeWill}(A)$, since Definition 9462.887 supplies no such context-free predicate.*

Proof. The first assertion is the defining equivalence in Definition 9462.885. The second follows from Definition 9462.888. The final sentence records that only indexed judgments are available in this schema. □

Proposition 9462.890 (Complexity is not dominance)**.** *Greater ledger complexity for B alone does not imply $B \triangleright_N A$.*

Proof. Ledger dominance requires the correct probe pattern, an identity classifier adequate for A, a state classifier adequate for A's feedback, a rule $T_B \in \mathcal{R}_B$, and ledger witnesses for the rule's success. A complexity comparison supplies none of these certificate fields by itself. □

Proposition 9462.891 (Freedom-like appearance is stronger than randomness)**.** *Freedom-like appearance implies identity closure. Hence randomness or unpredictability alone is insufficient for freedom-like appearance.*

Proof. By definition,

$$\mathsf{FreedomLike}^N_{\mathcal{O}_A}(F_A) \Longrightarrow \mathsf{IdCl}^N_{\mathcal{O}_A}(F_A).$$

Randomness may obstruct an orbit-closing rule, but without identity closure the prefix is noise-like or unformed rather than freedom-like. □

Definition 9462.892 (Exposed prediction and reflexive escape)**.** *Let $T_A \in \mathcal{R}_A$ be a rule by which A attempts to predict the next response of X, and write $p = T_A(r_i)$. The prediction is exposed to X when p becomes part of the feedback information available to X before the next response. The interface has reflexive escape capacity at that stage when there is a response operation D_X with*

$$r_{i+1} = D_X(p) \quad \textit{and} \quad \mathsf{Sep}_{S_A}(D_X(p), p).$$

Proposition 9462.893 (Exposed prediction obstructs complete orbit closure)**.** *Assume state-separation soundness for S_A. If $p = T_A(r_i)$ is exposed to X and X has reflexive escape capacity at stage i, then T_A does not orbit-close the prefix at that stage.*

Proof. If T_A orbit-closed the prefix, then

$$S_A(r_{i+1}, T_A(r_i)).$$

Since $p = T_A(r_i)$ and $r_{i+1} = D_X(p)$, this gives $S_A(D_X(p), p)$. Reflexive escape supplies $\mathsf{Sep}_{S_A}(D_X(p), p)$, contradicting state-separation soundness. □

Corollary 9462.894 (Hidden higher-layer prediction)**.** *If a higher-layer prediction by B is not visible to A, then the specific diagonal obstruction in Definition 9462.893 is not available to A. A hidden, ledger-certified, state-sound rule may therefore continue to materialize A relative to B over the given prefix.*

Proof. The diagonal obstruction requires exposure of the prediction to the interface whose next response is being classified. Without that exposure, the response operation using the prediction as input is not part of the displayed feedback context. □

Corollary 9462.895 (De-indexing is the illicit promotion)**.** *The appearance itself is not the illicit step. The illicit step is the promotion*

$$\mathsf{FreedomLike}^{N}_{\mathcal{O}_A}(F_A) \quad \rightsquigarrow \quad \mathsf{FreeWill}(X),$$

which removes the observer, ledger, classifiers, rule family, and prefix length.

Proof. The left-hand side is an admissible indexed judgment. The right-hand side is the forbidden context-free predicate of Definition 9462.887. □

The resulting philosophical reading is neither an assertion that free will absolutely exists nor a denial derived from a final global observer. A stone lacks freedom-like appearance relative to an observer who can identity-track it and close its fall under a ledger-certified rule. Likewise, an observer-history A lacks freedom-like appearance relative to a stronger observer-history B when B can identity-track and orbit-close A's feedback. These are indexed materializations, not absolute eliminations. BEDC records freedom-like appearance as real at the level of the finite ledger that witnesses identity-preserving non-closure, and invalid only when that indexed appearance is promoted into an observer-free substance claim.

Concretized in §2339: Materiality orbit escape is realized as finite observational-context, feedback-prefix, identity-closure, rule-family, separation, transport, and local NameCert rows.

9462.27.8 Hard problems as closure questions

Definition 9462.896 (BEDC hard problem form)**.** *A hard problem in BEDC asks which records are generated, which choices are ledgered, which compressions preserve provenance, which relations have finite witnesses, which invariants are classifier-stable, and which pressures remain exposed as gap or T-boundary readings.*

Concretized in §1236: Hard-problem closure questions are realized as finite records, ledger, witness, invariant, boundary, transport, replay, provenance, and NameCert rows.

Theorem 9462.897 (Hard problems become closure questions)**.** *Within a closed records-side frame, traditional hard problems about consciousness, universe, observer, time, space, and identity become boundary questions about finite carriers.*

Proof. The object layer can inspect records, ledgers, relations, invariants, and gap rows. It cannot close the corresponding traditional essence questions by adding new primitives. The problems are therefore translated into questions of generated records, transport, stability, and exposed boundary pressure. □

Corollary 9462.898 (Traditional questions receive records-side rewrites)**.** *Consciousness becomes focused self-tracking history; universe becomes a finite horizon slice; time becomes local continuation; space becomes locality-cell geometry; identity becomes* hsame*-stable trace; and the God's-eye view becomes a refused global synchronization.*

9462.27.9 Causality as forward binding

Definition 9462.899 (Causal commitment)**.** *A causal commitment of a conscious observational system is a gap tag whose content is that an observed regularity persists into not-yet-observed continuation.*

Theorem 9462.900 (Causality is not primitive law)**.** *In BEDC, causality is not a substrate-internal primitive law; it is a Type IV forward-binding commitment.*

Proof. Finite records can show observed regularity and prediction history. They do not generate universal future persistence. Treating the regularity as future law is therefore a gap-tagged causal commitment. □

Corollary 9462.901 (Scientific theories are records plus gap stack)**.** *A scientific theory, in BEDC terms, consists of empirical records, regularity summaries, gap-tagged future-persistence commitments, and possible refutation rows.*

Proof. The records and summaries are visible in the ledger. The projection to future cases exceeds the current record and is held as a Type IV socket. □

9462.27.10 Free will as inscription event

Definition 9462.902 (Inscription event)**.** *An inscription event is a transition $O_t \trianglerighteq O_{t+1}$ in which new records enter a conscious observational system and the arrival of those records is read as local actualization of T at the inscription point.*

Definition 9462.903 (Free will)**.** *Free will is the inscription-event aspect of conscious accumulation: the aspect under which new records arrive as inscriptions rather than as a separate faculty inhabiting the system.*

Theorem 9462.904 (Free will is not a faculty)**.** *Free will is not an additional power or substance attached to the system; it is an aspect of the accumulation chain.*

Proof. Adding a faculty would introduce a new carrier and transport surface. The BEDC reading instead identifies the event by which records enter a local history as the relevant aspect. □

Corollary 9462.905 (Freedom is compatible with records-side determinism)**.** *Records-side determinism does not eliminate inscription-event novelty.*

Proof. A derivation may be replayed or checked deterministically on the records side. The actuality of that row entering a local history is read at a different aspect-position. □

Example 9462.906 (Mathematical creation)**.** *The arrival of a theorem row after a visible gap and selected route can be read as an inscription event. The proof route may be mechanized; the event of the route becoming public record is the inscription aspect.*

Concretized in §1362: Action commitments realize inscription-event action as finite selected-route, local-actualization, gap, transport, replay, provenance, and NameCert rows.

9462.27.11 Other minds and cross-perspective alignment

Definition 9462.907 (Other-minds commitment)**.** *An other-minds commitment is a gap-tagged locality-cell commitment that treats external records of another system as records of another conscious observational system.*

Theorem 9462.908 (Other minds are locality-cell commitments)**.** *BEDC does not directly observe another self; it records behavior and may issue a gap-tagged locality-cell commitment that the behavior belongs to another closed observational system.*

Proof. The records side can contain communication, behavior, and coordination rows. The recognition of another inscription-bearing history is an additional Type V commitment rather than a direct record of another self. □

Corollary 9462.909 (Solipsism is commitment refusal)**.** *Solipsism is not a BEDC refutation theorem; it is the refusal to issue other-minds locality commitments.*

Proof. The substrate does not force the commitment. Refusing it remains records-side consistent, but impoverishes the locality-cell geometry. □

Corollary 9462.910 (Collaboration uses other-minds commitment)**.** *Accepting another contributor's checked record uses records-side evidence from rechecking, while recognizing the contributor as another inscription point is an other-minds commitment.*

Proof. The checker supplies audit evidence for the row. The recognition of another conscious observational system exceeds that evidence and is held as locality-cell commitment. □

9462.27.12 Mind and matter as double reading

Definition 9462.911 (Records-side)**.** *The records-side reading of an accumulation chain reads it as generated records, physical measurements, observable behavior, and ledgered dependencies.*

Definition 9462.912 (Inscription-side)**.** *The inscription-side reading of the same chain reads it as the arrival of records, local actualization of T, and first-person phenomenological aspect.*

Theorem 9462.913 (Mind–matter is not a two-substance relation)**.** *The mind–matter relation in BEDC is not a relation between two substances, but two readings of one accumulation chain.*

Proof. The records-side account and inscription-side account apply to the same transition. One reads measured dependencies and observable rows; the other reads the actuality of record arrival at an inscription point. No second substance is added. □

Corollary 9462.914 (Neural correlate and thought are double readings)**.** *A measured neural correlate and the corresponding thought are not two objects joined by a hidden relation, but records-side and inscription-side readings of the same accumulation event.*

Proof. The measurement belongs to the records-side ledger. The thought belongs to the inscription-side reading of the same local transition. □

9462.27.13 Self-reference as gap-on-gap

Definition 9462.915 (Self-reference attempt)**.** *A self-reference attempt records a statement about the complete record ledger of the very state in which the statement appears.*

Definition 9462.916 (Gap-on-gap hierarchy)**.** *A gap-on-gap hierarchy arises when a record about a current observation ledger becomes part of the next ledger, requiring a further record about the enlarged ledger, and so on.*

Theorem 9462.917 (Self-reference does not close)**.** *Complete self-reference cannot close as a gap-free record in BEDC; it appears as a hierarchy of gaps about gaps.*

Proof. A statement about the complete current ledger becomes a new record when entered. The new ledger differs from the ledger described. Recording that difference creates another layer, so complete closure is displaced into a hierarchy. □

Corollary 9462.918 (Russell-style closure is refused)**.** *A record whose content negates its own presence in the observation ledger cannot become a gap-free closed record.*

Proof. If the record enters the ledger, its content is false; if it does not, it is not the displayed record it claims to be. The attempt is held as a self-reference boundary rather than a closed object-layer fact. □

9462.27.14 Synthesis

Theorem 9462.919 (Phenomenological framework synthesis)**.** *BEDC rewrites consciousness, universe, time, space, identity, causality, freedom, other minds, mind–matter relation, and self-reference as focused records-side carrier, finite observation-history slice, local continuation chain, locality-cell geometry,* hsame*-stable trace, Type IV gap, Type VI inscription event, Type V locality commitment, double reading of one accumulation chain, and Type VII gap-on-gap hierarchy. The schema of subsection 9462.27.7 refines the records-side face of this list: material appearance is identity-stable orbit closure, while freedom-like appearance is identity-stable escape from the current ledger-certified orbit rules.*

Proof. The focused multi-history ledger supplies the finite carrier. Consciousness is read through the focused history and self-proxy. Universe is a finite slice of admitted histories. Time is local continuation. Space is graph-like inter-history locality. Identity is history-sameness-stable trace continuity. Causality, freedom, other minds, and self-reference align with the corresponding socket types. Mind and matter are two readings of the same accumulation chain. The orbit-closure schema preserves that reading because it classifies finite feedback prefixes by identity, state, rule, separation, and ledger data rather than by adding material substance or a free-will faculty. □

Corollary 9462.920 (No added phenomenological primitives)**.** *This framework adds no primitive consciousness substance, global universe, absolute time, spatial substrate, self entity, causal-law primitive, free-will faculty, direct access to other minds, mental substance, or truth totalizer.*

Corollary 9462.921 (Passage to scientific objects)**.** *The next layer may treat scientific and physical terms by asking which are records-side carriers, which are schema horizons, which require naming certificates, and which remain gap or T-boundary readings.*

Concretized in §1304: PhenomenologicalFrameUp realizes the phenomenological framework as finite focused-ledger, consciousness/universe, hard-problem/action, hsame, Cont, Pkg, audit-refusal, and NameCert rows.

9462.28 Scientific Objects, Physical Objects, and Model Bridges

The phenomenological layer rewrites consciousness, universe, time, space, causality, freedom, other minds, and self-reference as focused history ledgers, local continuation chains, inter-history invariants, gap sockets, and inscription events. The scientific layer asks how scientific objects, physical laws, constants, mature external models, and empirical adequacy enter BEDC without breaking certificate discipline. Its governing answer is that scientific content is records-side data plus inter-history invariants, naming and derivation certificates, conservative bridges, empirical ledgers, prediction gaps, and falsification surfaces.

9462.28.1 Scientific objects

Definition 9462.922 (Scientific object)**.** *A scientific object S is not a primitive. It is a certificate packet consisting of a naming certificate, a derivation certificate at a declared strength, an empirical ledger, an optional model bridge, and a gap report for unclosed commitments.*

Definition 9462.923 (Five sources of a scientific object)**.** *A scientific object must specify records, classifier, invariant, ledger, and bridge data. The records state which histories, continuations, or measurement rows generate the object. The classifier states which records count as the same object or state. The invariant states what remains stable across perspectives. The ledger states what has been compressed, averaged, fitted, projected, or sealed. The bridge states how the object corresponds to a mature scientific or mathematical model.*

Theorem 9462.924 (Scientific objects are not primitives)**.** *Scientific objects cannot enter BEDC as bare primitives.*

Proof. Every mature object requires a naming certificate. Every positive claim requires a witness. Every commitment beyond closed records must remain exposed as a gap. A scientific object combines object naming, observational records, classification, stability, prediction, and bridge obligations, so it is subject to all of these gates rather than exempt from them. □

Corollary 9462.925 (Scientific realism becomes audited entry)**.** *BEDC does not assert bare existence of electrons, fields, spacetime, or laws. It asks whether the corresponding upward interface has naming data, empirical rows, bridge fields, and exposed gap reports.*

Proof. To enter as an object, the name must be certified. To enter as a scientific object, it must also expose records, invariants, measurement surfaces, prediction commitments, and bridge status. □

9462.28.2 Physical records and relational content

Definition 9462.926 (Physical record)**.** *A physical record is a finite, ledgered, source-visible row: a history row, continuation row, measurement row, instrument row, calibration row, error row, relation row, or falsification row.*

Definition 9462.927 (Frame-independent physical content)**.** *Physical content is frame-independent when it is carried by an observer-symmetric and history-sameness-stable inter-history invariant.*

Theorem 9462.928 (Physical content is inter-history invariant)**.** *In a multi-history BEDC frame with no global synchronization, frame-independent physical content can only be carried by inter-history invariants.*

Proof. Individual histories carry local records and local continuation streams. The kernel supplies no shared base history, global time-step index, or privileged frame. A claim that survives a change of perspective must therefore be expressed through witnessed relations and classifier-stable invariant rows between histories. □

Corollary 9462.929 (Physical objects are not single-history objects)**.** *A physical object with frame-independent meaning cannot be identified with a single history alone.*

Proof. A single history gives only local record content. Frame-independent content requires stability across histories, supplied by inter-history relations and invariants. □

Corollary 9462.930 (Relational physical realism)**.** *BEDC physical realism is relational: physical reality is stable inter-history relational content rather than objects in a global spacetime container.*

Proof. A global container would require global synchronization. BEDC refuses that primitive and lets physical content stabilize through witnessed relations. □

9462.28.3 Mature mathematics and mature science

Definition 9462.931 (Mature mathematical object)**.** *A mature mathematical object has a naming certificate, a derivation certificate at a declared strength, and optionally a conservative bridge to a host theory.*

Definition 9462.932 (Mature scientific object)**.** *A mature scientific object adds an empirical ledger, inter-history invariant rows, prediction gaps, and falsification surfaces to the mathematical certificate surface.*

Theorem 9462.933 (Science adds an empirical layer)**.** *Mature science requires the mathematical certificate surface plus empirical record and prediction discipline.*

Proof. Mathematical maturity concerns carrier, classifier, stability, ledger, strength, and optional bridge. Scientific maturity also concerns measurements, instruments, errors, fits, future projections, and records of failure. Prediction adds a Type IV gap, and falsification adds records-side failure rows. □

Corollary 9462.934 (Theoretical physics has two certificate faces)**.** *A theoretical physics object needs a mathematical certificate for well-formedness and a physical certificate tying it to records, invariants, measurements, and falsification surfaces.*

Proof. A carrier may be mathematically coherent without empirical interpretation. An empirical fit may exist without a mature BEDC carrier. A theoretical physical object needs both surfaces. □

Concretized in §1214: Scientific objects are realized as finite NameCert, empirical-ledger, bridge, and gap-report packets.

Concretized in §1340: Physical record invariants realize frame-independent physical content as finite physical-record, inter-history-invariant, observer-symmetry, hsame, Cont, Pkg, and NameCert rows.

9462.28.4 Physical laws as records and gaps

Definition 9462.935 (Empirical regularity)**.** *An empirical regularity is a finite records-side pattern: observed rows satisfy a relation under a displayed measurement, classifier, and error ledger.*

Definition 9462.936 (Physical law)**.** *A physical law, in BEDC, is a two-layer object consisting of an empirical regularity over recorded cases and a Type IV gap asserting future persistence into not-yet-observed continuation.*

Theorem 9462.937 (Physical laws are not substrate primitives)**.** *Physical laws cannot be substrate primitives; they combine records-side regularity with a forward-binding gap.*

Proof. Finite records can show regularity among observed rows. They cannot generate a universal future claim. The law-like projection from records to not-yet-observed continuation is therefore a Type IV commitment, not a closed substrate theorem. □

Corollary 9462.938 (Scientific theories are not closed truth sets)**.** *A scientific theory is a packet of records, regularity summaries, inter-history invariants, model bridges, prediction gaps, and falsification ledgers, not a closed set of true laws.*

Proof. The packet exposes what is recorded, what is invariant, what is bridged to a mature model, what is projected into the future, and what would count as failure. A closed truth set would require the total truth predicate refused by the meta-loop discipline. □

Concretized in §1156: Empirical regularity persistence packets realize finite measurement, classifier, error-ledger, future-persistence GAP, LawCertificate, stability, failure, and NameCert rows.

9462.28.5 Maximum cross-history rate

Definition 9462.939 (Cross-history causal dependence)**.** *A cross-history causal dependence is a proposed relation saying that recent continuation steps of one history depend on recent continuation steps of another. At the current philosophical layer, it is a schema horizon until constructive predicates and concrete witnesses are provided.*

Definition 9462.940 (Maximum cross-history causal rate)**.** *A maximum cross-history causal rate is a unary-valued invariant form bounding the ratio at which displayed causal dependence can propagate between histories, once the underlying dependence relation is certified.*

Theorem 9462.941 (Maximum rate is invariant only after witnesses)**.** *If cross-history causal dependence and the maximum-rate construction are closed by witnesses, the resulting rate must be an inter-history invariant.*

Proof. A rate depending on a privileged frame would not be frame-independent physical content. Since BEDC supplies no global synchronization, the rate can become physical content only as an observer-symmetric and history-sameness-stable invariant over inter-history rows. □

Corollary 9462.942 (Light-speed form is structural skeleton)**.** *At this layer, BEDC can describe the structural form of an observer-independent maximum-rate constant, not the empirical numerical value of the speed of light.*

Proof. The structural form follows from inter-history invariance once the dependence relation is certified. The numerical value requires measurement records, unit conventions, calibration, and empirical bridges. □

Corollary 9462.943 (Physics roadmap is not proved physics)**.** *The multi-history physics route is a schema horizon until each carrier, dependence relation, rate invariant, geometric structure, and empirical bridge receives its own certificate.*

Proof. Skipping any layer would leave source, classifier, stability, ledger, or bridge obligations unsupplied. □

9462.28.6 Formal constants and empirical values

Definition 9462.944 (Formal constant)**.** *A formal constant is an invariant form or bound supplied by a structural theorem, such as the form of an observer-independent maximum-rate bound.*

Definition 9462.945 (Empirical value)**.** *An empirical value is supported by measurement records, calibration, unit bridge, uncertainty, instrument ledger, and reproducibility ledger.*

Theorem 9462.946 (Formal constants are not empirical values)**.** *BEDC may derive structural forms for constants, but the numerical empirical values of physical constants require empirical ledgers.*

Proof. An invariant form says what kind of value could be observer-independent. It does not supply the measurement protocol, unit convention, calibration, error estimate, or reproducibility record needed for a physical numerical value. □

Corollary 9462.947 (Units and dimensions are ledgered)**.** *Numerical physical constants require ledgers for units, dimensions, measurement protocol, uncertainty, calibration, and bridge to standard units.*

Proof. Numerical values are not pure kernel outputs. They depend on empirical practice and unit systems, which must be auditable. □

Concretized in §1208: Empirical values are realized as finite unit, calibration, uncertainty, instrument, and reproducibility ledger packets for physical-law consumers.

Concretized in §1297: Formal constants and empirical values are realized as a finite noncollapse boundary over invariant-form, unit, calibration, measurement, uncertainty, reproducibility, failure, and NameCert rows.

9462.28.7 Models are not worlds

Definition 9462.948 (Model)**.** *A model is an interpretive structure for records and invariants: carrier, interpretation map, classifier, theorem list, empirical fit ledger, and bridge field.*

Definition 9462.949 (Model bridge)**.** *A model bridge is an auditable correspondence between a BEDC records-side object and a mature model. It must specify encoding, decoding, round trips, theorem preservation, no-host-leak discipline, and unsupported fields.*

Theorem 9462.950 (Models are not worlds)**.** *A model cannot be identified with the world in BEDC.*

Proof. The universe object available to the BEDC object layer is a finite observation-history slice. A model interprets and compresses records, relations, and invariants. Equating model and world would replace the finite slice and its gaps by a global object. □

Corollary 9462.951 (Model fit is not world truth)**.** *A model may fit a ledger without becoming a globally true world picture.*

Proof. Fit is agreement with recorded rows under an interpretation. Future projection remains a Type IV gap, cross-model identity needs bridge and classifier data, and global truth is barred by the open meta loop. □

9462.28.8 Standard bridges

Definition 9462.952 (Standard bridge)**.** *For an accepted BEDC object N and a host theory T, a standard bridge is a six-field packet: encoding, decoding, decode-after-encode witness, encode-after-decode witness, finite theorem-preservation list, and no-host-leak witness.*

Definition 9462.953 (Bridge return witnesses)**.** *The bridge round trips say that decoding an encoded host object returns an equivalent host object, and encoding a decoded BEDC carrier returns a BEDC-equivalent carrier element under the licensed classifier.*

Definition 9462.954 (Theorem preservation)**.** *The theorem-preservation field is a finite list pairing host theorems with BEDC counterparts and translations. Nothing outside the finite list is claimed preserved.*

Definition 9462.955 (No-host-leak)**.** *The no-host-leak field says that host primitives used in bridge modules do not appear on the BEDC public surface as primitive inputs, public classifiers, or exported theorem statements.*

Theorem 9462.956 (Standard bridge is recognition, not fusion)**.** *A standard bridge conservatively identifies a BEDC object with a host model for recognition and finite theorem translation; it does not fuse host primitives into BEDC.*

Proof. Encoding, decoding, and round trips compare the two sides. The theorem-preservation list is finite. The no-host-leak field blocks host primitives from becoming BEDC public inputs. The bridge therefore supports recognition without fusion. □

Corollary 9462.957 (Bridge is not smuggling)**.** *A bridge is not host mathematics imported without audit when it exposes encoding, decoding, round trips, theorem preservation, and no-host-leak discipline.*

Proof. Smuggling occurs when host primitives enter the public surface. The bridge fields prevent that by keeping host use inside the bridge and pairing preserved theorems with BEDC counterparts. □

9462.28.9 Bridge conservativity and strength

Definition 9462.958 (Bridge conservativity)**.** *A standard bridge is conservative when no theorem about the BEDC export of N becomes available through the bridge unless it already has the required BEDC certificate strength.*

Theorem 9462.959 (No-host-leak yields bridge conservativity)**.** *When no-host-leak is discharged, the bridge is conservative over the BEDC export surface for N.*

Proof. Host theorem use is mediated by the finite theorem-preservation list and paired BEDC counterparts. Host primitives do not appear on the public surface. Therefore the bridge does not add free BEDC theorems. □

Corollary 9462.960 (External models do not expand BEDC truth)**.** *External models and host theories do not automatically add internal BEDC provability.*

Proof. Only finitely listed and paired preservation rows are recognized by the bridge. Other host theorems remain host-side results. □

Corollary 9462.961 (Theorem preservation is finite)**.** *The theorem-preservation list must remain finite and explicit.*

Proof. An infinite or schematic preservation field would silently import a host theorem schema, bypassing witness and certificate discipline. □

Definition 9462.962 (Bridge certificate)**.** *A bridge certificate is a checked certificate plus a standard bridge whose no-host-leak field is itself checked.*

Theorem 9462.963 (Checked is not bridged)**.** *Reaching checked certificate status does not automatically yield bridge certificate status.*

Proof. Checked status concerns internal formal targets and certificates. Bridge status additionally requires six bridge fields, finite theorem preservation, and checked no-host-leak discipline. □

Corollary 9462.964 (Host maturity does not replace BEDC certification)**.** *A mature host object cannot substitute for BEDC naming, derivation, and bridge certificates.*

Proof. The bridge starts from an accepted BEDC object. Replacing that object by the host object would turn host primitives into BEDC inputs. □

9462.28.10 Relative bridges

Definition 9462.965 (Host-relative bridge)**.** *A standard bridge is relative to a particular host theory. A bridge to one host does not automatically produce a bridge to another.*

Theorem 9462.966 (No absolute bridge)**.** *There is no host-independent standard bridge that replaces the six-field bridge obligations for each target theory.*

Proof. Different host theories have different equality, quotient, function, number, and type or set semantics. Encoding, decoding, round trips, preservation, and no-host-leak must therefore be discharged for each host separately. □

Corollary 9462.967 (Model plurality is audited)**.** *The same BEDC object may have multiple host model bridges, but each bridge is separately audited.*

Proof. Each host changes the interpretation and leakage risks. The bridge fields are therefore host-relative. □

Concretized in §1217: The six-field standard-bridge audit packet is realized as a finite NameCert carrier with no-host-leak and finite theorem-preservation rows.

Concretized in §1330: No-absolute-bridge audits realize host-relative bridge obligations as finite encoding, decoding, theorem-preservation, unsupported-field, and no-host-leak rows.

9462.28.11 Probability Projection Bridge

The probability interfaces already present in the concrete layer do not license the claim that a probability space, a Hilbert space, a Fourier analysis interface, a conditional-expectation row, a belief ledger, and a spectral-measure packet are one object. They license a narrower reading: each interface exposes finite scalar readbacks through named certificates, and a scientific bridge may compare those readbacks only when the comparison row itself is recorded.

Definition 9462.968 (Probability scalar shadow)**.** *Let P be a displayed* $\mathsf{ProbSpace}^{\uparrow}$ *packet with total event Ω, event ledger $\mathcal{A}$,* $\mathsf{Real}^{\uparrow}$*-valued measure readback μ, and total-mass row $\mu(\Omega) \sim_R 1_R$. For a displayed event row $A \in \mathcal{A}$, the probability scalar shadow of A is the exported* $\mathsf{Real}^{\uparrow}$ *endpoint*

$$\mathrm{Shadow}_P(A) := \mu(A).$$

It is a one-dimensional public readback of the event row, not a complete description of the internal structure that produced the event.

Definition 9462.969 (Hilbert projection shadow)**.** *Let H be a displayed* $\mathsf{Hilbert}^{\uparrow}$ *packet whose public surface includes an inner-product probe row. For a carried endpoint v and a displayed observable direction u, the Hilbert projection shadow along u is the scalar endpoint named by the finite probe*

$$\mathrm{ProjShadow}_H(v; u) := \langle v, u\rangle_H.$$

When the packet also carries a norm or energy readback, that readback remains a separate ledger row and is not inferred from an unrecorded ambient Hilbert space.

Definition 9462.970 (Prob-Hilbert projection bridge)**.** *A Prob-Hilbert projection bridge is a finite bridge packet*

$$B_{PH} = (P, H, A, \chi_A, \mathbf{1}, \pi, L)$$

where P is a $\mathsf{ProbSpace}^{\uparrow}$ *packet, H is a* $\mathsf{Hilbert}^{\uparrow}$ *packet, A is a displayed event row of P, χ_A is an indicator row exposed to the Hilbert side, $\mathbf{1}$ is the total-event direction, π is the inner-product probe endpoint, and L is the ledger that records the classifier comparison*

$$\mu(A) \sim_R \langle \chi_A, \mathbf{1}\rangle_H.$$

The packet is public only to the extent that A, χ_A, $\mathbf{1}$, π, the two scalar endpoints, the comparison row, and their provenance are all displayed in the same finite certificate surface.

Theorem 9462.971 (Probability readback as finite projection)**.** *Every accepted Prob-Hilbert projection bridge makes the probability scalar shadow of its displayed event readable as a Hilbert projection shadow along the displayed total-event direction.*

Proof. The bridge carrier includes the event row A, the indicator row χ_A, the direction $\mathbf{1}$, the probability readback $\mu(A)$, the Hilbert probe $\langle \chi_A, \mathbf{1}\rangle_H$, and the comparison row

$$\mu(A) \sim_R \langle \chi_A, \mathbf{1}\rangle_H.$$

By Definition 9462.968, the left endpoint is $\mathrm{Shadow}_P(A)$. By Definition 9462.969, the right endpoint is $\mathrm{ProjShadow}_H(\chi_A; \mathbf{1})$. Thus the bridge reads the probability endpoint as the named Hilbert projection endpoint. No further ambient L^2 equality is used. □

Definition 9462.972 (Fourier projection ledger)**.** *Let H be a displayed Hilbert-side packet and let $\Phi = \{\phi_i : i \in I\}$ be a finite family of observable probe directions. A Fourier projection ledger for a carried endpoint f is the finite packet*

$$\mathcal{F}_I(f) = \{(i, c_i, L_i) : i \in I,\ c_i = \langle f, \phi_i\rangle_H\},$$

where L_i records the source of ϕ_i, the inner-product probe, the integration or coefficient witness, the truncation window, classifier evidence, and package provenance attached to that coefficient row.

Theorem 9462.973 (Fourier coefficients are projection shadows)**.** *In a Fourier projection ledger, each displayed coefficient is a Hilbert projection shadow. The probability scalar shadow is the special case in which $f = \chi_A$ and the probe direction is the total-event direction $\mathbf{1}$, provided the corresponding Prob-Hilbert bridge row is present.*

Proof. For each retained index i, the ledger defines the coefficient endpoint as

$$c_i = \langle f, \phi_i\rangle_H.$$

This is exactly the endpoint $\mathrm{ProjShadow}_H(f;\phi_i)$ from Definition 9462.969. If the finite family contains the total-event direction and the bridge packet supplies the comparison

$$\mu(A) \sim_R \langle \chi_A, \mathbf{1} \rangle_H,$$

then Definition 9462.971 identifies the probability readback with that one coefficient row. The argument does not use Plancherel, inversion, convergence closure, or a complete orthonormal basis. □

Theorem 9462.974 (Conditional expectation is a projected update surface)**.** *A* $\mathsf{CondExp}^{\uparrow}$ *packet may be read as a projected update surface only through its displayed random-variable readback, Hilbert projection witness, residual continuation row, and ledger exactness rows. It does not export a completed sub-σ-algebra projection theorem beyond those rows.*

Proof. The conditional-expectation carrier is presented in chapter 188 through a random-variable total-readback certificate, a Hilbert projection witness, and a continuation ledger. A scientific projection bridge may therefore read the packet as an update by projection only by projecting those displayed rows. Since the packet has no public coordinate for a completed measurable-space quotient or an unrestricted closed subspace, the bridge cannot promote the row to an unbounded host theorem. □

Corollary 9462.975 (Belief updates consume probability projections)**.** *When a* $\mathsf{Belief}^{\uparrow}$ *packet consumes a probability row, the consumed datum is the displayed probability scalar shadow or a bridge-recorded projection shadow, together with the prior, observation, update trace, posterior endpoint, and evidence ledger. The belief packet does not gain access to hidden probability structure.*

Proof. The belief carrier of chapter 289 exposes only the prior row, observation row, update trace, probability row, posterior endpoint, evidence ledger, and provenance rows. If the probability row is supplied by a projection bridge, then its public content is the scalar comparison recorded in that bridge. All other probability or Hilbert data are outside the belief ledger and therefore unavailable to the consumer. □

Theorem 9462.976 (Projection bridge cannot-claim boundary)**.** *The projection bridge does not identify probability spaces with Hilbert spaces, Fourier theory, conditional expectation, belief dynamics, or spectral measures. It identifies only displayed scalar readbacks whose comparison rows are present in a finite certificate ledger.*

Proof. Each participating interface has its own carrier and classifier: probability exports event-measure rows, Hilbert exports inner-product and projection rows, Fourier exports finite coefficient probes, conditional expectation exports random-variable readback and projection rows, belief exports observation-update ledgers, and spectral measure exports projection-family and scalar-window rows. A bridge can compare endpoints across these surfaces only by displaying the relevant source rows, probe rows, scalar endpoints, classifier comparison, continuation replay, and provenance. Therefore the shared content is the recorded projection readback, not an ontology-level fusion of the participating interfaces. □

Concretized in §184: Probability scalar shadows are grounded in the finite $\mathsf{ProbSpace}^{\uparrow}$ event-measure and total-mass rows.

Concretized in §91: Hilbert projection shadows are grounded in the finite $\mathsf{Hilbert}^{\uparrow}$ inner-product and projection rows.

Concretized in §124: Fourier projection ledgers are grounded in finite $\mathsf{Fourier}^{\uparrow}$ coefficient, probe, truncation, and provenance rows.

Concretized in §188: Conditional expectation is read through the finite $\mathsf{CondExp}^{\uparrow}$ random-variable readback, projection witness, and residual continuation rows.

Concretized in §289: Belief updates consume probability rows only through the finite $\mathsf{Belief}^{\uparrow}$ observation-update ledger.

Concretized in §298: Spectral measures contribute only finite projection-family and scalar-window rows to this bridge.

9462.28.12 Quantum and Relativistic Model Bridges

The probability-projection reading has two immediate physical neighbours. Quantum mechanics gives the direct Hilbert-projection model: state, observable, spectral projection, and scalar probability are all already visible as finite certificate surfaces. Relativistic geometry gives the complementary no-global-frame model: locality, rate bounds, metric-facing geometry, and curvature are read only through local ledgers and observer-stable transport. The two readings are not fused into a single physical theory; they share the same refusal of hidden global objects.

Definition 9462.977 (Born-rule bridge packet)**.** *A Born-rule bridge packet is a finite scientific bridge*

$$B_Q = (Q, O, M, r, L)$$

where Q is a displayed $\mathsf{QuantumState}^{\uparrow}$ *packet, O is a displayed* $\mathsf{Observable}^{\uparrow}$ *packet over the same Hilbert source, M is the* $\mathsf{SpectralMeasure}^{\uparrow}$ *projection-family row consumed by the observable, r is a* $\mathsf{Real}^{\uparrow}$ *scalar window, and L records the comparison*

$$r \sim_R \langle \psi, \Pi_A(E)\psi \rangle.$$

Here ψ is read only through the state ray of Q, A only through the self-adjoint observable endpoint of O, and $\Pi_A(E)$ only through the finite projection row of M.

Theorem 9462.978 (Born probability is a certified projection shadow)**.** *An accepted Born-rule bridge packet reads a quantum measurement probability as a finite Hilbert projection shadow. It does not expose a hidden wavefunction representative, host operator equality, unrestricted spectral theorem, unlogged measurement primitive, or ambient probability oracle.*

Proof. Project the packet $B_Q = (Q, O, M, r, L)$. The $\mathsf{QuantumState}^{\uparrow}$ row supplies the Hilbert source, unit-vector endpoint, projective endpoint, global-phase classifier, and provenance. The $\mathsf{Observable}^{\uparrow}$ row supplies the displayed self-adjoint endpoint and its expectation-facing row. The $\mathsf{SpectralMeasure}^{\uparrow}$ row supplies the event-to-projection ledger and finite scalar-window boundary.

The ledger L then records the only cross-surface comparison needed for the measurement read:

$$r \sim_R \langle \psi, \Pi_A(E)\psi \rangle.$$

Thus the public probability is the displayed scalar endpoint r classified with the Hilbert projection expression named by the bridge. Since no field of B_Q is a selected vector representative beyond the projective state row, a host operator equality, an unrestricted spectral-theorem object, an unlogged measurement operation, or a detached probability source, none of those objects is exported by the bridge. □

Corollary 9462.979 (Phase and density boundaries)**.** *Pure-state measurements consume the projective state classifier, not host vector equality. Mixed-state measurements consume the* $\mathsf{DensityMatrix}^{\uparrow}$ *trace-class, positivity, trace-one, and finite affine ledger rows before any trace-form scalar window is read.*

Proof. For a pure state, the carrier of $\mathsf{QuantumState}^{\uparrow}$ identifies public state content through the projective endpoint and global-phase classifier. A measurement bridge cannot distinguish two representatives that the public state row has already classified.

For a mixed state, the $\mathsf{DensityMatrix}^{\uparrow}$ carrier exposes only positivity, trace-class membership, trace-one readback, restricted classifier comparison, and finite affine-mixture ledger data over the Hilbert source. A trace-form measurement read therefore consumes those rows before it reaches the scalar window. Spectral decompositions, purifications, or hidden ensembles are not part of that public surface. □

Corollary 9462.980 (Quantum-channel preservation of the measurement interface)**.** *A* $\mathsf{QuantumChannel}^{\uparrow}$ *row preserves the type of data needed by the Born-rule bridge: a density-matrix input is sent to a density-matrix output, so downstream scalar windows remain measurement-interface rows rather than untyped state updates.*

Proof. The $\mathsf{QuantumChannel}^{\uparrow}$ packet carries a completely positive trace-preserving linear-map row between density-matrix spaces. Its public image theorem sends accepted density-matrix rows to accepted density-matrix rows. Consequently a post-channel measurement bridge still starts from the same public interface: Hilbert source, density carrier, observable row, spectral projection ledger, and $\mathsf{Real}^{\uparrow}$ scalar window. □

Definition 9462.981 (Relativistic pre-geometry bridge)**.** *A relativistic pre-geometry bridge is a finite model bridge whose displayed rows may include* $\mathsf{Manifold}^{\uparrow}$, $\mathsf{RiemannianMetric}^{\uparrow}$, $\mathsf{Connection}^{\uparrow}$, $\mathsf{Curvature}^{\uparrow}$, $\mathsf{LeviCivitaConnection}^{\uparrow}$, $\mathsf{CrossHistCausalCone}^{\uparrow}$, $\mathsf{LorentzFrameRate}^{\uparrow}$, *and* $\mathsf{RelationalPhysics}^{\uparrow}$ *packets. Its public content is the local geometric, curvature, causal, observer-symmetry, model-audit, and no-global-frame ledger carried by those packets.*

Theorem 9462.982 (Relativistic bridge is pre-geometry, not completed field equation)**.** *The current relativistic bridge supports a certificate pre-structure for local geometry, curvature-facing rows, causal cones, observer-symmetric rate readback, and relational physics. It does not close a Lorentzian metric, Ricci tensor, scalar curvature, Einstein tensor, stress-energy tensor, or Einstein field-equation certificate.*

Proof. The manifold, Riemannian-metric, connection, curvature, and Levi-Civita-connection packets expose local carrier, fibre, derivative, commutator, torsion-free, metric-compatibility, curvature-facing, transport, and provenance rows. These are geometry-facing certificate rows, not a Lorentzian spacetime object or a field equation.

The causal and relational packets expose finite multi-history locality, maximum-rate, observer-symmetry, no-global-frame refusal, invariant readback, physical-model audit, and admissible rate or refusal rows. Their public boundaries explicitly exclude global frames, synchronized clocks, ambient spacetime, metric tensors as primitive inputs, and detached physical truth.

No listed packet supplies a Lorentzian metric carrier, curvature contractions to Ricci and scalar curvature, an Einstein tensor row, a stress-energy tensor row, or an empirical field-equation bridge tying those rows together. The current claim is therefore the pre-geometry boundary stated above, not a completed general-relativity certificate. □

Definition 9462.983 (General-relativity coordination bridge)**.** *A general-relativity coordination bridge is a relativistic bridge packet whose displayed rows include observer-coordinate frames, local clock-budget reads, observer-locality cells, cross-history causal-cone rows, Lorentz-frame-rate rows, Minkowski-rate geometry rows, and a* $\mathsf{CurvedSpacetime}^{\uparrow}$ *curved-gluing row. Its public object is the compatibility of these rows under componentwise* hsame *transport, displayed* Cont *replay, provenance, and no-global-frame refusal.*

Theorem 9462.984 (General relativity is interface coordination)**.** *An accepted general-relativity coordination bridge reads the relativistic model as a minimal compatibility geometry among local clocks, local frames, causal cones, inter-Hist coordination rows, metric-facing distance-shape ledgers, and curvature or transition ledgers. It does not export a pre-given four-dimensional host container, a global observer frame, a shared external time scalar, a primitive metric tensor, or an observer-independent event point.*

Proof. Project the coordination bridge. The observer-coordinate frame and local-clock-budget rows supply observer-local chart and clock reads, not a global frame. The observer-locality-cell and cross-history causal-cone rows supply finite inter-Hist coordination and bounded causal comparison, not a host event object. The Lorentz-frame-rate and Minkowski-rate geometry rows supply observer-symmetric rate and distance-shape readback, not a primitive metric tensor. The $\mathsf{CurvedSpacetime}^{\uparrow}$ row then records chart transition, curvature, transport, replay, and provenance data over the same finite surface.

Thus the bridge exports only the compatibility of displayed interfaces. Any coordinate system anchored at one observer history is a gauge-facing interface choice; the invariant physical content is the classifier-stable transport of the rows across the displayed histories. Since the packet has no coordinate for a host spacetime container, shared clock, primitive tensor, or detached event point, none of those objects is exported. □

Corollary 9462.985 (Events and metrics are coordination readbacks)**.** *Within a general-relativity coordination bridge, an event is public only as a licensed inter-Hist coordination of local records, and a metric expression is public only as a bridge readback compressing local-clock, causal-cone, distance-shape, transition, and curvature ledgers.*

Proof. The locality-cell and causal-cone rows identify which local records may be read by the same downstream consumer. That identification is the public event surface; no point of an ambient manifold is present in the carrier.

The metric-facing read is likewise downstream from the displayed clock, rate, distance-shape, transition, and curvature rows. It can serve as a host geometric expression only after a bridge-preservation row relates that expression back to the finite packet. Hence both event and metric are coordination readbacks rather than primitives. □

Definition 9462.986 (Geometric forcing certificate)**.** *A geometric forcing certificate is a finite scientific bridge packet*

$$\mathcal{F} = (\Lambda, \mathcal{G}, \mathcal{P}, \Gamma, R, S, U, M, A)$$

where Λ *is an observation ledger,* $\mathcal{G}$ *is the declared candidate geometry class,* $\mathcal{P}$ *is the audited probe class,* Γ *is the candidate bridge,* R *records realization of* Λ *by* Γ *within the declared tolerance,* S *records the separation tests for candidates not observationally equivalent to* Γ*,* U *records the gauge or representation freedom left invisible to* $\mathcal{P}$*,* M *records minimality of the exported structure, and* A *records residual gaps and no-host-leak boundaries.*

Definition 9462.987 (Ledger forcing up to gauge)**.** *For a geometric forcing certificate, write*

$$\Lambda \Vdash_{\mathcal{G},\mathcal{P}} [\Gamma]$$

when Γ *realizes* Λ*, and every candidate* $\Delta \in \mathcal{G}$ *that also realizes* Λ *is observationally equivalent to* Γ *on all probes in* $\mathcal{P}$*, up to the gauge or representation freedom recorded by* U*.*

Theorem 9462.988 (Geometric forcing is not empty-kernel derivation)**.** *A geometric forcing certificate does not derive general relativity, quantum mechanics, or any physical geometry from the empty BEDC kernel. It derives a relative claim: given an observation ledger, an admissible candidate class, an audited probe class, realization rows, separation rows, gauge rows, minimality rows, and residual-gap rows, the surviving candidates collapse to one observational equivalence class.*

Proof. The forcing judgment in Definition 9462.987 is parameterized by Λ, $\mathcal{G}$, and $\mathcal{P}$. Without these fields there is no candidate comparison and no probe surface on which surviving candidates could be tested.

Assume the certificate fields are present. The realization row R admits Γ as a candidate compatible with the ledger. For any $\Delta \in \mathcal{G}$, if Δ fails realization, the ledger excludes it. If Δ realizes the ledger but is not observationally equivalent to Γ on $\mathcal{P}$, the separation row S supplies a displayed probe that distinguishes the two and records the conflict with Λ. Hence every surviving candidate is equivalent to Γ on the audited probes, modulo the gauge row U. This proves only the relative forcing claim, not an unconditional derivation of a host physical theory. □

Corollary 9462.989 (Forced geometry is a gauge class)**.** *The public output of a geometric forcing certificate is a gauge or representation equivalence class, not a privileged coordinate presentation.*

Proof. The row U records transformations that preserve all audited probe readouts. No ledger row can distinguish two presentations related by such a transformation. Therefore the certificate can export only the invariant class $[\Gamma]$, together with the residual gaps recorded by A. □

Corollary 9462.990 (Physical geometry as invariant compression)**.** *In this layer, physical geometry is the invariant compression of observation ledgers. A relativistic packet compresses clock, causal, lightlike, free-route, transition, and curvature ledgers into Lorentzian-facing geometry when those rows separate all non-equivalent alternatives in the declared class. A quantum packet compresses preparation, measurement, probability, interference, symmetry, composition, and update ledgers into Hilbert/projective/operator-facing geometry under the same forcing pattern.*

Proof. Apply Definition 9462.988 with the relevant observation ledger and candidate class. In the relativistic case, the admissible probes inspect causal order, local clocks, causal-cone or lightlike rows, route comparison, transition, and curvature data. In the quantum case, the admissible probes inspect preparation equivalence, measurement partitions, probability weights, interference, symmetries, composition, and update rows. When the corresponding separation row excludes all non-equivalent candidates, the exported structure is the unique invariant compression of those ledgers up to the recorded gauge or representation row. □

Definition 9462.991 (Constraint container)**.** *A constraint container for an observation ledger* Λ *is a derived bridge-facing packet*

$$\mathcal{K}_\Lambda = (Q, C, I, T, U, G, A)$$

where Q is the current observational quotient induced by the displayed probes, C is the surviving candidate class compatible with the ledger, I is the invariant readback stable across the surviving candidates, T is the transport row between local interfaces, U is the gauge or representation freedom still invisible to the probes, G is the residual gap surface, and A is the audit row recording source, classifier, witness, ledger, and boundary data. The packet is a container only as a stabilized closure of constraints; it is not a primitive host arena.

Theorem 9462.992 (Constraint closure becomes container)**.** *Suppose a refinement sequence of observation ledgers keeps adding displayed records and probes, so that the observational quotient is refined and the surviving candidate class is restricted. If the surviving class stabilizes to one gauge or representation class $[\Gamma]$, and the corresponding packet has stable invariants, transport across local interfaces, compression of the ledger with residual gaps exposed, prediction rows for further probes, and auditable source/classifier/witness/boundary rows, then the stabilized packet is licensed as a constraint container.*

Proof. Each displayed record adds a constraint to the ledger. A new probe can only refine the observational quotient by making distinctions that were previously unavailable to the packet; it cannot by itself add an unrecorded global arena. Likewise, a new compatibility row can only restrict the declared candidate class unless it is accompanied by a new residual-gap row.

If every non-equivalent candidate is eventually excluded by displayed separation evidence, the surviving class is $[\Gamma]$ in the sense of Definition 9462.987. The additional stability, transport, compression, prediction, and audit rows state exactly that this class can be reused as a public interface for later reads. That reuse is the container role. Since the role is obtained only after refinement and candidate restriction, the container is the stabilized closure of observational constraints rather than a premise into which the records were placed. □

Corollary 9462.993 (Containers delimit future extensions)**.** *The container role of a stabilized geometric packet is its restriction of admissible future extensions. It says which further records, routes, probes, and bridge reads remain compatible with the current ledger, and which have already been excluded by the boundary rows.*

Proof. The stabilized packet contains the surviving candidate class, invariant readback, transport, gauge, residual-gap, prediction, and audit rows. A future extension is admissible only if it preserves those rows or records a declared gap or boundary pressure. Thus the container is not a box holding events; it is the public shape of the still-admissible continuation space after the ledger has excluded incompatible alternatives. □

Corollary 9462.994 (Relativistic and quantum containers are derived)**.** *The spacetime-facing container in a relativistic bridge and the Hilbert-facing container in a quantum bridge are derived interfaces. The former is licensed only after clock, causal, lightlike, route, transition, and curvature rows stabilize; the latter only after preparation, measurement, probability, interference, symmetry, composition, and update rows stabilize. Neither is a BEDC kernel primitive.*

Proof. Apply Definition 9462.992 to the two candidate classes named by Definition 9462.990. In the relativistic case, the stable rows are the local physical ledgers that support Lorentzian-facing readback. In the quantum case, the stable rows are the operational probability ledgers that support Hilbert/projective/operator readback. In both cases the public container appears only after the forcing and audit rows are present. □

Definition 9462.995 (Route-delay bridge packet)**.** *A route-delay bridge packet is a finite records-side comparison*

$$\mathcal{D} = (R_1, R_0, E, K, \Delta, A)$$

where R_1 and R_0 are two displayed routes with the same emitted and received locality-cell endpoints, E is the endpoint-equivalence certificate, K is a shared local-clock and accumulation-edge certificate, Δ is the route-pair clock-read token, and A records the refusal of a global clock, host event point, ambient metric, or unlisted host theorem. The delay row is first a comparison of two certified route reads, not an external real-valued time difference.

Theorem 9462.996 (Route delay is not host proper time)**.** *An accepted route-delay bridge packet does not identify BEDC clock reads with relativistic proper time, coordinate time, Shapiro delay, or Wigner–Smith scattering delay unless the relevant host correspondence is present as a displayed bridge-preservation row.*

Proof. The packet $\mathcal{D}$ supplies only two routes, endpoint equivalence, a shared local-clock certificate, an accumulation-edge read, and an audit row. These rows make the BEDC delay token well formed as a records-side comparison. Proper time, coordinate time, Shapiro delay, and Wigner–Smith delay are host-side readings involving additional metric, scattering, or asymptotic-state data. Since the audit row refuses host leakage and unlisted host theorems, such readings can enter only by a bridge-preservation row that relates the host expression back to the displayed route-pair token. □

Corollary 9462.997 (Scattering delay is a bridge reading)**.** *A scattering-delay expression may be used in this layer only as a host-side reading of a route-delay packet whose incoming route, outgoing route, free reference route, interaction ledger, clock certificate, and no-leak boundary are displayed.*

Proof. Scattering delay compares an interacting route with a free reference route. On the BEDC side, such a comparison is meaningful only after same-endpoint evidence and a shared clock certificate have been supplied by Definition 9462.995. The scattering formula belongs to the host model; the BEDC export is the finite route-pair token together with the bridge row that preserves it. □

Definition 9462.998 (Bridge-alignment learner)**.** *A bridge-alignment learner is a derived machine-learning packet that reads a records-side family $\mathcal{R}$, encodes it into a displayed representation Z_i, and applies a predictor or adapter $A_{\hat{\theta}} : Z_i \to Y$ to a declared readout family Y. Its effect claim is accepted only through the source, split, prediction, loss, NoLeak, stability, failure-surface, and NameCert rows of the machine-learning effect certificate.*

Definition 9462.999 (Readout alignment)**.** *Representations Z_i and Z_j are readout-aligned over a readout family Y when there are accepted bridge-alignment learners $A_i : Z_i \to Y$ and $A_j : Z_j \to Y$ whose certified errors lie inside the same declared budget. This is an alignment of observable reads, not an identity of the representation carriers.*

Theorem 9462.1000 (Readout alignment is not latent equivalence)**.** *If metric-facing, scattering-facing, and information-clock-facing representations all predict the same route-delay readout within a declared budget, BEDC may record readout alignment. It may not identify the latent representations without an additional bridge certificate.*

Proof. The accepted learners prove only that the composites $A_i : Z_i \to Y$ preserve the declared readout within the stated budget. Many non-equivalent representation carriers can admit predictors with the same readout behavior. Latent equivalence requires more data: translation in both

directions, classifier preservation, return-comparison witnesses, theorem or invariant preservation where claimed, and a NoLeak ledger for the translation. Those rows are not supplied by readout alignment alone. □

Corollary 9462.1001 (Bridge learning is evidence, not bridge closure)**.** *A machine-learning adapter from a metric, scattering, or information representation to a delay readout is evidence for a bridge candidate, not a completed standard bridge.*

Proof. The adapter may certify useful prediction from one representation to the declared readout. A standard bridge additionally requires displayed encoders and decoders, preservation rows, return-comparison witnesses, NoLeak boundaries, and failure-surface accounting between the interfaces being bridged. Prediction effectiveness is therefore a records-to-readout certificate, not representation-level bridge closure. □

Theorem 9462.1002 (Common physical bridge discipline)**.** *Quantum and relativistic model bridges share a certificate discipline: the world is not closed as a global object; only finite public projection, geometry, causal, invariant, empirical, and failure ledgers are exported.*

Proof. In the quantum bridge, unobserved state detail is not exported as a hidden complete object. Measurement passes through a state row, an observable row, a spectral projection row, and a scalar window.

In the relativistic bridge, global frame data is not exported as a primitive object. Physical structure passes through local geometry rows, cross-history causal rows, observer-symmetric rate rows, invariant readback, and model-audit ledgers.

Both bridges therefore replace hidden totality by finite public certificates. They differ in geometry and physical interpretation, but they obey the same BEDC rule: a scientific bridge exports only displayed rows and their classifier-stable transport, not an unlogged global world. □

Concretized in §217: Quantum-state packets supply the Hilbert unit-vector, projective phase, classifier, and provenance rows consumed by the Born-rule bridge.

Concretized in §218: Observable packets supply the self-adjoint endpoint, spectral row, expectation row, and no-host-operator-equality boundary.

Concretized in §298: Spectral-measure packets supply the event-to-projection ledger and finite scalar-window rows used by quantum measurement reads.

Concretized in §220: Density-matrix packets supply positive trace-class trace-one rows and finite affine-mixture ledgers for mixed-state measurement reads.

Concretized in §221: Quantum-channel packets preserve density-matrix measurement interfaces through CPTP ledger rows.

Concretized in §96: Manifold packets supply the local point, chart, and coordinate-transport substrate for relativistic pre-geometry.

Concretized in §133: Riemannian-metric packets supply fibrewise inner-product rows without closing Lorentzian spacetime.

Concretized in §134: Connection packets supply finite covariant-derivative rows consumed by curvature-facing geometry.

Concretized in §135: Curvature packets supply finite commutator-boundary and transport rows, not a completed field-equation object.

Concretized in §3638: Levi-Civita packets tie Riemannian metric, torsion-free connection, metric compatibility, and curvature-facing rows.

Concretized in §1112: Cross-history causal-cone packets supply finite causal route, maximum-rate, observer-symmetry, and no-global-frame refusal rows.

Concretized in §617: Lorentz-frame-rate packets supply observer-symmetric maximum-rate rows while excluding Lorentz geometry as a primitive input.

Concretized in §1275: Relational-physics packets supply finite observer-history, locality, invariant, audit, rate-or-refusal, and no-global-spacetime boundaries.

9462.28.13 Yang–Mills mass-gap bridge

The Yang–Mills mass-gap route is admissible in this scientific bridge layer only as a conditional certificate chain. The finite strong-coupling lattice surface may close inside a compact group integral and transfer-matrix packet. The continuum claim needs an additional renormalization bridge that preserves the physical Hilbert interface, Wilson packet readbacks, and every ultraviolet, infrared, gauge, topological, and soft-mode residual ledger. Without that bridge, the finite lattice theorem remains a regulated theorem and not a continuum mass-gap certificate.

Definition 9462.1003 (Yang–Mills bridge packet)**.** *A Yang–Mills bridge packet is a finite scientific bridge record*

$$\mathcal{Y} = (G, \mathcal{H}, \Omega, H, \mathcal{W}_{\mathrm{fin}}, L, A)$$

where G is a displayed compact simple gauge group row, $\mathcal{H}$ is the gauge-invariant physical Hilbert carrier, Ω is the vacuum row, $H \geq 0$ is the Hamiltonian readback with $H\Omega = 0$, $\mathcal{W}_{\mathrm{fin}}$ is the finite Wilson-loop or spin-network packet surface, L is the ledger for gauge quotient, ultraviolet cutoff, infrared volume, topological sector, zero mode, and soft residual data, and A is the audit row recording standard-bridge scope and no-host-leak boundaries.

Definition 9462.1004 (Finite Wilson packet correlation)**.** *For a finite Wilson packet*

$$O = \sum_{\alpha \in I} c_\alpha W_{\rho_\alpha, C_\alpha}$$

over a finite index set I, write

$$v_O = O\Omega - \langle \Omega, O\Omega \rangle \Omega$$

and

$$C_O(t) = \langle v_O, e^{-tH} v_O \rangle.$$

The packet is public only through the displayed loop, representation, coefficient, vacuum-subtraction, correlation, ledger, and provenance rows.

Definition 9462.1005 (Strong-coupling lattice gap certificate)**.** *A strong-coupling lattice gap certificate for a finite lattice Λ consists of compact edge variables $U_e \in G$, plaquette holonomy rows U_p, a Wilson action row, a character-expansion row*

$$e^{\beta \operatorname{Re} \chi_{\mathrm{fund}}(g)} = c_0(\beta) \left(1 + \sum_{\rho \neq \mathbf{1}} a_\rho(\beta) \chi_\rho(g) \right),$$

a polymer ledger with

$$\kappa(\beta) = \sum_{\rho \neq \mathbf{1}} d_\rho |a_\rho(\beta)| < 1,$$

and a transfer-matrix row. Its strong-coupling bound supplies constants $m_{\Lambda,\beta} > 0$ *and* K_O *such that every non-vacuum finite Wilson packet satisfies*

$$|C_O(t)| \leq K_O e^{-m_{\Lambda,\beta} t}.$$

Theorem 9462.1006 (Finite strong-coupling packet decay)**.** *If the character-expansion ledger of Definition 9462.1005 satisfies the displayed small-parameter bound strongly enough that the connected polymer expansion is absolutely convergent, then finite Wilson packet correlations decay exponentially on that regulated lattice surface.*

Proof. Every connected non-vacuum polymer contributing to a connected Wilson packet correlation contains a non-trivial representation row on each plaquette in its support. The coefficient ledger bounds the contribution of each such row by the strong-coupling parameter, while finite lattice connectivity supplies only a finite combinatorial factor per plaquette. Hence the total weight of a connected polymer with support size $|\Gamma|$ is bounded by

$$|w(\Gamma)| \leq C^{|\Gamma|} \kappa(\beta)^{|\Gamma|}.$$

When $C\kappa(\beta) < 1$, the polymer sum is absolutely convergent and separation in Euclidean time forces an exponential penalty for every connected surface linking the two Wilson packet reads. The transfer-matrix row reads this Euclidean decay as a non-vacuum transfer spectral gap on the finite regulated surface. □

Definition 9462.1007 (Wilson packet Hilbert gap certificate)**.** *A Wilson packet Hilbert gap certificate for Definition 9462.1003 consists of a number* $m > 0$ *and two displayed rows:*

- *the span of vacuum-orthogonal finite Wilson packet vectors* v_O *is dense in* $\Omega^\perp$*;*
- *for every such* v_O *there is a constant* K_O *with*

$$\langle v_O, e^{-tH} v_O \rangle \leq K_O e^{-mt}$$

  for all displayed Euclidean times $t \geq 0$*.*

Theorem 9462.1008 (Wilson decay and the physical Hilbert spectral gap)**.** *For a Yang–Mills bridge packet with self-adjoint non-negative Hamiltonian, unique vacuum row, and the density row of Definition 9462.1007, the following conditions are equivalent for a fixed* $m > 0$*.*

- *The restriction of* H *to* $\Omega^\perp$ *has spectrum contained in* $[m, \infty)$*.*
- *Every vacuum-orthogonal finite Wilson packet correlation has a spectral measure supported in* $[m, \infty)$*, equivalently it satisfies a uniform exponential decay certificate with exponent* m*.*

Proof. If the spectrum of H on $\Omega^\perp$ is contained in $[m, \infty)$, then the spectral theorem gives

$$\langle v, e^{-tH} v \rangle = \int_{[m,\infty)} e^{-tE} \, d\mu_v(E) \leq e^{-mt} \|v\|^2$$

for every $v \in \Omega^\perp$, hence in particular for finite Wilson packet vectors.

Conversely, suppose the displayed exponential certificate holds for each finite Wilson packet vector. For any $\varepsilon > 0$ and such a vector v, let μ_v be its spectral measure. The bound

$$\mu_v([0, m-\varepsilon])e^{-t(m-\varepsilon)} \leq \int e^{-tE}\, d\mu_v(E) \leq K_v e^{-mt}$$

holds for all $t \geq 0$. Letting t grow gives

$$\mu_v([0, m-\varepsilon]) = 0.$$

Thus every finite Wilson packet vector is annihilated by the spectral projection of H onto $[0, m-\varepsilon]$. Since those vectors are dense in $\Omega^\perp$ and spectral projections are bounded, the same projection annihilates all of $\Omega^\perp$. This holds for every $\varepsilon > 0$, so no non-vacuum spectral row lies below m. □

Definition 9462.1009 (Soft residual ledger)**.** *A soft residual below a proposed mass threshold m is a non-vacuum Hilbert state or approximating state family whose spectral mass meets $[0, m)$. It is ledgered when either some finite Wilson packet vector has nonzero projection against it, or the residual is recorded in the infrared, ultraviolet, renormalization, packet-complexity, topological, gauge, or zero-mode tail row of L.*

Definition 9462.1010 (Wilson packet complexity filtration)**.** *A Wilson packet complexity filtration for Definition 9462.1003 is an increasing family*

$$\mathcal{V}_1 \subseteq \mathcal{V}_2 \subseteq \cdots \subseteq \Omega^\perp$$

where $\mathcal{V}_M$ is generated by vacuum-orthogonal finite Wilson or spin-network packet vectors whose displayed loop support, representation weight, and coefficient-description ledgers have total complexity at most M. The filtration has a Peter–Weyl completeness row when

$$\overline{\bigcup_{M \geq 1} \mathcal{V}_M} = \Omega^\perp.$$

Each fixed $\mathcal{V}_M$ is a fixed packet-complexity surface. No conclusion about a growing sequence of packet complexities is licensed unless its tail ledger is also displayed.

Definition 9462.1011 (Complexity tail ledger)**.** *Given the filtration of Definition 9462.1010, a soft residual family $\psi_n \in \Omega^\perp$ is in the packet-complexity tail when*

$$\|P_M \psi_n\| \to 0$$

for every fixed M, where P_M is the projection onto the displayed fixed complexity surface. The corresponding ledger row records that detecting the residual requires packet complexity tending beyond every fixed stratum; it is not absence of a residual.

Theorem 9462.1012 (Soft residual fixed-packet or complexity-tail dichotomy)**.** *Let $\psi_n \in \Omega^\perp$ be a norm-one soft residual family for a Yang–Mills bridge packet equipped with a Wilson packet complexity filtration. Then either some fixed complexity surface has*

$$\limsup_n \|P_M \psi_n\| > 0,$$

or the family lies in the packet-complexity tail ledger of Definition 9462.1011.

Proof. This is the exhaustion dichotomy for an increasing filtration. If some fixed M has positive limsup projection, the residual is visible at that fixed packet-complexity surface. If no such M exists, then by definition $\|P_M\psi_n\| \to 0$ for every fixed M, which is exactly the packet-complexity tail condition. □

Definition 9462.1013 (Filtered uniform Wilson gap certificate)**.** *A filtered uniform Wilson gap certificate is a Wilson packet Hilbert gap certificate together with a complexity filtration and a number $m_0 > 0$ such that every vacuum-orthogonal finite Wilson packet vector v_O has*

$$\langle v_O, e^{-tH} v_O\rangle \le K_O e^{-m_0 t}$$

for all displayed Euclidean times $t \ge 0$. The constant K_O may depend on the packet, but the exponent m_0 is independent of O, of the fixed complexity stratum, of the loop-support ledger, and of the representation ledger.

Definition 9462.1014 (Block tube area-law certificate)**.** *A block tube area-law certificate is a fixed physical block-scale bridge row. It consists of a block scale $\ell_* > 0$, a blocked gauge graph $\mathcal{L}_{\ell_*}$, a class of blocked finite Wilson or spin-network packets on that graph, and a connected-tube expansion for every correlation $C_O(t)$. The certificate supplies constants*

$$\sigma > \kappa, \qquad c_* > 0$$

such that every connected tube Σ joining $O(0)$ to $O(t)$ has weight and area rows

$$|w(\Sigma)| \le e^{-\sigma|\Sigma|}$$

and

$$|\Sigma| \ge c_* t - b_O,$$

where b_O may depend on the displayed packet support but c_* does not. It also supplies an entropy row

$$\#\{\Sigma : |\Sigma| = n,\ \Sigma : O(0) \leftrightarrow O(t)\} \le A_O e^{\kappa n}.$$

All constants are read at the fixed block scale. The certificate makes no claim for changing block scales or growing packet windows unless those changes are recorded in the tail ledger.

Theorem 9462.1015 (Block tube area law gives filtered uniform Wilson decay)**.** *If a Yang–Mills bridge packet has a block tube area-law certificate, then its blocked finite Wilson packet correlations satisfy a filtered uniform Wilson gap certificate with exponent*

$$m_0 = (\sigma - \kappa)c_* > 0.$$

Proof. The connected-tube expansion bounds the connected correlation by the sum of absolute tube weights:

$$|C_O(t)| \le \sum_{\Sigma : O(0)\leftrightarrow O(t)} |w(\Sigma)|.$$

Group the tubes by area $n = |\Sigma|$. The tube lower bound and entropy row give

$$|C_O(t)| \le \sum_{n \ge c_* t - b_O} A_O e^{\kappa n} e^{-\sigma n}.$$

Since $\sigma > \kappa$, this is a convergent geometric tail:

$$|C_O(t)| \le A'_O e^{-(\sigma-\kappa)(c_* t - b_O)}.$$

Absorbing $e^{(\sigma-\kappa)b_O}$ into the packet-dependent constant gives

$$|C_O(t)| \le K_O e^{-(\sigma-\kappa)c_* t}.$$

Thus the exponent is $m_0 = (\sigma - \kappa)c_*$ and is independent of the packet, its complexity stratum, its support ledger, and its representation ledger. This is exactly the filtered uniform Wilson gap certificate. □

Corollary 9462.1016 (Block tube area law gives the fixed-sector gap)**.** *Assume the physical Hilbert construction, Wilson packet complexity filtration, Peter–Weyl completeness row, ledger-exhaustiveness row, and closedness boundary of Definition 9462.1019. A block tube area-law certificate then forces the non-vacuum physical Hilbert spectrum in the declared fixed block sector to be contained in* $[m_0, \infty)$*, with* $m_0 = (\sigma - \kappa)c_*$*.*

Proof. By Definition 9462.1015, the block tube certificate supplies the filtered uniform Wilson gap certificate with exponent m_0. The filtered gap theorem then excludes every fixed packet soft residual below m_0. Any residual escaping all fixed packet-complexity surfaces must enter the packet-complexity or physical tail ledger, and the closedness boundary rejects hidden unfinished tail data. □

Theorem 9462.1017 (Filtered gap excludes fixed-packet soft residuals)**.** *If a filtered uniform Wilson gap certificate with exponent* $m_0 > 0$ *is present, no soft residual can have nonzero spectral address in a fixed finite Wilson packet.*

Proof. Suppose a fixed packet vector v_O detects a soft residual. Then the spectral measure μ_O of v_O for H has positive mass in arbitrarily small non-vacuum energy windows. In particular, for some $0 < \varepsilon < m_0$ the measure of $[0, \varepsilon]$ is nonzero. The correlation then satisfies

$$\langle v_O, e^{-tH} v_O \rangle \ge \mu_O([0, \varepsilon]) e^{-\varepsilon t}.$$

Multiplying by $e^{m_0 t}$ contradicts the displayed bound $K_O e^{-m_0 t}$ as t grows. Hence a fixed packet address is impossible under the filtered uniform gap certificate. □

Theorem 9462.1018 (Gapless spectrum forces visible or ledgered residual)**.** *Under the density, complexity-filtration, and ledger-exhaustiveness rows of a Yang–Mills bridge packet, failure of the Hilbert spectral gap cannot disappear silently. A gapless non-vacuum spectral residual is either detected by a fixed finite Wilson packet correlation, appears on a fixed packet-complexity surface, or belongs to the displayed packet-complexity, infrared, ultraviolet, renormalization, topological, gauge, or zero-mode tail ledger.*

Proof. Apply Definition 9462.1012. If a fixed complexity projection has positive limsup, the displayed fixed stratum contains a finite packet witness after choosing the corresponding packet row in that stratum; the residual changes the spectral measure of that packet below every proposed positive threshold. If every fixed complexity projection vanishes, the residual is not absent; it has escaped the fixed packet surfaces and must be recorded as packet-complexity tail. Any further ultraviolet, infrared, renormalization, topological, gauge, or zero-mode loss is likewise a ledger row. Therefore an unledgered soft residual is incompatible with the packet assumptions. □

Theorem 9462.1019 (Filtered Yang–Mills gap theorem)**.** *Let a Yang–Mills bridge packet have a physical Hilbert construction, compact gauge Wilson packet rows, Peter–Weyl completeness for the packet-complexity filtration, a filtered uniform Wilson gap certificate with exponent* $m_0 > 0$*,*

and a ledger-exhaustiveness row saying that every residual escaping all fixed packet-complexity surfaces enters the packet-complexity or physical tail ledger. If the accepted object is closed against unfinished tail ledgers, then its physical Hilbert spectrum on $\Omega^\perp$ is contained in $[m_0, \infty)$.

Proof. Assume instead that the non-vacuum spectrum meets energies below m_0. Choose a norm-one approximating soft residual family in $\Omega^\perp$ with energy tending below the proposed gap. By Definition 9462.1012, this family either has a fixed packet-complexity address or lies in the packet-complexity tail.

The first case is excluded by Definition 9462.1017. In the second case, ledger exhaustiveness requires a packet-complexity or physical tail row. Such a row is unfinished residual data unless it is resolved by the bridge, and closedness forbids carrying it as hidden content. Thus both cases contradict the accepted closed packet assumptions. Therefore the non-vacuum spectrum is contained in $[m_0, \infty)$. □

Definition 9462.1020 (Filtered renormalization gap stability certificate)**.** *A filtered renormalization gap stability certificate is a bridge row from a lattice tower*

$$\mathcal{Y}_0 \leftarrow \mathcal{Y}_1 \leftarrow \mathcal{Y}_2 \leftarrow \cdots \longrightarrow \mathcal{Y}_\infty$$

to a continuum Yang–Mills bridge packet. It contains:

- *scale-time rows for blocking and continuum refinement;*
- *contractive or isometric Hilbert transport rows on the physical vacuum-orthogonal surfaces;*
- *convergence of finite Wilson packet correlations from the lattice tower to the continuum packet;*
- *a uniform lower bound $m_0 > 0$ for the lattice physical gaps in every declared fixed Wilson packet-complexity sector, with exponent independent of the sector;*
- *a complete ledger for ultraviolet, infrared, renormalization, gauge, packet-complexity, topological, and zero-mode residuals.*

Theorem 9462.1021 (Renormalization bridge preserves the mass gap)**.** *Assume a lattice tower has strong-coupling finite Wilson packet decay with a uniform exponent $m_0 > 0$ independent of packet complexity, and assume the tower is connected to a continuum Yang–Mills bridge packet by a filtered renormalization gap stability certificate. Then the continuum packet has a physical Hilbert spectral gap at least m_0 on the declared Wilson packet sector, unless a packet-complexity or physical tail ledger remains open.*

Proof. Choose a continuum finite Wilson packet vector. By the correlation convergence row of Definition 9462.1020, it is the limit of lattice Wilson packet vectors in the declared sector. The uniform lattice gap gives the bound

$$C_{O,n}(t) \leq K_{O,n} e^{-m_0 t}$$

with the same exponent m_0 along the tower, after the packet normalization specified by the bridge row. Passing to the continuum correlation yields the same spectral-support exclusion below m_0 for the continuum packet.

The density and filtration rows then invoke Definition 9462.1019: finite Wilson packet decay with exponent m_0 forces the physical Hilbert spectrum on the vacuum-orthogonal declared sector to avoid $[0, m_0)$, except for residuals that escape every fixed packet-complexity surface. If such a residual tried to appear during the limit, Definition 9462.1018 would place it in the displayed packet-complexity or physical tail ledger. The filtered stability certificate therefore blocks an unrecorded loss of the mass gap and leaves only explicitly ledgered open tail data. □

Theorem 9462.1022 (Yang–Mills mass-gap bridge boundary)**.** *The Yang–Mills mass-gap route in this layer has exactly two admissible positive surfaces: the regulated finite strong-coupling packet theorem, and the conditional continuum theorem obtained after a renormalization gap stability certificate is displayed. It does not claim an unconditional continuum construction, a continuum gap without the stability certificate, a gap outside the declared Wilson packet sector, or a host-theory theorem not listed in the bridge preservation row.*

Proof. Definition 9462.1006 closes only the finite regulated strong-coupling surface. The passage to a continuum Hilbert mass gap additionally uses the density, correlation-convergence, Hilbert transport, packet-complexity filtration, uniform-gap, and tail-ledger rows of Definition 9462.1020. Without those rows the bridge has no public path from lattice transfer-matrix decay to continuum spectral support. In particular, the statement that every fixed finite packet has some gap does not imply a uniform physical mass gap; the exponent must be independent of packet complexity, or the escaping modes must be recorded in the packet-complexity or physical tail ledger. Standard bridge discipline also restricts the export to the declared theorem-preservation list and no-host-leak boundary. The stated positive surfaces are therefore the only ones licensed here. □

9462.28.14 Yang–Mills tube geometry certificates

The block tube area-law certificate of Definition 9462.1014 separates into two finite combinatorial geometry rows and one physical weight row. The geometry rows are internal to the fixed block lattice: a connected tube joining two time-separated Wilson packet supports must contain a linearly long plaquette chain, and the number of connected plaquette sets of a given area grows at most exponentially. The physical row is the area decay of tube weights. Only the physical row carries the confinement content; the two geometry rows are finite block-scale certificates.

Definition 9462.1023 (Blocked Wilson support)**.** *Fix a physical block scale $\ell_* > 0$ and let $\mathcal{L}_{\ell_*}$ be the corresponding four-dimensional block lattice with integer time coordinate τ. A blocked Wilson packet O has finite support* $\mathrm{supp}(O)$ *in the cells and edges of this lattice. Its time diameter is*

$$d_t(O) = \max_{\xi,\eta\in\mathrm{supp}(O)} |\tau(\xi) - \tau(\eta)|.$$

The translate $O(T)$ is obtained by shifting the support by T block time steps; the corresponding physical time is $t = T\ell_*$.

Definition 9462.1024 (Plaquette tube)**.** *A plaquette tube Σ is a finite set of block plaquettes equipped with the plaquette adjacency inherited from the fixed lattice. It joins $O(0)$ to $O(T)$ when its adjacency graph has a connected component meeting a fixed finite neighbourhood of* $\mathrm{supp}(O(0))$ *and a fixed finite neighbourhood of* $\mathrm{supp}(O(T))$*. Its area is the plaquette count*

$$|\Sigma| = \#\{p : p \in \Sigma\}.$$

In physical units the area is $\ell_*^2|\Sigma|$.

Theorem 9462.1025 (Tube area lower bound)**.** *For each fixed blocked Wilson packet O there are constants $c_* > 0$ and $b_O < \infty$ such that every plaquette tube joining $O(0)$ to $O(T)$ satisfies*

$$|\Sigma| \geq c_* T - b_O.$$

Equivalently, in physical time $t = T\ell_*$,

$$|\Sigma| \geq \frac{c_*}{\ell_*} t - b_O.$$

Proof. Since the tube joins the two packet supports, its adjacency graph contains a plaquette chain

$$\Pi_0, \Pi_1, \ldots, \Pi_L$$

from the fixed neighbourhood of $O(0)$ to the fixed neighbourhood of $O(T)$. In the fixed block lattice, adjacent plaquettes can change the time coordinate by at most a uniform finite constant D_t. The two packet supports themselves occupy only the time diameter $d_t(O)$, together with the fixed neighbourhood thickness. Hence the chain must cross at least

$$T - 2d_t(O) - B_O$$

units of time distance, where B_O records the fixed neighbourhood and support boundary. Therefore

$$L \geq D_t^{-1}T - B'_O.$$

Every plaquette in the chain belongs to Σ, so

$$|\Sigma| \geq L + 1 \geq c_* T - b_O$$

after setting $c_* = D_t^{-1}$ and absorbing the finite packet boundary into b_O. □

Definition 9462.1026 (Tube counting function)**.** *For a fixed blocked packet O, let $N_O(n, T)$ be the number of connected plaquette tubes of area n that join $O(0)$ to $O(T)$. The count is taken inside the fixed block lattice and with the fixed plaquette adjacency of Definition 9462.1024.*

Theorem 9462.1027 (Tube entropy bound)**.** *For each fixed blocked Wilson packet O there are constants $A_O < \infty$ and $\kappa < \infty$ such that for all n and T,*

$$N_O(n, T) \leq A_O e^{\kappa n}.$$

Proof. The block dimension and plaquette adjacency are fixed, so every plaquette has at most $D < \infty$ adjacent plaquettes. A connected tube of area n meeting the finite neighbourhood of $O(0)$ can be explored by a depth-first traversal of a spanning tree for its adjacency component. The starting plaquette has at most $A_O^{(0)}$ choices, because the packet support is finite. The traversal has length at most $2n$ and each step has at most D choices. Thus the number of such connected plaquette sets is bounded by

$$A_O^{(0)} D^{2n}.$$

Taking $A_O = A_O^{(0)}$ and $\kappa = 2 \log D$ gives the claimed exponential entropy bound. The additional requirement that the tube also meets $O(T)$ only decreases the count. □

Definition 9462.1028 (Tube weight area decay)**.** *Tube weight area decay at the fixed block scale is the physical weight row asserting that there is a $\sigma > 0$ such that every connected tube contribution satisfies*

$$|w(\Sigma)| \leq e^{-\sigma|\Sigma|}.$$

In a strong-coupling polymer expansion this row is supplied by the non-trivial plaquette character-expansion parameter. If the effective plaquette excitation weight is $\eta < 1$, the row has $\sigma = |\log \eta|$ after the fixed normalization of the tube weights.

Definition 9462.1029 (Strong-coupling character ledger)**.** *On a finite block lattice, let the normalized plaquette weight be*

$$\widetilde{K}_\beta(g) = \frac{\exp(\beta \operatorname{Re} \chi_{\mathrm{fund}}(g))}{\int_G \exp(\beta \operatorname{Re} \chi_{\mathrm{fund}}(h))\, dh}.$$

Its character ledger is the expansion

$$\widetilde{K}_\beta(g) = 1 + \sum_{\rho \neq \mathbf{1}} a_\rho(\beta)\chi_\rho(g),$$

together with the summability row

$$\eta(\beta) = \sum_{\rho \neq \mathbf{1}} d_\rho |a_\rho(\beta)| < \infty.$$

If a finite representation cutoff is used, the cutoff and the omitted tail are recorded as part of the same ledger.

Lemma 9462.1030 (Strong-coupling small parameter)**.** *For the character ledger of Definition 9462.1029, the non-trivial coefficient norm satisfies*

$$\eta(\beta) \to 0$$

as $\beta \to 0$, within the displayed summability or truncation ledger.

Proof. At $\beta = 0$ the normalized plaquette weight is the constant function 1, so all non-trivial character coefficients vanish. For each fixed irreducible representation, $a_\rho(\beta)$ varies analytically with β and therefore tends to zero. Under a finite representation cutoff this proves the claim immediately. Under the complete character expansion, the ledger supplies the uniform summability needed to pass the limit through the tail. Hence the total non-trivial norm tends to zero. □

Lemma 9462.1031 (Single plaquette excitation bound)**.** *For every group element $g \in G$,*

$$\left| \sum_{\rho \neq \mathbf{1}} a_\rho(\beta)\chi_\rho(g) \right| \leq \eta(\beta).$$

Proof. Every finite-dimensional representation of the compact group G may be unitarized, so its character satisfies $|\chi_\rho(g)| \leq d_\rho$. Thus

$$\left| \sum_{\rho \neq \mathbf{1}} a_\rho(\beta)\chi_\rho(g) \right| \leq \sum_{\rho \neq \mathbf{1}} |a_\rho(\beta)|\, |\chi_\rho(g)| \leq \sum_{\rho \neq \mathbf{1}} d_\rho |a_\rho(\beta)| = \eta(\beta).$$

□

Definition 9462.1032 (Local contraction ledger)**.** *The local contraction ledger for a fixed block lattice and fixed expansion rule records a constant $C_{\mathrm{loc}} < \infty$ bounding all local Haar integral contractions, intertwiner multiplicities, orientation choices, and nearest-neighbour representation couplings produced by one plaquette step of a connected tube. It asserts that the total local contraction factor for a tube Σ is at most $C_{\mathrm{loc}}^{|\Sigma|}$.*

Theorem 9462.1033 (Strong-coupling tube weight area decay)**.** *Assume the strong-coupling character ledger and the local contraction ledger. For every connected tube Σ,*

$$|w(\Sigma)| \leq (C_{\mathrm{loc}}\eta(\beta))^{|\Sigma|}.$$

If $C_{\mathrm{loc}}\eta(\beta) < 1$, then tube weight area decay holds with

$$\sigma(\beta) = -\log(C_{\mathrm{loc}}\eta(\beta)) > 0.$$

Proof. A connected tube of area $|\Sigma|$ contains exactly that many non-trivial plaquette excitation rows. By Definition 9462.1031, each such plaquette contributes at most $\eta(\beta)$ in absolute value before local edge integrations are accounted for. The local contraction ledger bounds all Haar-integration and intertwiner factors by $C_{\mathrm{loc}}^{|\Sigma|}$. Hence

$$|w(\Sigma)| \leq C_{\mathrm{loc}}^{|\Sigma|}\eta(\beta)^{|\Sigma|} = (C_{\mathrm{loc}}\eta(\beta))^{|\Sigma|}.$$

When $C_{\mathrm{loc}}\eta(\beta) < 1$, this is $e^{-\sigma(\beta)|\Sigma|}$ with the stated value of $\sigma(\beta)$. □

Theorem 9462.1034 (Strong coupling dominates tube entropy)**.** *For the entropy constant κ of Definition 9462.1027, there is a strong-coupling range in which*

$$\sigma(\beta) > \kappa.$$

Proof. By Definition 9462.1030, $\eta(\beta) \to 0$ as $\beta \to 0$. Therefore $C_{\mathrm{loc}}\eta(\beta) \to 0$, and

$$\sigma(\beta) = -\log(C_{\mathrm{loc}}\eta(\beta)) \to +\infty.$$

Thus $\sigma(\beta) > \kappa$ holds throughout a sufficiently strong-coupling range. □

Definition 9462.1035 (Strong-coupling tube area-law certificate)**.** *A strong-coupling tube area-law certificate is the block tube area-law certificate whose area row is supplied by Definition 9462.1025, whose entropy row is supplied by Definition 9462.1027, and whose weight row is supplied by Definition 9462.1033, with $\sigma(\beta) > \kappa$ as in Definition 9462.1034.*

Theorem 9462.1036 (Strong-coupling block mass-gap surface)**.** *At fixed block scale, a strong-coupling tube area-law certificate gives the filtered uniform Wilson gap certificate and hence the fixed-sector Hilbert gap of Definition 9462.1016.*

Proof. The strong-coupling tube area-law certificate is a block tube area-law certificate by construction. Therefore Definition 9462.1015 gives filtered uniform Wilson decay with exponent

$$m_0 = (\sigma(\beta) - \kappa)c_* > 0.$$

The fixed-sector Hilbert gap follows from Definition 9462.1016. Any soft residual escaping fixed packet surfaces is not hidden by this finite layer; it is a packet-complexity, infrared, ultraviolet, topological, or renormalization tail row for the bridge layer. □

Definition 9462.1037 (Tube domination defect)**.** *Fix the entropy exponent κ from Definition 9462.1027. For a proposed decay exponent $\sigma > 0$, the tube defect of a connected tube is*

$$\mathfrak{D}_\sigma(\Sigma) = e^{\sigma|\Sigma|}|w(\Sigma)|.$$

A tube domination defect is present when no exponent $\sigma > \kappa$ admits a uniform bound

$$\mathfrak{D}_\sigma(\Sigma) \leq C$$

over the fixed block scale, fixed packet class, and fixed tube adjacency surface.

Definition 9462.1038 (Tube closure certificate)**.** *A tube closure certificate at fixed block scale consists of three ledger rows. The finite-detection row says that every bounded-complexity tube domination defect is detected by a finite Wilson or spin-network packet read. The tail-ledger row says that every domination defect escaping all bounded tube-complexity surfaces enters the packet-complexity, infrared, ultraviolet, topological, or renormalization tail ledger. The closedness row says that an accepted closed Yang–Mills bridge packet carries no unresolved tube-defect tail ledger as hidden content.*

Theorem 9462.1039 (Tube defect localization)**.** *If tube domination fails at fixed block scale, then the failure has a finite or tail address: either some bounded tube-complexity surface carries a finite tube defect, or there is a defect sequence whose tube areas escape every fixed bound and therefore belongs to the tube tail ledger.*

Proof. Failure of domination means that for each $\sigma > \kappa$ and each constant C there is a connecting tube with

$$|w(\Sigma)| > Ce^{-\sigma|\Sigma|}.$$

Fix one $\sigma_0 > \kappa$. Then there is a sequence Σ_n such that

$$e^{\sigma_0|\Sigma_n|}|w(\Sigma_n)| \to \infty.$$

If the areas $|\Sigma_n|$ are bounded along a subsequence, then all those tubes lie in one finite tube-complexity surface. Since the packet support, block dimension, and plaquette adjacency are fixed, only finitely many bounded tube patterns occur up to the displayed finite neighbourhood data. Thus a finite tube pattern carries the defect address.

If no bounded-area subsequence exists, then $|\Sigma_n| \to \infty$ along a subsequence. The defect has not disappeared; it has left every fixed tube-complexity surface. By the tail-ledger discipline, this is precisely a tube complexity, infrared, ultraviolet, topological, or renormalization tail row. These are the only two possibilities. □

Theorem 9462.1040 (Tube closure forces block tube area law)**.** *At fixed block scale, a Yang–Mills bridge packet with three-properties ledger discipline, closedness, and a tube closure certificate cannot have a hidden tube domination defect. Hence the block tube area-law weight row holds for some $\sigma > \kappa$ on the declared fixed packet surface.*

Proof. Assume that no such $\sigma > \kappa$ exists. By Definition 9462.1039, there is either a finite tube defect or a tail tube defect. In the finite case, the finite-detection row of Definition 9462.1038 makes the defect visible to a finite Wilson or spin-network packet read; that read must be ledgered, and an unledgered read violates the three-properties discipline. In the tail case, the tail-ledger row requires the defect to enter the appropriate tail ledger. Carrying that unresolved tail ledger contradicts closedness, while omitting it violates ledger discipline. Both cases contradict the stated assumptions. Therefore a hidden tube domination defect is impossible, and a block tube area-law weight row with $\sigma > \kappa$ is forced on the declared fixed surface. □

Corollary 9462.1041 (Tube closure gives the fixed-block gap route)**.** *Together with the tube area lower bound, tube entropy bound, Wilson completeness, and the Hilbert spectral bridge of Definition 9462.1019, a tube closure certificate gives the fixed-block Yang–Mills mass-gap route. The continuum claim still requires a renormalization certificate preserving this fixed block closure and exposing every ultraviolet, infrared, topological, complexity, or renormalization residual.*

Proof. The tube closure theorem supplies the missing weight row with $\sigma > \kappa$. The tube area lower bound and entropy bound then give the block tube area-law certificate, and Definition 9462.1015 gives filtered uniform Wilson decay. The Hilbert spectral bridge turns that decay into a fixed-sector non-vacuum spectral lower bound, except for residuals explicitly recorded in the tail ledger. Passing from this fixed block surface to a continuum Clay-level statement is therefore exactly the renormalization stability question, not an automatic consequence of the finite block proof. □

Theorem 9462.1042 (Tube geometry and weight give block area law)**.** *For a fixed block scale and fixed blocked Wilson packet class, the tube area lower bound, tube entropy bound, and tube weight area decay with $\sigma > \kappa$ supply the block tube area-law certificate of Definition 9462.1014.*

Proof. Definition 9462.1025 gives the area row $|\Sigma| \geq c_* T - b_O$ for every connecting tube. Definition 9462.1027 gives the entropy row $N_O(n, T) \leq A_O e^{\kappa n}$. The tube weight area decay definition gives $|w(\Sigma)| \leq e^{-\sigma|\Sigma|}$. When $\sigma > \kappa$, these are exactly the three fields required by the block tube area-law certificate. □

Corollary 9462.1043 (Finite geometry part of the Yang–Mills gap bridge)**.** *At fixed block scale, the finite geometry part of the Yang–Mills mass-gap bridge is closed by Definition 9462.1025 and Definition 9462.1027. The remaining physical input is tube weight area decay with decay exponent strictly larger than the tube entropy exponent.*

Proof. The two geometry theorems depend only on the fixed block lattice, finite packet support, and finite plaquette adjacency. They do not use continuum limiting, gauge dynamics, or an unbounded packet window. Therefore the only non-combinatorial field left in the block tube area-law certificate is the physical decay row for tube weights, with the strict inequality $\sigma > \kappa$ needed by Definition 9462.1015. □

9462.28.15 Yang–Mills RG scale-tail closure

The fixed block tube certificates locate failures inside one declared physical block surface. The remaining renormalization question is whether a positive block gap can disappear only in the limit of the RG tower. In BEDC form this disappearance is not allowed to be silent: it must be a finite block tube defect, a finite Wilson or spin-network residual, or a scale-tail ledger row.

Definition 9462.1044 (Yang–Mills RG tower)**.** *A Yang–Mills RG tower at physical block scale $\ell_* > 0$ is a sequence of bridge packets*

$$\mathcal{Y}_n = (\Lambda_n, \ell_*, G, \mathcal{H}_n, \Omega_n, H_n, \mathcal{W}_{n,\mathrm{fin}}, L_n)$$

together with blocking rows

$$B_{n+1,n} : \mathcal{Y}_{n+1} \longrightarrow \mathcal{Y}_n$$

and a continuum target $\mathcal{Y}_\infty$. The displayed tower has the scale direction

$$\mathcal{Y}_0 \leftarrow \mathcal{Y}_1 \leftarrow \mathcal{Y}_2 \leftarrow \cdots \longrightarrow \mathcal{Y}_\infty.$$

Every $\mathcal{W}_{n,\mathrm{fin}}$ is a finite Wilson-loop or spin-network packet surface, and every L_n contains the ultraviolet, infrared, topological, gauge, packet-complexity, and scale-tail ledger rows visible at that layer.

Definition 9462.1045 (RG tube gap row)**.** *For a tower layer $\mathcal{Y}_n$, an RG tube gap row consists of displayed constants*

$$\sigma_n, \qquad \kappa_n, \qquad c_n$$

where σ_n is the tube weight area-decay exponent, κ_n is the tube entropy exponent, and c_n is the tube area lower-bound constant at the fixed physical block scale. When $\sigma_n > \kappa_n$ and $c_n > 0$, the corresponding physical decay rate is

$$m_n = \frac{(\sigma_n - \kappa_n)c_n}{\ell_*}.$$

The row is interpreted only at the displayed layer and block scale; changing the scale, packet window, or tower index is a ledgered operation.

Definition 9462.1046 (Uniform RG gap certificate)**.** *A uniform RG gap certificate for Definition 9462.1044 consists of a number $m_* > 0$ and an index N such that every layer $n \geq N$ has an RG tube gap row with*

$$m_n \geq m_*.$$

Equivalently, on the displayed tail of the tower,

$$\frac{(\sigma_n - \kappa_n)c_n}{\ell_*} \geq m_* > 0.$$

Definition 9462.1047 (RG scale-tail defect)**.** *An RG scale-tail defect is a tower tail for which every sufficiently late finite layer still has a positive displayed rate $m_n > 0$, but no uniform positive lower bound exists:*

$$\inf_{n \geq N} m_n = 0$$

for every N. A scale-tail ledger row records a subsequence and the degrading certificate data

$$n_j \to \infty, \qquad m_{n_j} \to 0, \qquad (\sigma_{n_j}, \kappa_{n_j}, c_{n_j}, L_{n_j}).$$

This row says that the loss of gap is not visible inside any one fixed finite block layer, but appears only as the tower index escapes every fixed tail cutoff.

Theorem 9462.1048 (Finite RG tube defect is visible or ledgered)**.** *If a finite layer of a Yang–Mills RG tower fails to supply a positive tube gap row, then the failure has a finite Wilson or spin-network packet address or a tube tail ledger address inside that same finite layer.*

Proof. At a fixed tower layer, the block scale, packet class, plaquette adjacency, and tube complexity surface are fixed data. If $\sigma_n \leq \kappa_n$, then the tube weight decay cannot dominate the tube entropy on that surface. If $c_n = 0$, the tube area lower-bound row does not force linear separation in block time. In either case the block tube area-law certificate fails at a finite layer. Applying Definition 9462.1039 at that layer gives the two permitted addresses: a bounded tube-complexity defect detected by a finite Wilson or spin-network packet read, or a tube tail row recorded in the layer ledger. □

Theorem 9462.1049 (RG scale-tail localization)**.** *If a Yang–Mills RG tower has no uniform RG gap certificate, then either some finite layer has a finite RG tube defect, or the tower has an RG scale-tail defect.*

Proof. The absence of a uniform certificate means that no $m_* > 0$ bounds the displayed rates on all sufficiently late layers. If infinitely many late layers fail the positivity conditions $\sigma_n > \kappa_n$ and $c_n > 0$, then one of those layers is a finite RG tube defect.

Otherwise there is an index N such that every $n \geq N$ has $m_n > 0$. Since no uniform lower bound exists, for every j there is $n_j \geq N$ with $m_{n_j} < 1/j$. Passing to an increasing subsequence gives

$$n_j \to \infty, \qquad m_{n_j} \to 0.$$

This is exactly the RG scale-tail defect of Definition 9462.1047. These alternatives exhaust the failure of uniform positivity. □

Definition 9462.1050 (RG scale-tail closure certificate)**.** *An RG scale-tail closure certificate for a Yang–Mills RG tower consists of three rows:*

- *a finite-layer row saying that every finite RG tube defect is handled by the tube closure certificate of that layer;*
- *a scale-tail row saying that every sequence $n_j \to \infty$ with $m_{n_j} \to 0$ enters the scale-tail ledger;*
- *a closedness row saying that the accepted continuum Yang–Mills packet carries no unresolved finite-layer or scale-tail defect as hidden content.*

Theorem 9462.1051 (RG scale-tail closure)**.** *Let a Yang–Mills RG tower have three-properties ledger discipline on every finite layer, tube closure certificates on finite layers, and an RG scale-tail closure certificate. If the continuum Yang–Mills packet is accepted as closed, then the tower has a uniform RG gap certificate.*

Proof. Assume that no uniform RG gap certificate exists. By Definition 9462.1049, either there is a finite RG tube defect or there is an RG scale-tail defect.

In the finite-layer case, Definition 9462.1048 gives a finite Wilson or spin-network packet address or a finite-layer tube tail address. The finite-layer row of Definition 9462.1050 sends this defect to the corresponding tube closure ledger. Omitting that ledger violates ledger discipline; carrying it unresolved contradicts closedness.

In the scale-tail case, the scale-tail row records the sequence $n_j \to \infty$ with $m_{n_j} \to 0$. Omitting that row violates ledger discipline, while carrying it unresolved contradicts the closedness row. Both alternatives contradict the stated assumptions. Therefore a uniform $m_* > 0$ and a tail index N must exist. □

Definition 9462.1052 (Spectral convergence certificate)**.** *A spectral convergence certificate from an RG tower to $\mathcal{Y}_\infty$ consists of comparison rows J_n for the physical Hilbert carriers and a vacuum row $J_n\Omega_n \to \Omega_\infty$ such that for every $f \in C_c((0,\infty))$,*

$$J_n f(H_n) J_n^* \longrightarrow f(H_\infty)$$

strongly on the displayed continuum Hilbert surface. Any failure of this strong convergence is a spectral-convergence defect and must enter the renormalization ledger.

Theorem 9462.1053 (Uniform RG gap passes to the continuum)**.** *Assume a Yang–Mills RG tower has a uniform RG gap certificate with constant $m_* > 0$ and has a spectral convergence certificate with no open spectral-convergence defect. Then the continuum physical Hilbert spectrum on $\Omega_\infty^\perp$ is disjoint from $(0, m_*)$.*

Proof. Let $f \in C_c((0, m_*))$. On every sufficiently late finite layer, the vacuum-orthogonal spectrum of H_n is contained in $[m_*, \infty)$. Since f is supported below m_* and away from the vacuum point, the operator $f(H_n)$ vanishes on the displayed physical surface after the vacuum row is removed. The spectral convergence certificate gives

$$J_n f(H_n) J_n^* \longrightarrow f(H_\infty).$$

The left side is eventually zero on the vacuum-orthogonal surface, hence $f(H_\infty)$ vanishes there. If the continuum vacuum-orthogonal spectrum met $(0, m_*)$, functional calculus would supply such an f with $f(H_\infty) \neq 0$ on that spectral subspace. This contradiction proves the claim. □

Corollary 9462.1054 (RG scale-tail closure gives the continuum gap route)**.** *For a Yang–Mills bridge packet with Wilson–Peter–Weyl completeness, finite-layer tube closure, RG scale-tail closure, spectral convergence, and closed tail ledgers, the continuum vacuum-orthogonal spectrum is bounded away from zero by some $m_* > 0$.*

Proof. Definition 9462.1051 supplies a uniform RG gap certificate. By Definition 9462.1053, spectral convergence transfers that uniform lower bound to the continuum Hilbert surface. Wilson–Peter–Weyl completeness identifies the finite packet surface with the declared dense gauge-invariant vacuum-orthogonal sector. Any residual outside that sector is an ultraviolet, infrared, renormalization, topological, gauge, packet-complexity, or scale-tail ledger row; closedness rejects it as hidden unfinished content. Hence the accepted continuum packet has a positive physical mass gap on the declared sector. □

Theorem 9462.1055 (Yang–Mills RG closure boundary)**.** *The RG side of the Yang–Mills mass-gap route is closed exactly by the combination of finite-layer tube closure, RG scale-tail closure, spectral convergence, Wilson–Peter–Weyl completeness, and closed tail ledgers. If a continuum gap failed under those hypotheses, the failure would have to be a finite Wilson packet residual, a finite tube domination defect, an RG scale-tail defect, an ultraviolet, infrared, topological, gauge, or packet-complexity tail defect, or a spectral-convergence defect.*

Proof. Finite-layer tube defects are localized by Definition 9462.1048. Loss of uniform positivity along the RG tower is localized by Definition 9462.1049. Once uniform positivity is present, the passage to the continuum is exactly the content of Definition 9462.1053; any failure of that passage is, by definition, a spectral-convergence defect. All other ways for a residual to escape the fixed packet surface are precisely the physical and packet-complexity tail ledgers already named in the Yang–Mills bridge packet. Thus a closed accepted object cannot let the mass gap vanish without producing one of the displayed addresses. □

9462.28.16 Channel encoding and genetic-code bridge

The relation between the BEDC channel compiler and biological genetic coding is structural rather than token-identical. The BEDC channel code is a minimal self-delimiting event-stream codec. The DNA and RNA genetic codes are fixed-frame biological translation codecs over finite alphabets. Both systems combine a finite alphabet, a local reading discipline, a boundary or stop class, and an interpretation layer, but the corresponding objects live at different layers.

This subsection is a vision-level scientific-model bridge. It is not a CheckedCert claim about molecular biology, and it does not turn a channel glyph into a biological base, codon, or biochemical law. Its governing discipline is the decode-first principle of Definition 9221.2: channel strings may be analyzed only after they have been decoded to source event flows.

Definition 9462.1056 (Active channel event)**.** *Let $\Sigma = \{0, 1\}$. A raw event is a finite word in Σ^*, and an event flow is a finite sequence of raw events. The active BEDC channel layer uses the Zeckendorf-safe body substitution*

$$\begin{aligned} \zeta(\epsilon) &= \epsilon, \\ \zeta(0w) &= 0\,\zeta(w), \\ \zeta(1w) &= 10\,\zeta(w), \end{aligned}$$

with event terminator 11*. The channel event associated to a raw event w is*

$$\mathsf{Ev}(w) = \zeta(w)\,11.$$

Definition 9462.1057 (Legal channel stream)**.** *A legal BEDC channel stream is a finite concatenation of channel events:*

$$\mathsf{LegalZStream} = \big((0 \mid 10)^*\,11\big)^*.$$

Equivalently, the active local channel rules are

$$\begin{aligned} \text{raw } 0 &\longmapsto 0, \\ \text{raw } 1 &\longmapsto 10, \\ \text{End} &\longmapsto 11. \end{aligned}$$

Theorem 9462.1058 (The active channel body has no terminator)**.** *For every raw event w, the encoded body $\zeta(w)$ contains no adjacent substring* 11*.*

Proof. The body is a finite concatenation of fragments from $\{0, 10\}$. Neither fragment contains 11. The only possible fragment junctions are 00, 010, 100, and 1010, and none of these contains 11. Hence no adjacent 11 occurs before the appended terminator. □

Corollary 9462.1059 (The first 11 is the channel terminator)**.** *For every raw event w, the first adjacent occurrence of* 11 *in $\mathsf{Ev}(w) = \zeta(w)\,11$ is the appended event terminator.*

Proof. By Definition 9462.1058, the encoded body has no adjacent 11. The only remaining adjacent 11 is the appended terminator. □

Theorem 9462.1060 (Channel round trip)**.** *For every event flow S, decoding the compiled channel stream recovers the original source event flow:*

$$\mathsf{Decode}(\mathsf{Compile}(S)) = \mathsf{some}(S).$$

On legal channel streams, Compile *and* Decode *form an inverse pair between* EventFlow *and* LegalZStream*.*

Proof. Each encoded event has a unique first 11 terminator by Definition 9462.1059. The stream decoder therefore segments a compiled string exactly at event boundaries, then decodes each body by the inverse local readings $0 \mapsto$ raw 0 and $10 \mapsto$ raw 1. This is the vision-level restatement of the checked channel bijection recorded in Definition 9208.19. □

Remark 9462.1061 (The rejected channel rule)**.** *The displayed rule* raw $1 \mapsto 01$ *is not the active BEDC channel rule. If it were paired with the same terminator* 11*, the event* 1 *would be displayed as* 0111*. A streaming decoder would consume the leading* 0 *as body data, read* 11 *as a terminator, and leave an isolated malformed* 1*. This is exactly the failure isolated by Definition 9208.15. The active rule* raw $1 \mapsto 10$ *avoids the collision.*

Theorem 9462.1062 (Layer separation for channel and source readings)**.** *The channel-level terminator* 11 *cannot be reinterpreted as a source-level raw substring, a source-level rewrite, a DNA base, a stop codon, or a theorem judgment without an explicit bridge.*

Proof. The source layer and the channel layer share displayed glyphs but not typing judgments. In the source layer, 11 may occur inside a raw event. In the channel layer, 11 marks the end of a channel-encoded event. By Definition 9209.27, a displayed channel substring is not, in general, a decoded source event. A biological or theorem-level reading therefore requires a separate bridge after decoding. □

Definition 9462.1063 (DNA four-phase alphabet bridge)**.** *The canonical DNA alphabet is the four-base alphabet*

$$\mathsf{DNA}_4 := \{\mathrm{A}, \mathrm{C}, \mathrm{G}, \mathrm{T}\}.$$

A DNA four-phase alphabet bridge is a conservative external readback from the BEDC product of two Bool-like interfaces to this external alphabet:

$$\beta_{\mathsf{DNA}} \colon \mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow} \rightsquigarrow \mathsf{DNA}_4.$$

One biologically meaningful readback uses one axis for purine versus pyrimidine shape and the other for AT-family versus GC-family pairing.

Concretized in §2260: Realizes the four-phase DNA alphabet readback as a conservative finite NameCert bridge.

Definition 9462.1064 (Complementation readback)**.** *Under the shape-family readback, the four displayed phases are*

$$\begin{aligned} \mathrm{A} &= (\text{purine}, \mathrm{AT}), \\ \mathrm{G} &= (\text{purine}, \mathrm{GC}), \\ \mathrm{T} &= (\text{pyrimidine}, \mathrm{AT}), \\ \mathrm{C} &= (\text{pyrimidine}, \mathrm{GC}). \end{aligned}$$

The biological complementation operation is then read as the partial external involution

$$\mathrm{comp}(\text{shape}, \text{family}) = (\mathrm{flip}(\text{shape}), \text{family}),$$

which displays $\mathrm{A} \leftrightarrow \mathrm{T}$ *and* $\mathrm{G} \leftrightarrow \mathrm{C}$.

Theorem 9462.1065 (DNA four-base product bridge)**.** *The canonical DNA alphabet has a natural conservative readback as a four-phase atlas over the product* $\mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow}$.

Proof. The interface $\mathsf{Bool}^{\uparrow}$ supplies a licensed two-endpoint BEDC finite data surface, and $\mathsf{Prod}^{\uparrow}$ supplies the displayed product discipline for componentwise finite data. The external biological bridge maps the four displayed pairs to A, C, G, and T. The bridge is conservative because the biological names remain target-side readbacks; they do not become BEDC primitives. □

Corollary 9462.1066 (Four as double distinction)**.** *Within this bridge, the displayed number* 4 *is read as a product of two binary distinctions rather than as a biological primitive:*

$$4 = 2 \times 2.$$

Proof. Each coordinate of $\mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow}$ is a binary classifier. The product has four displayed phase positions, and the biological readback assigns those positions to the four canonical bases. □

Definition 9462.1067 (DNA four-phase bridge certificate template)**.** *At vision strength, the paper certificate template for the four-phase DNA alphabet has the form*

$$\mathsf{NameCert}(\mathsf{DNA4Alphabet}^{\uparrow}) = (\mathsf{SourceSpec}, \mathsf{PatternSpec}, \mathsf{ClassifierSpec}, \mathsf{StabilityCert}, \mathsf{LedgerPolicy}).$$

The template records obligations for a conservative bridge target; it is not a completed paper certificate and not a checked Lean target.

Concretized in §5177: The decoded channel, DNA four-phase product, codon atlas, translation classifier, and stop-role boundary are realized as finite NameCert rows.

Definition 9462.1068 (DNA four-phase source and pattern fields)**.** *The source field consists of two previously licensed* $\mathsf{Bool}^{\uparrow}$ *interfaces combined through the* $\mathsf{Prod}^{\uparrow}$ *product interface, together with the external biological target* DNA_4*. The pattern field consists of the four visible product phases*

$$\begin{aligned} &(\text{purine}, \text{AT}), \quad (\text{pyrimidine}, \text{AT}), \\ &(\text{purine}, \text{GC}), \quad (\text{pyrimidine}, \text{GC}), \end{aligned}$$

and the complement involution

$$\text{comp}(\text{shape}, \text{family}) = (\text{flip}(\text{shape}), \text{family}).$$

The source is the BEDC product carrier; the DNA alphabet is an external readback target.

Definition 9462.1069 (DNA four-phase classifier, stability, and ledger fields)**.** *The classifier field is the componentwise* $\mathsf{Bool}^{\uparrow}$ *classifier on the product surface, together with external* β_{DNA} *readback rows. The stability field requires product carrier closure under the componentwise classifier, complement descent through the classifier, the involution law for complement, absence of fixed points on the four canonical rows, triple-product closure for the codon atlas, and translation-classifier respect for codon classification at the external bridge layer. The ledger policy is the displayed pair ledger for* $\mathsf{DNA4Alphabet}^{\uparrow}$*, the displayed triple ledger for the codon atlas, and the biological readback provenance* β_{DNA}*.*

Theorem 9462.1070 (Complement is a fixed-point-free involution)**.** *For*

$$\text{comp}(\text{shape}, \text{family}) = (\text{flip}(\text{shape}), \text{family}),$$

the composite $\text{comp} \circ \text{comp}$ *classifies with the identity on the product phase level. On the four canonical DNA rows, the complement map has no fixed point.*

Proof. The first coordinate is flipped twice, so it returns to its original classifier value, while the second coordinate is preserved. Since flip has no fixed point on the two visible shape phases, the product map has no fixed point on the four canonical rows. □

Corollary 9462.1071 (Watson–Crick complement as product-axis flip)**.** *Under* β_{DNA}*, the complement map reads externally as*

$$\text{A} \leftrightarrow \text{T}, \qquad \text{G} \leftrightarrow \text{C}.$$

Proof. A and T share the AT-family coordinate and differ in shape; G and C share the GC-family coordinate and differ in shape. Flipping shape while preserving family gives the displayed pairings. □

Definition 9462.1072 (Codon phase atlas)**.** *The codon phase atlas is the triple product of the DNA four-phase alphabet:*

$$\mathsf{Codon}_{64}^{\uparrow} := (\mathsf{DNA}_4^{\uparrow})^3.$$

Its external biological classifier separates amino-acid-emitting codons from stop codons.

Corollary 9462.1073 (Codon phase-space bridge)**.** *The codon layer has* 64 *displayed phase positions.*

Proof. The bridge target has four DNA phases, and a codon is a triple of such phases. Therefore its displayed phase space has cardinality

$$4^3 = 64.$$

The stop classifier is an external biological partition of this phase-space. It is not the BEDC channel terminator. □

Definition 9462.1074 (Genetic translation classifier)**.** *A genetic translation classifier is an external biological classifier of the form*

$$\mathsf{TranslateClassifier} : \mathsf{Codon}_{64}^{\uparrow} \rightsquigarrow \mathsf{AminoAcid}^{\uparrow} \oplus \mathsf{Stop}^{\uparrow}.$$

It may be many-to-one: distinct codon positions may classify to the same amino-acid class. The original codon remains part of the ledger.

Definition 9462.1075 (Genetic-code ledger)**.** *A genetic-code ledger records the original codon triple, its three* $\mathsf{DNA4Alphabet}^{\uparrow}$ *component positions, the translation-classifier output, whether that output is amino-acid emitting or stop, and the external biological bridge provenance used to read each BEDC phase as a biological base.*

Theorem 9462.1076 (Translation is a classifier quotient)**.** *Genetic translation, at this bridge strength, is represented by a classifier from the codon atlas to amino-acid or stop classes, and that classifier may be many-to-one.*

Proof. A codon position is source-side phase material for the bridge. An amino-acid or stop class is the classified visible output. Multiple codon positions may classify to the same amino-acid class. BEDC reads this as classifier quotient rather than as source erasure because Definition 9462.1075 keeps the original codon triple and component readbacks visible. □

Corollary 9462.1077 (Synonymous codons are ledger-preserving compression)**.** *If two codons classify to the same amino-acid class, the visible translation meaning is compressed while each original codon remains in the ledger.*

Proof. This is the biological bridge instance of BEDC compression with memory: classification may hide distinctions at the visible meaning level, but the source map remains recoverable through the ledger. □

Corollary 9462.1078 (Codon length and alphabet size generate the phase space)**.** *The codon layer combines binary distinction, double distinction, a three-position reading window, and a stop classifier:*

$$2 = \textit{binary distinction},$$
$$4 = 2 \times 2 = \textit{DNA four-phase alphabet},$$
$$4^3 = 64 = \textit{codon phase space}.$$

Definition 9462.1079 (Stop-role bridge)**.** *The stop-role bridge relates two typed termination roles:*

$$\mathsf{ChannelEndRole}(11): \ \textit{event-boundary termination},$$
$$\mathsf{GeneticStopRole}(\text{codon}): \ \textit{protein-translation termination}.$$

The bridge asserts role analogy under finite-stream reading, not identity of tokens.

Theorem 9462.1080 (Stop-role analogy is not token identity)**.** *The BEDC channel terminator and biological stop codons have the same abstract role of ending a finite reading process, but they are not the same object.*

Proof. The BEDC terminator 11 ends one channel-encoded raw event inside $\mathsf{LegalZStream}$. A biological stop codon ends protein synthesis inside a codon reading frame. The former is a channel-boundary marker; the latter is a translation-class marker in an external biological model. Hence the licensed relation is role-equivalence under a conservative bridge, not token identity. □

Theorem 9462.1081 (Channel/genetic bridge cannot-claim boundary)**.** *The channel/genetic-code bridge does not license any of the following claims:*

- *that BEDC channel encoding is DNA;*
- *that the channel glyph pair* 11 *is a DNA or RNA stop codon;*
- *that* 01 *is the active BEDC encoding of raw* 1*;*
- *that a DNA base can be read directly from a compiled BEDC channel substring;*
- *that a biological bridge replaces BEDC NameCert obligations;*
- *that* $\mathsf{DNA4Alphabet}^{\uparrow}$ *is already a checked BEDC theorem;*
- *that the codon classifier is already a checked BEDC theorem.*

Proof. The active channel rule for raw 1 is 10, not 01, by Definition 9462.1057. Channel substrings must be decoded before source analysis by Definition 9462.1062. The DNA and codon readings are external scientific-model bridges in the sense of Definition 9462.949, and bridge targets do not replace internal certificates by Definition 9462.964. The certificate fields in Definition 9462.1067 are displayed as a vision-strength template, so they do not by themselves supply a checked theorem for either the DNA alphabet bridge or the translation classifier. □

Corollary 9462.1082 (Allowed bridge claim)**.** *The allowed claim is that BEDC channel encoding supplies a minimal self-delimiting event-stream skeleton, while DNA and RNA genetic coding supply biological fixed-frame translation systems. Their formal relation is a conservative finite-reading and stop-role bridge mediated by decoding, the product surface* $\mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow}$*, and the codon phase atlas.*

Corollary 9462.1083 (Minimal channel skeleton and biological parser)**.** *The BEDC channel parser and the genetic-code parser share a finite reading motif:*

$$0 \longmapsto \text{emit raw } 0, \qquad 10 \longmapsto \text{emit raw } 1, \qquad 11 \longmapsto \text{stop current event},$$
$$\text{codon} \longmapsto \text{emit amino acid}, \qquad \text{stop codon} \longmapsto \text{stop protein synthesis}.$$

The shared structure is finite stream, local reading rule, stop class, and ledger. The objects remain layer-distinct.

9462.28.17 Codons as six-bit finite windows

The four-phase DNA and RNA bridge of subsection 9462.28.16 has a direct finite-window reading. A codon is a three-position word over a four-phase alphabet. Once each base is read through two binary axes, a codon is exactly a six-bit window at the source-space level:

$$4^3 = 64 = 2^6.$$

This is the strongest window-six contact point. It is a source-space isomorphism, not an identification of the genetic-code translation table with a BEDC fold table.

Definition 9462.1084 (Codon six-bit source atlas)**.** *Let*

$$\mathsf{RNA4Alphabet}^{\uparrow} := \mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow}$$

be read externally by the two axes of Definition 9462.1094. The codon source atlas is

$$\mathsf{Codon64}^{\uparrow} := (\mathsf{RNA4Alphabet}^{\uparrow})^3.$$

The six-bit flattening map is the displayed reassociation

$$\mathsf{Flat}_6 : (\mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow})^3 \rightsquigarrow (\mathsf{Bool}^{\uparrow})^6,$$

which reads a codon as three consecutive two-bit blocks.

Theorem 9462.1085 (Codon source space is a six-bit window)**.** *At the source-space level, the codon atlas has the same finite carrier size as the six-bit binary window:*

$$\left|(\mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow})^3\right| = |(\mathsf{Bool}^{\uparrow})^6| = 64.$$

Proof. Each $\mathsf{Bool}^{\uparrow}$ coordinate has two visible endpoints. Hence $\mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow}$ has $2 \cdot 2 = 4$ visible phases, and a triple of such phases has $4^3 = 64$ visible positions. Reassociation exposes the same six binary coordinates, whose carrier size is $2^6 = 64$. □

Definition 9462.1086 (RNA two-axis binary display)**.** *Using the shape-family readback*

$$\mathrm{U} = 00, \quad \mathrm{C} = 01,$$
$$\mathrm{A} = 10, \quad \mathrm{G} = 11,$$

the four codons in the $\mathrm{U} + \mathrm{RR}$ *square flatten as*

codon	Flat_6 *display*
UAA	00 10 10
UAG	00 10 11
UGA	00 11 10
UGG	00 11 11

The DNA coding-strand display is obtained by replacing the first U *with* T*; the six-bit source calculation is unchanged.*

Definition 9462.1087 (Window-six Zeckendorf target)**.** *The window-six source space is*

$$\Omega_6 := \{0,1\}^6.$$

Its Zeckendorf-legal no-adjacent subspace is

$$X_6 := \{w \in \Omega_6 \mid w \text{ has no adjacent } 11\}.$$

*For a length-six binary path, the no-adjacent-*1 *count is the Fibonacci count* $F_8 = 21$*. This is the same finite-path no-adjacent pattern carried by the* $\mathsf{FibonacciCube}^{\uparrow}$ *packet of chapter 401.*

Corollary 9462.1088 (Two parallel 64-to-21 readings)**.** *The window-six no-adjacent target and the standard genetic-code bridge share the same coarse source-and-class count:*

$$\begin{aligned} \textit{window-six fold:}\quad & 64 \textit{ binary source positions} \rightsquigarrow 21 \textit{ no-adjacent window types},\\ \textit{standard genetic code:}\quad & 64 \textit{ codons} \rightsquigarrow 20 \textit{ amino-acid classes} + 1 \textit{ stop class.} \end{aligned}$$

This is a count-and-window analogy. It is not equality of classifiers or equality of fiber ledgers.

Concretized in §2234: The codon source atlas is realized as a six-coordinate BoolUp finite-window NameCert packet with Flat6 readback.

Concretized in §8421: The local stop-face classifier realizes the U+RR face, UGG exclusion, six-bit atlas, transport, replay, provenance, and NameCert rows.

Theorem 9462.1089 (The two 64-to-21 ledgers are not the same table)**.** *The window-six fold and the standard genetic-code translation classifier are not the same map.*

Proof. The window-six fold is a finite binary-window classifier whose target is the no-adjacent finite-path surface X_6. The standard genetic-code translation classifier is an external biological bridge from codons to amino-acid classes plus a stop class. Even when both displays have source size 64 and target-class count 21, their fibers are governed by different ledgers: the window fold records its own finite binary collision rows, while the genetic code records biological degeneracy rows, including singleton, doublet, triplet, quartet, and sextet amino-acid classes in the standard table. A shared count therefore does not license identity of maps. □

Theorem 9462.1090 (Global no-11 is not the stop-codon classifier)**.** *The standard stop codons are not obtained by applying the global no-adjacent-*11 *predicate to the entire flattened six-bit codon.*

Proof. By Definition 9462.1086, the relevant flattened strings are

$$\begin{aligned} \mathrm{UAA} &\longmapsto 001010,\\ \mathrm{UAG} &\longmapsto 001011,\\ \mathrm{UGA} &\longmapsto 001110,\\ \mathrm{UGG} &\longmapsto 001111. \end{aligned}$$

The string 001010 has no adjacent 11, but 001011, 001110, and 001111 do contain adjacent 11. Thus a global no-adjacent predicate on Ω_6 would keep only UAA among the three standard stop codons. The stop-codon reconstruction of Definition 9462.1100 instead applies the no-11 motif locally to the family suffix in the $\mathrm{U} + \mathrm{RR}$ square. □

Definition 9462.1091 (Local suffix rule inside the six-bit atlas)**.** *Inside the six-bit codon atlas, the stop reconstruction uses the following typed local rule:*

$$\textit{select the } \mathrm{U}+\mathrm{RR} \textit{ sector},$$
$$\textit{project positions } 2 \textit{ and } 3 \textit{ to the family axis},$$
$$\textit{exclude only the suffix } 11.$$

Equivalently,

$$\{\mathrm{AA}, \mathrm{AG}, \mathrm{GA}, \mathrm{GG}\} \longmapsto \{00, 01, 10, 11\}$$

and the Zeckendorf-legal suffixes are 00*,* 01*, and* 10*. The excluded corner is* GG*, so the surviving codons are* UAA*,* UAG*, and* UGA*.*

Theorem 9462.1092 (Codon-window bridge cannot-claim boundary)**.** *The codon-window bridge does not license any of the following claims:*

- *that the biological genetic code is the window-six fold;*
- *that the standard translation table is obtained by quotienting* Ω_6 *by the no-adjacent predicate;*
- *that the standard stop codons are exactly the globally no-adjacent flattened codons;*
- *that the equality* $4^3 = 2^6$ *supplies a biological derivation of codon length three;*
- *that a shared* 64*-to-*21 *count identifies the two fiber distributions;*
- *that* $\mathrm{G} = 11$ *in the bridge readback is the BEDC channel terminator.*

Proof. The first five refusals follow from Definition 9462.1089 and Definition 9462.1090. The last refusal follows from the layer-separation theorem Definition 9462.1107: the displayed binary readback of a biological base and the BEDC channel terminator occupy different typed layers. □

Corollary 9462.1093 (Allowed codon-window claim)**.** *A codon is naturally a six-bit finite window once the four DNA or RNA bases are read as two binary axes. The window-six bridge gives the source-space isomorphism*

$$\mathsf{Codon64}^{\uparrow} \cong \Omega_6,$$

and it explains why the numbers 64*,* 21*, and the no-*11 *motif are structurally adjacent. The stop-codon theorem remains local: in the* $\mathrm{U}+\mathrm{RR}$ *sector, excluding the family suffix* 11 *removes* UGG *and leaves the standard stop-codon L-shape* $\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$*.*

9462.28.18 Stop codons as Zeckendorf-legal family suffixes

The stop-codon bridge refines subsection 9462.28.16 at the codon boundary. It is a conditional biological bridge, not a checked BEDC theorem and not a derivation of the biological genetic code from Zeckendorf coding alone. Once a two-axis RNA or DNA readback, a three-base codon window, and the standard genetic-code bridge are fixed, the standard stop codons are exactly the Zeckendorf-legal corners of a distinguished two-bit family suffix.

Definition 9462.1094 (Two-axis RNA base readback)**.** *Let the shape axis have visible values* Y *and* R*, read externally as pyrimidine and purine, and let the family axis have visible values* W *and* S*, read externally as AU-family and GC-family. The RNA four-phase atlas is*

$$\mathsf{RNA4Alphabet}^{\uparrow} := \mathrm{Shape} \times \mathrm{Family}.$$

The external biological readback is

$$\begin{aligned} \mathrm{U} &= (\mathrm{Y}, \mathrm{W}), \\ \mathrm{C} &= (\mathrm{Y}, \mathrm{S}), \\ \mathrm{A} &= (\mathrm{R}, \mathrm{W}), \\ \mathrm{G} &= (\mathrm{R}, \mathrm{S}). \end{aligned}$$

After choosing $\mathrm{Y} = 0$, $\mathrm{R} = 1$, $\mathrm{W} = 0$, *and* $\mathrm{S} = 1$, *this displays*

$$\begin{aligned} \mathrm{U} &= 00, \\ \mathrm{C} &= 01, \\ \mathrm{A} &= 10, \\ \mathrm{G} &= 11. \end{aligned}$$

This is a bridge readback from a product of licensed binary classifiers; it is not a BEDC assertion that biological bases are primitive binary strings.

Definition 9462.1095 (Purine-purine stop square)**.** *The purine-purine stop square is the four-codon region*

$$\begin{aligned} \mathsf{UPurPur} &:= \{\mathrm{U}xy \mid x \in \{\mathrm{A}, \mathrm{G}\}, y \in \{\mathrm{A}, \mathrm{G}\}\} \\ &= \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\}. \end{aligned}$$

Equivalently, it is the codon-cube corner cut out by

$$c_1 = \mathrm{U}, \\ \mathrm{shape}(c_2) = \mathrm{R}, \qquad \mathrm{shape}(c_3) = \mathrm{R}.$$

Definition 9462.1096 (Family suffix)**.** *For a codon* $\mathrm{U}xy$ *with* $x, y \in \{\mathrm{A}, \mathrm{G}\}$, *its family suffix is the two-bit projection of the second and third positions to the family axis:*

$$\mathsf{FamSuffix}(\mathrm{U}xy) := \mathrm{family}(x)\,\mathrm{family}(y).$$

Thus

$$\begin{aligned} \mathsf{FamSuffix}(\mathrm{UAA}) &= 00, \\ \mathsf{FamSuffix}(\mathrm{UAG}) &= 01, \\ \mathsf{FamSuffix}(\mathrm{UGA}) &= 10, \\ \mathsf{FamSuffix}(\mathrm{UGG}) &= 11. \end{aligned}$$

Definition 9462.1097 (Zeckendorf-legal family suffix)**.** *A length-two family suffix is Zeckendorf-legal when it is not the high-high corner:*

$$\mathsf{ZLegal}_2(s) \;:\Longleftrightarrow\; s \neq 11.$$

*This imports only the Zeckendorf no-*11 *motif. It does not import the BEDC channel token* 11 *into the biological layer.*

Definition 9462.1098 (Zeckendorf stop-candidate classifier)**.** *The Zeckendorf stop-candidate classifier is*

$$\begin{aligned} \mathsf{ZStopCandidate}(c_1, c_2, c_3) :\Longleftrightarrow\; & c_1 = \mathrm{U} \\ & \wedge\, \mathrm{shape}(c_2) = \mathrm{R} \\ & \wedge\, \mathrm{shape}(c_3) = \mathrm{R} \\ & \wedge\, \mathsf{ZLegal}_2(\mathsf{FamSuffix}(c_1, c_2, c_3)). \end{aligned}$$

Equivalently, this classifier reads

$$\mathrm{U} + \mathrm{RR} + \textit{not-family}\text{-}11.$$

Definition 9462.1099 (Standard stop bridge)**.** *A standard stop bridge is an external biological bridge*

$$\beta_{\mathsf{StopStd}} : \mathsf{ZStopCandidate} \rightsquigarrow \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$$

equipped with a ledger recording the RNA or DNA notation choice, the two-axis base readback, the codon triple, the family suffix, the standard-code table, the exclusion of UGG *as the family-*11 *corner, and the variant-code caveat.*

Theorem 9462.1100 (Three-stop reconstruction)**.** *Under the two-axis RNA readback and the Zeckendorf-legal family-suffix condition,*

$$\mathsf{ZStopCandidate} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}.$$

Proof. The $\mathrm{U} + \mathrm{RR}$ region contains exactly four codons:

$$\mathrm{UAA}, \quad \mathrm{UAG}, \quad \mathrm{UGA}, \quad \mathrm{UGG}.$$

Projecting the last two positions to the family axis gives

$$\begin{aligned} \mathrm{AA} &\longmapsto 00, \\ \mathrm{AG} &\longmapsto 01, \\ \mathrm{GA} &\longmapsto 10, \\ \mathrm{GG} &\longmapsto 11. \end{aligned}$$

The Zeckendorf-legal length-two suffixes are exactly 00, 01, and 10. The surviving codons are therefore UAA, UAG, and UGA, while UGG is the unique excluded corner. □

Corollary 9462.1101 (Why three and not four)**.** *Inside the* $\mathrm{U}+\mathrm{RR}$ *square, the Zeckendorf-family legality filter excludes exactly one of four raw corners. Hence the visible stop class has size three:*

$$|\mathsf{ZStopCandidate}| = 4 - 1 = 3.$$

Corollary 9462.1102 (The excluded corner)**.** *In the standard-code bridge,*

$$\mathrm{UGG} \notin \mathsf{ZStopCandidate}.$$

Proof. The codon UGG has purine-purine suffix GG, whose family projection is 11. Since $\mathsf{ZLegal}_2(11)$ is false, UGG is excluded. In the standard genetic-code bridge, this agrees with the external biological assignment of UGG to tryptophan rather than to stop. □

Corollary 9462.1103 (Release-factor L-shape bridge)**.** *For the standard bacterial release-factor bridge, the two recognition arms have the same L-shape inside the* $\mathrm{U} + \mathrm{RR}$ *square:*

$$\begin{aligned} \mathsf{RF1} &= \{\mathrm{UAA}, \mathrm{UAG}\}, \\ \mathsf{RF2} &= \{\mathrm{UAA}, \mathrm{UGA}\}, \\ \mathsf{RF1} \cup \mathsf{RF2} &= \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}. \end{aligned}$$

The stop set is the L-shape obtained by removing the GG *corner.*

Corollary 9462.1104 (RNA and DNA notation bridge)**.** *The same construction can be displayed in DNA coding-strand notation by replacing* U *with* T*:*

$$\textit{RNA stop set} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\},$$
$$\textit{DNA display} = \{\mathrm{TAA}, \mathrm{TAG}, \mathrm{TGA}\}.$$

The family-suffix calculation is unchanged; only the first-position pyrimidine symbol is displayed differently.

Definition 9462.1105 (Stop-candidate certificate fields)**.** *A paper certificate for* $\mathsf{ZStopCandidate}^{\uparrow}$ *or* $\mathsf{StopCodonBridge}^{\uparrow}$ *must expose five fields. The source field contains* $\mathsf{RNA4Alphabet}^{\uparrow} := \mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow}$*, the codon atlas* $(\mathsf{RNA4Alphabet}^{\uparrow})^3$*, the standard-code table bridge, and the RNA/DNA notation policy. The pattern field states first position* U*, purine shape in positions* 2 *and* 3*, and Zeckendorf-legal family suffix in positions* 2 *and* 3*. The classifier field identifies the standard-code bridge equality*

$$\mathsf{ZStopCandidate}(c) \iff c \in \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}.$$

Definition 9462.1106 (Stop-candidate stability and ledger fields)**.** *The stability field must preserve the construction under the chosen RNA/DNA notation bridge, the two-axis base readback, classifier transport for the stop-shape predicate, family-suffix readback for* ZLegal_2*, separation of the excluded* UGG *corner, and layer separation from the BEDC channel token* 11*. The ledger policy records the codon triple source, base-level shape and family bits, the family suffix for positions* 2 *and* 3*, the Zeckendorf-legality row, the standard-code reference, the* UGG *exclusion witness, the variant-code caveat, and the fact that no direct channel-token interpretation is used.*

Theorem 9462.1107 (No channel-token collapse)**.** *The family suffix* 11 *used to exclude* UGG *is not the BEDC channel terminator* $\mathrm{End} = 11$*.*

Proof. The BEDC channel terminator is a glyph-level boundary marker in the self-delimiting channel codec. The family suffix is a biological-bridge projection of the second and third bases of a codon through a two-axis alphabet classifier. They share a displayed binary pattern, but they occupy different typed layers. By Definition 9462.1062, the only licensed comparison is a role bridge; token identity is not licensed. □

Corollary 9462.1108 (Stop codons are classifier-level)**.** *The standard stop codons are classified at the codon layer:*

$$\mathsf{Codon}_{64}^{\uparrow} \rightsquigarrow \mathsf{AminoAcid}^{\uparrow} \oplus \mathsf{Stop}^{\uparrow}.$$

They are not obtained by scanning compiled BEDC channel substrings for 11*.*

Theorem 9462.1109 (Zeckendorf legality does not force the biological code)**.** *Zeckendorf legality alone does not prove that biology must use exactly* UAA*,* UAG*, and* UGA *as stop codons.*

Proof. The reconstruction requires external bridge choices: an RNA or DNA alphabet read as a four-phase product, the particular two-axis assignment of U, C, A, and G, codon length three, selection of the $\mathrm{U} + \mathrm{RR}$ square, the standard genetic-code table, and the no-11 family-suffix filter. Without those choices, Zeckendorf legality supplies only the abstract no-11 motif. It does not specify nucleotides, codons, release factors, or protein synthesis. □

Corollary 9462.1110 (Variant genetic codes remain bridge targets)**.** *Biological genetic-code variants may reassign one or more of the standard stop codons. Such variants do not refute Definition 9462.1100; they show that the theorem is a standard-code bridge rather than a universal biological law.*

Theorem 9462.1111 (Stop-codon suffix cannot-claim boundary)**.** *The stop-codon suffix bridge does not license any of the following claims:*

- *that Zeckendorf legality alone proves the biological genetic code;*
- *that BEDC* $\mathrm{End} = 11$ *is identical to a DNA or RNA stop codon;*
- *that the family suffix* 11 *in* UGG *is the channel terminator* 11*;*
- *that* UAA*,* UAG*, and* UGA *are stop codons in every biological genetic code;*
- *that* UGG *is tryptophan by BEDC logic alone;*
- *that* $\mathsf{ZStopCandidate}^{\uparrow}$ *is already a checked certificate;*
- *that a compiled BEDC channel substring directly denotes a nucleotide base.*

Proof. The first five refusals follow from Definition 9462.1109 and Definition 9462.1110. The channel-token refusals follow from Definition 9462.1107. The checked certificate refusal follows because Definition 9462.1105 and Definition 9462.1106 record paper obligations, not Lean targets. □

Corollary 9462.1112 (Allowed stop-codon suffix bridge claim)**.** *Under the two-axis RNA or DNA bridge and a Zeckendorf-style no-*11 *family-suffix legality condition, the standard stop-codon set is structurally reconstructed as*

$$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\},$$

with UGG *as the unique excluded family-*11 *corner.*

Concretized in §1374: The stop-codon Zeckendorf suffix bridge is realized as a finite codon-window NameCert packet with an explicit cannot-claim boundary.

9462.28.19 Research program for Zeckendorf-legal termination

The stop-codon suffix bridge of subsection 9462.28.18 gives a paper-level reconstruction of the standard stop set from a two-axis RNA readback and a no-11 family-suffix condition. The research program attached to that reconstruction has a narrower purpose: it separates the finite theorem that can be checked internally from the biological bridge evidence that must remain external, and it names the certificate fields needed before the bridge may be exported at stronger status.

The guiding question is why the standard stop codons UAA, UAG, and UGA appear together. In BEDC form, the question becomes whether the standard stop-codon set can be reconstructed as the Zeckendorf-legal part of the $\mathrm{U} + \mathrm{RR}$ square under a conservative two-axis bridge for RNA bases:

$$\mathsf{UPurineSquare} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\},$$
$$\mathrm{AA} \mapsto 00, \qquad \mathrm{AG} \mapsto 01, \qquad \mathrm{GA} \mapsto 10, \qquad \mathrm{GG} \mapsto 11.$$

The finite claim keeps 00, 01, and 10 and excludes the unique 11 corner. The biological claim then reads the surviving L-shape as the standard stop set.

Definition 9462.1113 (Conditional stop-codon reconstruction problem)**.** *The stop-codon reconstruction problem is the following conditional bridge target. Given*

- *the product atlas* $\mathsf{RNA4Alphabet}^{\uparrow} := \mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow}$*;*
- *the readback* $\mathrm{U} = (\mathrm{Y}, \mathrm{W})$*,* $\mathrm{C} = (\mathrm{Y}, \mathrm{S})$*,* $\mathrm{A} = (\mathrm{R}, \mathrm{W})$*, and* $\mathrm{G} = (\mathrm{R}, \mathrm{S})$*;*

- *codons as triples* $(\mathsf{RNA4Alphabet}^{\uparrow})^3$*;*
- *the stop-shape region* $\mathrm{U}+\mathrm{RR}$*;*
- *the family-suffix legality condition excluding* 11*;*
- *a standard-code biological bridge,*

prove that the reconstructed stop-candidate class is exactly

$$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}.$$

The problem is a bridge problem, not a kernel-level derivation of the biological genetic code.

Concretized in §1374: The finite U+RR suffix legality route is realized by the StopCodonZeckendorfSuffixUp NameCert surface.

Definition 9462.1114 (Research inputs)**.** *The BEDC-side inputs are the active channel theorem package of subsection 9462.28.16, the derived interfaces* $\mathsf{Bool}^{\uparrow}$ *and* $\mathsf{Prod}^{\uparrow}$*, classifier transport, displayed pair and triple ledgers, layer separation, and cannot-claim registry discipline. The biological inputs are external rows: RNA bases, three-position codons, the standard stop set, the assignment of* UGG *as a sense codon in the standard code, release-factor recognition data where used, and variant genetic-code tables where used.*

Definition 9462.1115 (Research subquestions)**.** *The program decomposes into nine subquestions:*

- *why adjacent* 11 *is the BEDC channel boundary pattern and which no-internal-*11 *theorem supports it;*
- *how RNA or DNA bases are read as a conservative* $\mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow}$ *target;*
- *how the triple product yields the* 64*-position codon atlas;*
- *why the standard stop set is analyzed inside the* $\mathrm{U}+\mathrm{RR}$ *square;*
- *whether excluding the family suffix* 11 *reconstructs exactly the three standard stop codons;*
- *how* UGG *functions as the excluded square corner while remaining a standard-code sense codon;*
- *how bacterial release-factor recognition arms compare with the same L-shape;*
- *which bridge field changes when a genetic-code variant reassigns a stop codon;*
- *which part is finite enumeration suitable for Lean checking and which part remains biological bridge evidence.*

Definition 9462.1116 (Four-phase stop-square data)**.** *The finite data of the stop square consists of a shape axis* $\{\mathrm{Y}, \mathrm{R}\}$*, a family axis* $\{\mathrm{W}, \mathrm{S}\}$*, the readback*

$$\begin{aligned} \mathrm{U} &= (\mathrm{Y}, \mathrm{W}), \quad \mathrm{C} = (\mathrm{Y}, \mathrm{S}), \\ \mathrm{A} &= (\mathrm{R}, \mathrm{W}), \quad \mathrm{G} = (\mathrm{R}, \mathrm{S}), \end{aligned}$$

and the family projection on the purine-purine suffix:

$$\mathrm{family}(\mathrm{A}) = 0, \qquad \mathrm{family}(\mathrm{G}) = 1.$$

Thus the second and third positions of the $\mathrm{U}+\mathrm{RR}$ *square display the binary family square* 00*,* 01*,* 10*,* 11*.*

Definition 9462.1117 (Research module boundaries)**.** *The program has six module boundaries.*

Channel termination. *Define the legal channel body, event marker, no-internal-*11 *theorem, first-*11 *terminator theorem, decode-compile inverse theorem, and layer-separation theorem.*

Four-phase alphabet bridge. *Package* $\mathsf{RNA4Alphabet}^{\uparrow}$ *as a product of two binary interfaces; record the two-axis biological readback, complement involution, codon triple product, and translation classifier as bridge data.*

Stop-codon enumeration. *Define the* U+RR *square, family suffix, Zeckendorf-legality predicate, and stop-candidate classifier; prove by four cases that* UGG *is the unique excluded corner.*

Release-factor bridge. *Record the standard bacterial recognition arms* $\{\mathrm{UAA}, \mathrm{UAG}\}$ *and* $\{\mathrm{UAA}, \mathrm{UGA}\}$ *as external data and compare their union with the reconstructed L-shape.*

Variant-code boundary. *Compare standard and alternative genetic-code tables by identifying which external bridge field changes: stop-shape region, translation classifier, release-factor bridge, or standard-code table.*

Formalization boundary. *Keep the finite enumeration over* $\mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow}$ *inside the checked layer, while keeping base names, biochemical translation, and empirical recognition data as external bridge rows.*

Theorem 9462.1118 (Finite stop-square enumeration target)**.** *Inside the* $\mathrm{U} + \mathrm{RR}$ *square, the predicate "family suffix is not* 11*" selects exactly* UAA*,* UAG*, and* UGA*.*

Proof. The square has four elements:

$$\mathrm{UAA}, \quad \mathrm{UAG}, \quad \mathrm{UGA}, \quad \mathrm{UGG}.$$

Their family suffixes are respectively 00, 01, 10, and 11. The predicate rejects exactly the fourth suffix. Hence the selected class is precisely

$$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}.$$

□

Corollary 9462.1119 (Distinguished non-stop corner)**.** *Within the standard-code bridge,* UGG *is the unique non-selected corner of the* $\mathrm{U} + \mathrm{RR}$ *square.*

Proof. By Definition 9462.1118, the only rejected family suffix is 11. The codon UGG is the unique square element whose second and third positions both have family bit 1. □

Theorem 9462.1120 (Variant-code deformation boundary)**.** *A genetic-code variant that reassigns one of the standard stop codons changes external biological bridge data rather than the finite enumeration of Definition 9462.1118.*

Proof. The enumeration uses only the two-axis readback, the U+RR square, and the no-11 family-suffix condition. A variant genetic code changes the biological interpretation of at least one codon position or recognition field. That change belongs to the translation classifier, the release-factor bridge, the standard-code table, or the chosen stop-shape bridge. It therefore alters the bridge target, not the four-case finite calculation. □

Definition 9462.1121 (Certificate ladder for the stop program)**.** *The vision-level program has three strength layers. At paper-certificate strength it supplies proofs of no-internal-*11*, first-*11 *termination, the finite stop-square enumeration, the excluded-corner result, and layer separation. At checked-certificate strength it supplies Lean definitions for the four-element alphabet, codons, the* U + RR *square, family suffix, Zeckendorf-legality predicate, and finite enumeration theorem. At biological-bridge strength it supplies the external standard genetic-code table, release-factor recognition rows, variant-code boundary report, and ledger statement forbidding host leakage.*

Definition 9462.1122 (External biological reference rows)**.** *The biological bridge report records external references as rows rather than as BEDC primitives. The minimum rows are: a standard stop-codon row recording the* 64 *codons,* 61 *amino-acid codons, and three standard stop signals; a genetic-code table row recording standard and alternative code tables, including RNA/DNA notation policy; and a release-factor row recording the bacterial* RF1 *and* RF2 *recognition arms when that comparison is used.*

Definition 9462.1123 (Lean finite skeleton)**.** *The internal finite theorem can be represented by a small closed alphabet, codon triples, and Boolean predicates:*

```
inductive Bit where
  | zero
  | one

abbrev Shape  := Bit
abbrev Family := Bit

structure Base where
  shape  : Shape
  family : Family

def U : Base := { shape := Bit.zero, family := Bit.zero }
def C : Base := { shape := Bit.zero, family := Bit.one }
def A : Base := { shape := Bit.one,  family := Bit.zero }
def G : Base := { shape := Bit.one,  family := Bit.one }

structure Codon where
  b1 : Base
  b2 : Base
  b3 : Base

def isPurine (b : Base) : Prop := b.shape = Bit.one
def familyBit (b : Base) : Bit := b.family

def UPurineSquare (c : Codon) : Prop :=
  c.b1 = U /\ isPurine c.b2 /\ isPurine c.b3

def ZLegalSuffix (c : Codon) : Prop :=
  not (familyBit c.b2 = Bit.one /\ familyBit c.b3 = Bit.one)

def ZStopCandidate (c : Codon) : Prop :=
```

```
UPurineSquare c /\ ZLegalSuffix c
```

The target theorem states that ZStopCandidate *is equivalent to membership in the three displayed codons* UAA*,* UAG*, and* UGA*. The proof is a finite case split over the second and third bases in* $\{\mathrm{A}, \mathrm{G}\}$*.*

Definition 9462.1124 (Stop-square diagram)**.** *The standard-code bridge target is displayed by the square*

	third A	*third* G
second A	UAA : 00 ✓	UAG : 01 ✓
second G	UGA : 10 ✓	UGG : 11 ×

The check marks denote Zeckendorf-legal family suffixes. The crossed corner is the unique high-high suffix. The diagram is a biological bridge target: the channel token 11 *and the family suffix* 11 *remain layer-distinct.*

Theorem 9462.1125 (Research-program cannot-claim boundary)**.** *The research program does not license any claim that Zeckendorf coding alone proves the biological genetic code, that the BEDC channel terminator is identical to a DNA or RNA stop codon, that the family suffix* 11 *is the channel terminator, that the standard stop codons are universal across all genetic codes, that* UGG *is tryptophan by BEDC logic alone, that* ZStopCandidate *is already checked, or that a compiled channel substring directly denotes a nucleotide base.*

Proof. The refusals are inherited from Definition 9462.1111. The present program only organizes the route from vision-strength reconstruction to finite enumeration and external bridge reporting; it does not discharge the external biological bridge fields or collapse the channel and codon layers. □

Corollary 9462.1126 (Allowed research-program claim)**.** *Under the two-axis RNA bridge and Zeckendorf-family suffix legality, the standard stop-codon set is structurally reconstructed as the L-shape*

$$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$$

inside the $\mathrm{U} + \mathrm{RR}$ *square. The theorem is conditional and layered: Zeckendorf supplies the no-*11 *pattern, BEDC supplies classifier and ledger discipline, and biology supplies the standard-code bridge target.*

9462.28.20 DNA window-six symbolic-physical dynamics

The codon-window bridge of subsection 9462.28.17 identifies a codon with a six-bit local source window, and the stop-codon bridge of subsection 9462.28.18 identifies the standard stop class as a Zeckendorf-legal L-shape inside the $\mathrm{U} + \mathrm{RR}$ square. The dynamic bridge adds a further discipline: DNA and RNA should not be treated merely as static code tables. They form a relative symbolic-physical layer with local windows, frames, stop boundaries, raw-codon ledgers, and state transitions executed through cellular machinery.

The word "relative" is load-bearing. Replication, transcription, repair, translation, release, accessibility changes, and chromatin updates are performed by polymerases, ribosomes, release factors, repair enzymes, chromatin proteins, tRNA pools, regulatory factors, and cellular context. The bridge therefore does not claim that DNA is a closed autonomous dynamics. It claims that DNA/RNA reading has a symbolic state space and transition surface rich enough to require its own ledger rather than collapsing into the final protein class.

Definition 9462.1127 (DNA window-six dynamics bridge)**.** *A DNA window-six dynamics bridge is a conservative biological bridge whose source field contains RNA or DNA sequence histories together with the two-axis base readback of Definition 9462.1094. Its pattern field records local codon windows, frame movement, stop-boundary transitions, replication, transcription, repair, mutation, recombination, and accessibility updates. Its classifier field includes the codon classifier, stop classifier, amino-acid classifier, and microstate-preserving synonymous-codon classifier. Its stability field requires frame-step closure, window-six readback stability, stop-boundary determinacy under a fixed biological code table, and ledger transport under explicit cellular-context parameters. Its ledger policy preserves the raw codon, frame position, base-axis bits, code table, release-factor or tRNA context when used, accessibility state, and biological bridge metadata.*

Definition 9462.1128 (Translation state)**.** *A translation state has the schematic form*

$$q_t := (f_t, c_t, r_t, \kappa_t),$$

where f_t records the current frame, c_t records the current codon, r_t records ribosomal or release status, and κ_t records the cellular context relevant to the bridge. In the minimal finite model, the context is suppressed and the state is

$$q_t := (f_t, c_t).$$

Definition 9462.1129 (Elongation and stop transitions)**.** *For a non-stop codon c_t with*

$$\mathsf{TranslateClassifier}(c_t) = \mathsf{AminoAcid}(a),$$

the elongation transition advances the frame by one codon and records the emitted amino-acid class together with the raw codon:

$$q_t \longrightarrow q_{t+1}.$$

For a stop codon with

$$\mathsf{TranslateClassifier}(c_t) = \mathsf{Stop},$$

the transition enters a halted or release state:

$$q_t \longrightarrow q_{\mathsf{halt}}.$$

Theorem 9462.1130 (Stop codons are boundary states)**.** *Under the standard-code biological bridge, the codons* UAA, UAG, *and* UGA *are translation boundary states.*

Proof. By Definition 9462.1100, the Zeckendorf-family stop candidate under the chosen two-axis readback is exactly $\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$. The external standard-code bridge supplies the biological classifier row that reads these codons as stop signals. Combining the finite reconstruction with that bridge row gives the transition $q_t \to q_{\mathsf{halt}}$ for precisely those three standard-code codons. This is a bridge theorem, not a BEDC kernel theorem about biology. □

Definition 9462.1131 (Expanded DNA dynamic state)**.** *The local six-bit codon cube*

$$Q_6 := \{0,1\}^6$$

is sufficient for local codon classification but not for the full symbolic-physical dynamics. A minimal expanded state has the form

$$S_{\mathsf{DNA}} := \Sigma^n \times \mathsf{FrameState} \times \mathsf{EpigeneticState} \times \mathsf{ChromatinTopologyState} \times \mathsf{CellularEnzymeContext} \times \mathsf{TranslationContext} \times \mathsf{F}$$

Equivalently, a compressed state may be displayed as

$$D_t := (s_t, f_t, e_t, c_t, \kappa_t),$$

where s_t is the sequence state, f_t is the frame and window position, e_t records epigenetic marks, c_t records accessibility and topology, and κ_t records cellular machinery and regulatory context.

Definition 9462.1132 (DNA transition families)**.** *The dynamic bridge names transition families rather than imposing a universal execution order:*

R	*replication*
T	*transcription or selective readout*
L	*translation*
M	*mutation*
P	*repair*
G	*recombination or genome rearrangement*
E	*epigenetic update*
C	*chromatin or topology update*
F	*feedback from protein or translation state*

The schematic form is

$$D_{t+1} = \Phi(D_t; \kappa_t),$$

where the active components of Φ depend on cell state and bridge context. No fixed composition such as $C \circ E \circ P \circ M \circ R \circ T \circ L$ is licensed as a universal biological sequence.

Theorem 9462.1133 (Window six is local but incomplete)**.** *The local state Q_6 captures the codon-level classifier domain, but it does not exhaust DNA dynamics.*

Proof. Two biological states may share the same local six-bit codon window and differ in frame, methylation, histone-related marks, chromatin accessibility, polymerase status, ribosome state, repair status, release-factor availability, tRNA context, or code-table variant. Those differences may change whether the sequence is copied, read, repaired, translated, released, or ignored. Hence Q_6 is a local classifier domain, while the dynamic bridge must also record sequence position, frame, accessibility, repair, and cellular-machine context. □

Definition 9462.1134 (Codon microstate ledger)**.** *A codon microstate ledger is a bridge row*

$$\mathsf{CodonLedger}(c, o, \kappa)$$

recording the raw codon c, frame position, output class o, tRNA or release-factor context when used, codon-usage or optimality data when used, source code table, and variant-code metadata. The ledger separates the codon microstate from the amino-acid or stop class to which it is classified.

Theorem 9462.1135 (Translation does not collapse codon microstates)**.** *If two codons classify to the same amino-acid class, the biological bridge must still retain their raw codon rows whenever dynamic effects are in scope.*

Proof. The amino-acid output is a many-to-one classifier. If the raw codon were discarded, the bridge could not express codon usage, elongation-rate differences, mRNA-stability effects, tRNA-context dependence, or variant-code reassignment. Therefore the translation classifier is a ledger-preserving quotient, not a deletion of source microstate. □

Definition 9462.1136 (Variant-code deformation fields)**.** *Non-standard genetic codes are recorded as deformations of biological bridge fields. A variant may change the stop-shape region, the translation classifier, release-factor or release-mechanism rows, the biological code table attached to the readback, or the cellular context that permits readthrough, recoding, or organellar translation. Such deformations do not refute the finite stop-square enumeration; they change the bridge target in which that enumeration is interpreted.*

Definition 9462.1137 (Dynamic bridge modules)**.** *The dynamic research program decomposes into seven modules:*

Channel and Zeckendorf termination. *Preserve the no-internal-*11*, first-*11*, and layer-separation theorems for the BEDC channel.*

RNA four-phase and window six. *Record* $\mathsf{RNA4Alphabet}^{\uparrow} := \mathsf{Bool}^{\uparrow} \times \mathsf{Bool}^{\uparrow}$*, the* Flat_6 *map, and the codon-window ledger.*

Stop L-shape reconstruction. *Retain* UPurPur*, family suffix, Zeckendorf-legality, the three-stop theorem, and the* UGG *excluded-corner row.*

Translation dynamics. *Define translation states, elongation transitions, stop transitions, and the halted or release state.*

DNA state-space dynamics. *Define expanded sequence, frame, accessibility, chromatin, repair, mutation, and cellular-context fields.*

Microstate ledger. *Separate raw codon rows from amino-acid or stop output classes and record synonymous-codon non-collapse.*

Release factors and variants. *Compare the RF1/RF2 L-shape bridge with variant-code deformation fields.*

Definition 9462.1138 (Dynamic bridge figures)**.** *The bridge has three stable display forms. The two-axis base atlas is*

	W	S
Y	U	C
R	A	G

The stop square is the L-shape of Definition 9462.1124. The dynamic state inclusion is

$$Q_6 \subset S_{\mathsf{DNA}},$$

where Q_6 *is the local codon window and* S_{DNA} *is the expanded sequence-frame-accessibility-context state.*

Theorem 9462.1139 (Dynamic bridge cannot-claim boundary)**.** *The DNA window-six dynamics bridge does not license any claim that Zeckendorf or window six forces DNA biology, that DNA has a fully autonomous closed dynamics independent of cellular machinery, that the BEDC channel terminator is identical to a biological stop codon, that the family suffix* 11 *in* UGG *is the channel terminator, that the standard stop codons are universal across all genetic codes, that* UGG *is tryptophan by BEDC logic alone, that synonymous codons are dynamically identical after amino-acid classification, that the DNA state space is exhausted by* Q_6*, that* Φ *has a universal fixed composition order, that the biological bridge replaces* NameCert *obligations, or that* $\mathsf{DNAWindow6Dynamics}^{\uparrow}$ *is already checked.*

Proof. The channel-token and stop-codon refusals are inherited from Definition 9462.1111 and Definition 9462.1092. The autonomy and state-space refusals follow from Definition 9462.1133. The synonymous codon refusal follows from Definition 9462.1135. The fixed-order refusal follows from Definition 9462.1132. The checked-status refusal follows because the present subsection is a vision-level biological bridge plan rather than a Lean target. □

Corollary 9462.1140 (Allowed dynamic bridge claim)**.** *Under a standard-code biological bridge, window six and the no-*11 *motif supply a structural model for local DNA and RNA reading and stop-boundary dynamics. The three standard stop codons form the Zeckendorf-legal L-shape in the* $\mathrm{U} + \mathrm{RR}$ *square, and the broader DNA layer is modeled as a relative symbolic-physical dynamics with state, context, transitions, and ledger-preserved codon microstates.*

Concretized in §2161: CodonWindowSpectralInverseUp realizes the DNA window-six dynamics bridge as a finite codon-cube spectral inverse packet.

9462.28.21 Local tile dynamics of the genetic code

This subsection records a finite, non-axiomatic analysis of the standard RNA genetic-code table under the two-axis readback

$$\mathrm{U} = 00, \qquad \mathrm{C} = 01, \qquad \mathrm{A} = 10, \qquad \mathrm{G} = 11.$$

It does not claim that DNA must obey Zeckendorf rules, that the genetic code is the window-six fold, or that the biological code is globally equal to a no-11 language. The claims have three layers: a coordinate definition, a finite enumeration over the standard table, and biological bridge readings supplied by external genetic-code data.

Definition 9462.1141 (Local tile dynamics bridge status)**.** *The local-tile dynamics bridge* $\mathsf{LocalTileDynamics}^{\uparrow}$ *is a* $\mathsf{VisionSeed/BiologicalBridge}$ *target and a finite-enumeration paper-certificate candidate. A future certificate must separate source, pattern, classifier, stability, and ledger fields. The source field records the finite RNA alphabet, the two-axis readback, the codon cube, and the standard genetic-code table. The pattern field records local* Q_2 *faces,* $3+1$ *translation-class splits, corner partitions, and alternative-code deformations. The classifier field records codon labels. The stability field records closure of the finite enumeration under the chosen readback. The ledger policy preserves the codon, six-bit display, local face, free coordinates, translation label, and table provenance.*

Definition 9462.1142 (RNA alphabet and window-six readback)**.** *Let*

$$\Sigma := \{\mathrm{U}, \mathrm{C}, \mathrm{A}, \mathrm{G}\}.$$

The coordinate map $b : \Sigma \to \{0,1\}^2$ *is*

$$\begin{aligned} b(\mathrm{U}) &= 00, \quad b(\mathrm{C}) = 01, \\ b(\mathrm{A}) &= 10, \quad b(\mathrm{G}) = 11. \end{aligned}$$

For a codon $c = c_1c_2c_3 \in \Sigma^3$*, the six-bit readback is*

$$\beta(c) := b(c_1)\, b(c_2)\, b(c_3) \in \{0,1\}^6.$$

Write $Q_6 := \{0,1\}^6$.

Definition 9462.1143 (Standard translation label map)**.** *The standard translation label map is the external biological table*

$$\tau_{\mathsf{std}} : \Sigma^3 \rightsquigarrow \mathsf{AminoAcidClass} \oplus \mathsf{Stop}.$$

The rows used by this subsection are

label	*codons*
Stop	UAA, UAG, UGA
Trp	UGG
Ile	AUU, AUC, AUA
Met	AUG
Phe	UUU, UUC
Leu	UUA, UUG, CUU, CUC, CUA, CUG.

The biological labels are bridge data, not BEDC primitives.

Definition 9462.1144 (Axis-aligned local Q_2 face)**.** *An axis-aligned local Q_2 face of Q_6 is obtained by choosing two of the six bit positions to vary and fixing the other four. Such a face has four vertices and is displayed as*

$$F \simeq Q_2 := \{00, 01, 10, 11\}.$$

Definition 9462.1145 (Three-plus-one face)**.** *An axis-aligned local Q_2 face F is a $3+1$ face under a translation label map τ when the multiset of labels on its four codons has exactly two labels with multiplicities 3 and 1. The size-three label class is the three-point class, and the remaining codon is the singleton corner.*

Definition 9462.1146 (Local two-bit tile and corner mechanisms)**.** *The local no-11 triangle is*

$$X_2 := \{00, 01, 10\}$$

inside

$$Q_2 := \{00, 01, 10, 11\}.$$

Thus

$$Q_2 = X_2 \sqcup \{11\}.$$

An 11-control tile is a $3+1$ face whose three-point class is X_2 and whose singleton corner is 11. A 00-singleton tile is a $3+1$ face whose singleton corner is 00 and whose three-point class is $Q_2 \setminus \{00\}$.

Concretized in §3393: The local two-bit boundary-tile classifier is realized as finite codon-window, boundary-tile, transport, provenance, and NameCert rows.

Definition 9462.1147 (Distinguished local faces)**.** *The two 11-control faces are*

$$\mathsf{AUFace} := \{\mathrm{AUU}, \mathrm{AUC}, \mathrm{AUA}, \mathrm{AUG}\},$$
$$\mathsf{StopTrpFace} := \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\}.$$

The two 00-singleton faces are

$$\mathsf{PheLeuFace}_{\mathrm{U}} := \{\mathrm{UUU}, \mathrm{UUA}, \mathrm{CUU}, \mathrm{CUA}\},$$
$$\mathsf{PheLeuFace}_{\mathrm{C}} := \{\mathrm{UUC}, \mathrm{UUG}, \mathrm{CUC}, \mathrm{CUG}\}.$$

Definition 9462.1148 (Reserved local corner)**.** *For a local codon Q_2 face F, a reserved local corner is a singleton corner whose biological bridge row is separated from the three-point class. Reserved means singleton or control-sensitive under the translation classifier. It does not mean absent, deleted, or identified with the BEDC channel terminator.*

Definition 9462.1149 (Stop graph and release-factor arms)**.** *On*

$$X_2 = \{00, 01, 10\}$$

put the Hamming-distance-one graph

$$01 \ - \ 00 \ - \ 10.$$

Under the stop-face readback this is

$$\mathrm{UAG} \ - \ \mathrm{UAA} \ - \ \mathrm{UGA}.$$

The bacterial release-factor arms are external biological bridge rows:

$$\begin{aligned} \mathsf{RF1Arm} &:= \{\mathrm{UAA}, \mathrm{UAG}\}, \\ \mathsf{RF2Arm} &:= \{\mathrm{UAA}, \mathrm{UGA}\}. \end{aligned}$$

Definition 9462.1150 (Local reassignment modes)**.** *A leaf reassignment on an $X_2 \sqcup \{11\}$ tile moves one leaf of the X_2 part to another translation class. The central displayed case is*

$$\{00, 01, 10\}/\{11\} \rightsquigarrow \{00, 01\}/\{10, 11\}.$$

An arm reassignment on the stop graph moves an edge such as $\{00, 01\}$ as one biological classifier row.

Definition 9462.1151 (Local translation state)**.** *A local translation state has the schematic form*

$$S_t := (f_t, w_t, r_t, \kappa_t),$$

where f_t is the frame, $w_t \in Q_6$ is the current window, r_t records release or ribosome state, and κ_t records cellular context. Under the standard-code bridge:

$$\begin{aligned} w_t \notin \mathrm{Stop} \quad &\Longrightarrow \quad S_t \to S_{t+1}, \\ w_t \in \mathrm{Stop} \quad &\Longrightarrow \quad S_t \to S_{\mathsf{halt}}. \end{aligned}$$

This is a modeling interface, not a closed autonomous biological dynamics.

Lemma 9462.1152 (Codon cube and window-six bijection)**.** *The readback β gives a finite bijection*

$$\Sigma^3 \cong Q_6.$$

Proof. Each base in Σ has a unique two-bit coordinate under b, so a three-base codon has a unique six-bit display. Conversely, every six-bit word splits uniquely into three two-bit blocks, and each block is one of 00, 01, 10, and 11, hence decodes uniquely to one of U, C, A, and G. □

Lemma 9462.1153 (Local two-bit partition)**.** *The two-bit square satisfies*

$$Q_2 = X_2 \sqcup \{11\}, \qquad X_2 = \{00, 01, 10\}.$$

Proof. The four two-bit words are exactly 00, 01, 10, and 11. Removing the word 11 leaves exactly 00, 01, and 10. The displayed union is disjoint and exhaustive. □

Theorem 9462.1154 (Stop and tryptophan 11-control tile)**.** *In the* $\mathrm{U} + \mathrm{RR}$ *face,*

$$\begin{aligned} \mathrm{U} + \mathrm{RR} + X_2 &= \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\} = \mathrm{Stop}, \\ \mathrm{U} + \mathrm{RR} + 11 &= \{\mathrm{UGG}\} = \mathrm{Trp} \end{aligned}$$

under the standard-code biological bridge.

Proof. The family suffix coordinates are

$$\begin{aligned} \mathrm{UAA} &\longmapsto 00, \\ \mathrm{UAG} &\longmapsto 01, \\ \mathrm{UGA} &\longmapsto 10, \\ \mathrm{UGG} &\longmapsto 11. \end{aligned}$$

By Definition 9462.1153, the X_2 part is $\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$ and the 11 corner is UGG. The labels Stop and Trp are supplied by the standard genetic-code bridge. □

Corollary 9462.1155 (UGG is the stop-face 11 corner)**.** *Inside the stop face,*

$$\mathrm{UGG} = \mathrm{U} + \mathrm{RR} + 11.$$

Proof. Both varying suffix bases are G, and G has family coordinate 1. Hence GG has local family suffix 11. □

Theorem 9462.1156 (Isoleucine and methionine 11-control tile)**.** *In the* AU *face,*

$$\begin{aligned} \mathrm{AU} + X_2 &= \{\mathrm{AUU}, \mathrm{AUC}, \mathrm{AUA}\} = \mathrm{Ile}, \\ \mathrm{AU} + 11 &= \{\mathrm{AUG}\} = \mathrm{Met} \end{aligned}$$

under the standard-code biological bridge. In an initiation context, the same AUG *row carries the canonical start bridge row.*

Proof. The third-base coordinates in the AU face are

$$\begin{aligned} \mathrm{AUU} &\longmapsto 00, \\ \mathrm{AUC} &\longmapsto 01, \\ \mathrm{AUA} &\longmapsto 10, \\ \mathrm{AUG} &\longmapsto 11. \end{aligned}$$

Thus the X_2 part is $\{\mathrm{AUU}, \mathrm{AUC}, \mathrm{AUA}\}$ and the 11 corner is AUG. The labels Ile, Met, and the canonical-start reading are external standard-code bridge rows. □

Corollary 9462.1157 (Dual 11-control tiles)**.** *The standard genetic-code bridge contains two dual* $X_2 \sqcup \{11\}$ *tiles:*

$$\begin{aligned} \mathrm{Ile/Met} &= \mathrm{AU} + X_2 \ / \ 11, \\ \mathrm{Stop/Trp} &= \mathrm{U} + \mathrm{RR} + X_2 \ / \ 11. \end{aligned}$$

Proof. Combine Definition 9462.1154 and Definition 9462.1156. □

Concretized in §3393: The finite stop/Trp and Ile/Met boundary tiles are realized as a concrete NameCert packet.

Theorem 9462.1158 (Phe and Leu 00-singleton tiles)**.** *The two Phe/Leu faces are* 00*-singleton tiles:*

face	00 *singleton*	$Q_2 \setminus \{00\}$ *class*
$\{\mathrm{UUU}, \mathrm{UUA}, \mathrm{CUU}, \mathrm{CUA}\}$	$\mathrm{UUU} = \mathrm{Phe}$	$\mathrm{UUA}, \mathrm{CUU}, \mathrm{CUA} = \mathrm{Leu}$
$\{\mathrm{UUC}, \mathrm{UUG}, \mathrm{CUC}, \mathrm{CUG}\}$	$\mathrm{UUC} = \mathrm{Phe}$	$\mathrm{UUG}, \mathrm{CUC}, \mathrm{CUG} = \mathrm{Leu}.$

Proof. For the first face, vary the second bit of the first base and the second bit of the third base while keeping the other four bits fixed. The local coordinates are

$$\begin{aligned} 00 &\longmapsto \mathrm{UUU}, \quad 01 \longmapsto \mathrm{UUA}, \\ 10 &\longmapsto \mathrm{CUU}, \quad 11 \longmapsto \mathrm{CUA}. \end{aligned}$$

For the second face, the same free bit positions give

$$\begin{aligned} 00 &\longmapsto \mathrm{UUC}, \quad 01 \longmapsto \mathrm{UUG}, \\ 10 &\longmapsto \mathrm{CUC}, \quad 11 \longmapsto \mathrm{CUG}. \end{aligned}$$

The standard-code bridge labels the 00 vertices as Phe and the remaining three vertices as Leu. □

Theorem 9462.1159 (Number of axis-aligned local Q_2 faces)**.** *The codon cube Q_6 contains exactly*

$$\binom{6}{2} 2^4 = 240$$

axis-aligned local Q_2 faces.

Proof. Choose the two free bit positions in $\binom{6}{2}$ ways. The remaining four bit positions are fixed, each independently to 0 or 1, giving 2^4 choices. Thus the number is $\binom{6}{2}2^4 = 15 \cdot 16 = 240$. □

Theorem 9462.1160 (Standard-code axis-aligned $3+1$ face enumeration)**.** *Under the two-axis readback and the standard translation label map, the axis-aligned Q_2 faces with a $3+1$ translation-class split are exactly the following four faces:*

face	*three-point class*	*singleton class*	*singleton corner*
$\{\mathrm{UUU}, \mathrm{UUA}, \mathrm{CUU}, \mathrm{CUA}\}$	Leu	Phe	00
$\{\mathrm{UUC}, \mathrm{UUG}, \mathrm{CUC}, \mathrm{CUG}\}$	Leu	Phe	00
$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\}$	Stop	Trp	11
$\{\mathrm{AUU}, \mathrm{AUC}, \mathrm{AUA}, \mathrm{AUG}\}$	Ile	Met	11.

Proof. The enumeration is finite. By Definition 9462.1159, there are 240 axis-aligned Q_2 faces. For each face, decode its four vertices through β^{-1}, apply τ_{std}, and retain exactly those faces whose label multiplicities are 3 and 1. Direct enumeration yields the four displayed rows. The table is independent of any BEDC biological axiom beyond the external standard-code label map. □

Corollary 9462.1161 (Two corner mechanisms)**.** *The four standard-code $3+1$ faces split into two corner mechanisms: two* 11*-control tiles,* Ile/Met *and* Stop/Trp*, and two* 00*-singleton tiles, both* Phe/Leu*.*

Proof. Read the singleton-corner column in Definition 9462.1160. □

Theorem 9462.1162 (Total local tile theorem)**.** *Every standard-code axis-aligned* $3+1$ *split in the two-axis codon cube is one of the following:*

tile mechanism	*codon split*
11-*control*	AUU, AUC, AUA | AUG
11-*control*	UAA, UAG, UGA | UGG
00-*singleton*	UUU | UUA, CUU, CUA
00-*singleton*	UUC | UUG, CUC, CUG.

Proof. The four rows are exhaustive by Definition 9462.1160. Their mechanism labels follow from Definition 9462.1161. □

Theorem 9462.1163 (Reserved-corner interpretation)**.** *In the two* 11-*control tiles, the local* 11 *corner is not a claim of biological absence. It is a separated singleton or control-sensitive corner.*

Proof. The local 11 corners are actual standard-code codons:

$$\begin{aligned} &\mathrm{AUG} = \mathrm{Met} \quad \text{and may carry the canonical start row,} \\ &\mathrm{UGG} = \mathrm{Trp}. \end{aligned}$$

Therefore the bridge-level reading cannot be that local 11 is absent from biology. The licensed reading is that the local 11 corner is separated from the ordinary three-point class. □

Theorem 9462.1164 (Stop structure is local, not global)**.** *The standard stop set is local* X_2 *inside the* $\mathrm{U}+\mathrm{RR}$ *face. It is not the global* X_6 *no-adjacent language on flattened codons.*

Proof. The flattened displays are

$$\begin{aligned} \mathrm{UAA} &= 001010, \\ \mathrm{UAG} &= 001011, \\ \mathrm{UGA} &= 001110. \end{aligned}$$

The word 001010 has no adjacent 11, but 001011 and 001110 do. Hence the standard stop set is not contained in global X_6. By Definition 9462.1154, the stop structure is instead the local face equality

$$\mathrm{Stop} = \mathrm{U} + \mathrm{RR} + X_2.$$

□

Corollary 9462.1165 (Correct window-six reading)**.** *The correct finite-window reading is*

$$\mathsf{CodonCube} = Q_6, \qquad \mathrm{Stop} = \mathrm{U} + \mathrm{RR} + X_2,$$

not $\mathrm{Stop} = X_6$.

Proof. The codon-cube equality is Definition 9462.1152; the local stop equality is Definition 9462.1154; the global reading is rejected by Definition 9462.1164. □

Definition 9462.1166 (Complete global fiber $3+1$ tile)**.** *Let* $E : Q_6 \to C$ *be a translation classifier. An axis-aligned* Q_2 *face* F *is a complete global fiber* $3+1$ *tile when there are classes* $a, b \in C$ *such that*

$$F = E^{-1}(a) \sqcup E^{-1}(b), \qquad |E^{-1}(a)| = 3, \qquad |E^{-1}(b)| = 1.$$

Thus the local three-point side is not merely a local multiplicity: it is the whole global tripleton fiber. Likewise the singleton corner is the whole global singleton fiber.

Theorem 9462.1167 (Complete global fiber tiles in the standard code)**.** *Under the two-axis readback and the standard translation classifier, the complete global fiber* $3+1$ *tiles are exactly*

face	*global tripleton*	*global singleton*	*singleton corner*
{AUU, AUC, AUA, AUG}	Ile	Met	11
{UAA, UAG, UGA, UGG}	Stop	Trp	11.

Proof. By Definition 9462.1859, the only global tripleton classes of the standard classifier are Ile and Stop, and the only global singleton classes are Met and Trp. The exhaustive local Q_2 enumeration of Definition 9462.1160 has four $3+1$ faces. The two Phe/Leu faces are excluded because Phe is a global doubleton and Leu is a global sextupleton. The remaining two faces are the displayed Ile/Met and Stop/Trp faces, and both have singleton corner 11. □

Corollary 9462.1168 (Global fibers select the dual control tiles)**.** *The pair* Ile/Met *and* Stop/Trp *is not selected by choosing two examples from the four local* $3+1$ *faces. It is selected by imposing the global-fiber condition on the local* Q_2 *spectrum.*

Proof. The global-fiber condition eliminates the Phe/Leu local slices and keeps exactly the two rows of Definition 9462.1167. □

Theorem 9462.1169 (Standard-code Q_1 edge spectrum)**.** *The standard translation classifier has* 50 *same-class Hamming edges and* 142 *cross-class Hamming edges in* Q_6*. By bit direction*

$$(b_1^s, b_1^f, b_2^s, b_2^f, b_3^s, b_3^f),$$

the same-class edge counts are

direction	b_1^s	b_1^f	b_2^s	b_2^f	b_3^s	b_3^f
same-class edges	0	2	0	1	17	30
cross-class edges	32	30	32	31	15	2.

Proof. For each of the six bit directions, enumerate the 32 Hamming edges $x \leftrightarrow x \oplus e_i$. Decode both endpoints to codons and compare their standard translation labels. The displayed table is the finite count over the resulting $6 \cdot 32 = 192$ edges. □

Corollary 9462.1170 (Third-position softness)**.** *The third-position family bit* b_3^f *is the most stable Hamming direction in the standard classifier, with* 30 *same-class edges out of* 32*. The first and second shape bits have no same-class edge.*

Proof. Read the direction counts in Definition 9462.1169. □

Theorem 9462.1171 (Same-histogram random edge baseline)**.** *Keep only the standard-code degeneracy histogram*

$$1:2, \qquad 2:9, \qquad 3:2, \qquad 4:5, \qquad 6:3,$$

and randomly assign the resulting fibers to the 64 *codons. For a random unordered pair of distinct codons, the same-class probability is*

$$p_{\text{same}} = \frac{\sum_a \binom{d_a}{2}}{\binom{64}{2}} = \frac{5}{112}.$$

Thus the expected number of same-class Hamming edges among the 192 *edges of* Q_6 *is*

$$192\, p_{\text{same}} = \frac{60}{7} \approx 8.57.$$

The observed standard-code value is 50*, namely*

$$\frac{50}{60/7} = \frac{35}{6} \approx 5.83$$

times the same-histogram random expectation. The exact variance of the same-edge count under this same-histogram model is

$$\frac{686964}{92659} \approx 7.41,$$

so the standard deviation is about 2.72 *and the observed value has z-score about* 15.2*.*

Proof. The standard degeneracy histogram gives

$$\sum_a \binom{d_a}{2} = 2\binom{1}{2} + 9\binom{2}{2} + 2\binom{3}{2} + 5\binom{4}{2} + 3\binom{6}{2} = 90.$$

Since $\binom{64}{2} = 2016$, the probability is $90/2016 = 5/112$. Multiplying by the 192 Hamming edges gives $60/7$. The observed count 50 is Definition 9462.1169. For the variance, separate unordered pairs of Hamming edges into adjacent edge-pairs, of which there are $64\binom{6}{2} = 960$, and disjoint edge-pairs, of which there are $\binom{192}{2} - 960 = 17376$. Evaluating the two corresponding same-fiber probabilities from the fixed fiber sizes gives the displayed finite variance. □

Corollary 9462.1172 (Local edge smoothness is not a histogram artifact)**.** *The standard classifier is not merely a code table with the listed global degeneracy histogram. It is locally smooth on the Hamming graph: same-class adjacency is about* 5.83 *times the same-histogram random expectation, and the smoothness is concentrated in the third-base directions.*

Proof. The excess over the histogram baseline is Definition 9462.1171. The directional concentration is Definition 9462.1170. □

Theorem 9462.1173 (Single-nucleotide substitution edge spectrum)**.** *If edges are taken to be ordinary one-base substitutions rather than one-bit flips, then there are* 288 *unordered edges. The standard classifier has the following position-wise spectrum:*

codon position	1	2	3	*total*
same-class substitution edges	4	1	64	69
cross-class substitution edges	92	95	32	219.

Proof. For each codon position, fix the other two bases in 4^2 ways and connect the four choices at the chosen position by the complete graph on four bases. This gives $16\binom{4}{2} = 96$ edges per position and 288 total edges. Decoding both endpoints and comparing their standard translation labels gives the displayed finite spectrum. □

Corollary 9462.1174 (Two-axis stability matches nucleotide substitution)**.** *The two-axis* Q_6 *edge spectrum is not only a formal bit-cube phenomenon. Ordinary one-base substitution edges show the same asymmetry: the third codon position has* 64 *same-class edges out of* 96*, while the first two positions have only* 4 *and* 1*.*

Proof. Compare Definition 9462.1169 with Definition 9462.1173. □

Theorem 9462.1175 (Standard-code Q_2 face spectrum)**.** *The* 240 *axis-aligned* Q_2 *faces of the standard classifier have the following multiplicity spectrum:*

local pattern	4	$3+1$	$2+2$	$2+1+1$	$1+1+1+1$
face count	9	4	83	44	100.

By geometric type, the same spectrum refines to

face type	4	$3+1$	$2+2$	$2+1+1$	$1+1+1+1$	*total*
same base	8	1	6	6	27	48
cross-base same axis	1	1	39	18	37	96
cross-base mixed axis	0	2	38	20	36	96.

Proof. The first table is the exhaustive face enumeration already used in Definition 9462.1160, with all multiplicity patterns retained rather than only the $3+1$ rows. The second table partitions the same faces by whether the two free bits lie in the same base, in different bases along the same axis, or in different bases along different axes. □

Theorem 9462.1176 (Standard-code Q_3 cube spectrum)**.** *The* 160 *axis-aligned* Q_3 *cubes of the standard classifier have the following multiplicity spectrum:*

local pattern	*cube count*
$2+2+2+2$	46
$1+1+1+1+1+1+1+1$	21
$2+1+1+1+1+1+1$	21
$2+2+2+1+1$	18
$2+2+1+1+1+1$	11
$4+2+2$	10
$4+4$	10
$3+2+2+1$	9
$3+2+1+1+1$	5
$4+2+1+1$	4
$3+1+1+1+1+1$	2
$4+3+1$	2
$6+2$	1.

Proof. Choose three free bit positions and fix the remaining three bits, giving $\binom{6}{3}2^3 = 160$ cubes. On each cube, decode the eight vertices and count the translation-label multiplicities. The displayed table is the resulting finite spectrum. □

Corollary 9462.1177 (Phe/Leu is the unique $6+2$ cube)**.** *The unique* $6+2$ *cube is*

$$\{\mathrm{UUU}, \mathrm{UUC}, \mathrm{UUA}, \mathrm{UUG}, \mathrm{CUU}, \mathrm{CUC}, \mathrm{CUA}, \mathrm{CUG}\},$$

with $\{\mathrm{UUU}, \mathrm{UUC}\} = \mathrm{Phe}$ *and the remaining six codons classified as* Leu.

Proof. The exhaustive Q_3 enumeration in Definition 9462.1176 contains one cube of type $6+2$. Its vertices are the displayed Phe/Leu support. □

Theorem 9462.1178 (Neighborhoods of the complete control tiles)**.** *The Stop/Trp tile is contained in four axis-aligned Q_3 cubes, and all four have pattern $3+2+2+1$. The Ile/Met tile is contained in four axis-aligned Q_3 cubes; two have pattern $3+2+2+1$, and two have pattern $4+3+1$.*

Proof. Every Q_2 face in Q_6 has four one-bit extensions to a Q_3 cube. Enumerating those four extensions for the Stop/Trp face gives four cubes whose labels are

$$\mathrm{Stop}_3 + \mathrm{Trp}_1 + \text{doubleton} + \text{doubleton}.$$

Enumerating the four extensions for the Ile/Met face gives two cubes of the same $3+2+2+1$ form and two cubes of the form

$$\text{quadrupleton} + \mathrm{Ile}_3 + \mathrm{Met}_1.$$

□

Corollary 9462.1179 (Control-tile neighborhood contrast)**.** *The Stop/Trp tile is locally isolated as a boundary/continuation tile in all of its Q_3 neighborhoods. The Ile/Met tile retains the same 11-corner control form, but two of its Q_3 neighborhoods embed it beside a four-codon sense block.*

Proof. This is the distinction between the two neighborhood spectra in Definition 9462.1178. □

Concretized in §3778: Global fiber spectra are realized as finite codon-cube fiber, tile, edge, trigger, transport, replay, provenance, and NameCert rows.

Definition 9462.1180 (Synonymous induced graph)**.** *Let $E : Q_6 \to C$ be the standard translation classifier. For a class $a \in C$, write G_a for the subgraph of the Hamming graph on Q_6 induced by the fiber $E^{-1}(a)$.*

Theorem 9462.1181 (Synonymous induced graph types)**.** *The standard classifier has exactly the following synonymous component types:*

component type	*classes*
1	Met, Trp
2	Phe, Tyr, Cys, His, Gln, Asn, Lys, Asp, Glu
3	Ile, Stop
4	Pro, Thr, Val, Ala, Gly
$4+2$	Ser, Arg
6	Leu.

Proof. For each translation class, restrict the Q_6 Hamming graph to the codons in that class and compute connected component sizes. The standard table gives the displayed finite list. □

Corollary 9462.1182 (Dual tripleton shape)**.** *The two tripleton classes* Ile *and* Stop *have the same induced X_2 graph shape. In local coordinates they are*

$$\{00, 01, 10\},$$

with Hamming path $01 - 00 - 10$.

Proof. The tripleton component type in Definition 9462.1181 is connected of size 3. Substituting the coordinates of the Ile/Met and Stop/Trp faces from Definition 9462.1167 gives the displayed X_2 shape. □

Theorem 9462.1183 (Internal edge and boundary spectrum)**.** *For each class a, let*

$$e_a = |\{x \sim y : E(x) = E(y) = a\}|.$$

The internal edge and external boundary degrees are:

class type	$\lvert E^{-1}(a)\rvert$	e_a	$6\lvert E^{-1}(a)\rvert - 2e_a$
Met, Trp	1	0	6
doubleton classes	2	1	10
Ile, Stop	3	2	14
Pro, Thr, Val, Ala, Gly	4	4	16
Ser, Arg	6	5	26
Leu	6	7	22.

Proof. Enumerate the 192 Hamming edges of Q_6 and count those whose two endpoints lie in the same translation class. The boundary degree formula subtracts twice the internal edges from the total incident degree $6|E^{-1}(a)|$. □

Corollary 9462.1184 (Leu is the tight sextupleton)**.** *Among the three sextupleton classes,* Leu *has the largest internal Hamming edge count:*

$$e_{\text{Leu}} = 7, \qquad e_{\text{Ser}} = e_{\text{Arg}} = 5.$$

Thus the Phe/Leu block is a sense expansion geometry rather than a halt/continue control geometry.

Proof. Read the sextupleton rows of Definition 9462.1183 and compare with the unique $6 + 2$ Q_3 cube described in Definition 9462.1176. □

Definition 9462.1185 (Class adjacency and coarse bit-flip transition)**.** *The class adjacency matrix is*

$$A_{ab} = |\{x \sim y : E(x) = a,\ E(y) = b\}|.$$

For the coarse one-bit transition from class a to class b, set

$$P(b \mid a) = \frac{|\{x \in E^{-1}(a),\ y \sim x,\ E(y) = b\}|}{6|E^{-1}(a)|}.$$

Theorem 9462.1186 (Largest class-adjacency weights)**.** *The largest off-diagonal entries of the*

class adjacency matrix are

class pair	A_{ab}
Ser−Thr	6
Gly−Arg	6
Phe−Leu	4
Pro−Ser	4
Cys−Ser	4
Leu−Val	4
Leu−Pro	4
Ala−Pro	4
Pro−Arg	4
Ala−Thr	4
Ala−Val	4
Ala−Gly	4.

The two control pairs satisfy

$$A_{\mathrm{Ile,Met}} = 2, \qquad A_{\mathrm{Stop,Trp}} = 2.$$

Proof. Each Hamming edge is decoded at both endpoints and then accumulated by the unordered pair of translation classes. The displayed rows are the largest finite counts; the two control-pair counts are the corresponding entries for the singleton/tripleton contacts. □

Corollary 9462.1187 (Control pairs are corner contacts)**.** *The Ile/Met and Stop/Trp pairs are not maximal by adjacency weight. Their distinction is geometric: each is a singleton* 11 *corner adjacent to a tripleton X_2 fiber.*

Proof. The weights are only 2 by Definition 9462.1186. The global singleton/tripleton 11-corner geometry is Definition 9462.1167. □

Theorem 9462.1188 (Dual singleton transition probabilities)**.** *The coarse one-bit transition probabilities satisfy*

$$P(\mathrm{Ile} \mid \mathrm{Met}) = \frac{2}{6} = \frac{1}{3}, \qquad P(\mathrm{Stop} \mid \mathrm{Trp}) = \frac{2}{6} = \frac{1}{3}.$$

Moreover

$$P(\mathrm{Met} \mid \mathrm{Ile}) = \frac{2}{18} = \frac{1}{9}, \qquad P(\mathrm{Trp} \mid \mathrm{Stop}) = \frac{2}{18} = \frac{1}{9}.$$

Proof. The Met singleton has six one-bit neighbors, two of which lie in the Ile fiber. The Trp singleton has six one-bit neighbors, two of which lie in the Stop fiber. Reversing direction divides the same two boundary contacts by the total directed degree 18 of each tripleton fiber. □

Definition 9462.1189 (Q_4 neighborhood of a tile)**.** *An axis-aligned Q_4 cube is obtained by fixing two bits of Q_6 and freeing the remaining four. A Q_2 tile has six direct Q_4 neighborhoods, one for each choice of two additional free bits.*

Theorem 9462.1190 (Standard-code Q_4 spectrum)**.** *The* 60 *axis-aligned Q_4 cubes of the standard classifier have maximal within-cube class sizes distributed as*

$\max_a \lvert Q_4 \cap E^{-1}(a)\rvert$	2	3	4	6
cube count	17	15	23	5.

The complete sextupleton appearances inside Q_4 cubes are

$$\mathrm{Leu} : 3, \qquad \mathrm{Ser} : 1, \qquad \mathrm{Arg} : 1.$$

Proof. Enumerate the $\binom{6}{4}2^2 = 60$ axis-aligned Q_4 cubes. For each cube count the multiplicities of translation labels inside it and record the maximum. A complete sextupleton appearance is counted when all six codons of a global six-codon class lie in the cube. □

Theorem 9462.1191 (Dual control Q_4 neighborhoods)**.** *All six Q_4 neighborhoods of the Stop/Trp tile retain* $\mathrm{Stop}_3 + \mathrm{Trp}_1$*. All six Q_4 neighborhoods of the Ile/Met tile retain* $\mathrm{Ile}_3 + \mathrm{Met}_1$*. However, the Ile/Met neighborhoods also include ordinary large sense blocks, including*

$$\mathrm{Ala}_4 + \mathrm{Thr}_4 + \mathrm{Val}_4 + \mathrm{Ile}_3 + \mathrm{Met}_1$$

and

$$\mathrm{Leu}_6 + \mathrm{Val}_4 + \mathrm{Ile}_3 + \mathrm{Phe}_2 + \mathrm{Met}_1.$$

Proof. Enumerate the six Q_4 cubes containing each displayed Q_2 tile and record their translation-class multiplicities. The Stop/Trp neighborhoods always keep the same Stop_3 and Trp_1 core. The Ile/Met neighborhoods keep the Ile_3 and Met_1 core, while two of the neighborhoods contain the displayed larger sense blocks. □

Corollary 9462.1192 (Boundary tile versus entry tile)**.** *Stop/Trp is a locally closed halt/continue boundary through the Q_3 and Q_4 neighborhoods. Ile/Met has the same local $X_2/11$ shape, but its higher neighborhoods attach it to ordinary four-codon and six-codon sense regions.*

Proof. Combine the Q_3 neighborhood counts in Definition 9462.1176 with the Q_4 neighborhood statement in Definition 9462.1191. □

Definition 9462.1193 (Control half-cube)**.** *A Q_5 half-cube in Q_6 is obtained by fixing one bit and freeing the other five bits.*

Theorem 9462.1194 (Unique shared control half-cube)**.** *The Ile/Met tile and the Stop/Trp tile share exactly one fixed-bit condition:*

$$b_1^f = 0.$$

Thus both lie in the unique half-cube whose first codon base has family bit 0*, equivalently whose first base lies in* $\{\mathrm{U}, \mathrm{A}\}$*. Inside this Q_5 half-cube, the class multiplicities are*

$$\mathrm{Ser}_6,\ \mathrm{Thr}_4,\ \mathrm{Stop}_3,\ \mathrm{Ile}_3,$$
$$\mathrm{Phe}_2,\ \mathrm{Leu}_2,\ \mathrm{Tyr}_2,\ \mathrm{Cys}_2,\ \mathrm{Asn}_2,\ \mathrm{Lys}_2,\ \mathrm{Arg}_2,\ \mathrm{Trp}_1,\ \mathrm{Met}_1.$$

Proof. The Stop/Trp tile has first base $\mathrm{U} = 00$, while the Ile/Met tile has first base $\mathrm{A} = 10$. The two first-base shape bits differ, but their first-base family bit is the common value 0. Checking the remaining four bit coordinates across the eight tile vertices shows no other common fixed coordinate. Enumerating the resulting 32 vertices gives the displayed multiplicities. □

Corollary 9462.1195 (Co-localized dual control tiles)**.** *The two $X_2/11$ control tiles are not isolated coincidences in Q_6. They are co-localized in the single half-cube $b_1^f = 0$, where the two tripleton fibers and the two singleton fibers appear together:*

$$\mathrm{Stop}_3, \quad \mathrm{Ile}_3, \quad \mathrm{Trp}_1, \quad \mathrm{Met}_1.$$

Proof. This is the control-class sublist of Definition 9462.1194. □

Corollary 9462.1196 (Half-cube reading of dual 10-to-11 reassignment)**.** *The alternative assignments* AUA $\to$ Met *and* UGA $\to$ Trp *have the same local form inside the shared half-cube:*

$$\{00, 01, 10\} \mid \{11\} \rightsquigarrow \{00, 01\} \mid \{10, 11\}.$$

Proof. By Definition 9462.1197, both assignments move the local 10 vertex into the class containing the 11 corner. By Definition 9462.1194, the two instances lie in the same $b_1^f = 0$ half-cube. □

Concretized in §5799: The synonymous transition graph is realized as finite codon-window, class-adjacency, boundary-spectrum, and trigger-threshold NameCert data.

Proposition 9462.1197 (Dual 10-to-11 reassignment)**.** *In genetic-code tables where* AUA *is assigned to* Met *and* UGA *is assigned to* Trp*, the two dual* 11*-control tiles undergo the same displayed deformation:*

$$\{00, 01, 10\}/\{11\} \rightsquigarrow \{00, 01\}/\{10, 11\}.$$

Proof. In the AU tile, AUA has local coordinate 10 and AUG has coordinate 11. In the U + RR tile, UGA has local coordinate 10 and UGG has coordinate 11. Assigning AUA with AUG or assigning UGA with UGG therefore has the same local displayed form: the 10 leaf joins the class containing the 11 corner. □

Corollary 9462.1198 (AUA-to-Met and UGA-to-Trp share a tile form)**.** *The reassignments* AUA $\to$ Met *and* UGA $\to$ Trp *are structurally the same local tile operation under the two-axis coordinates:* 10 *joins the class containing* 11*.*

Proof. This is Definition 9462.1197 applied to the two distinguished 11-control tiles. □

Proposition 9462.1199 (Stop-arm reassignment)**.** *In genetic-code tables where* UAA *and* UAG *are assigned to a sense class while* UGA *remains a termination row, the stop tile displays an arm reassignment:*

$$\{00, 01\} \quad \textit{moves as one stop-graph arm.}$$

Proof. In the stop graph, UAA has coordinate 00, UAG has coordinate 01, and UGA has coordinate 10. The pair $\{00, 01\}$ is one Hamming edge of the local L-shape. If UAA and UAG are assigned together to a sense class while UGA remains termination, the local deformation moves that edge as a unit. □

Corollary 9462.1200 (Stop-tile deformation modes)**.** *Alternative-code changes of the stop tile can be recorded at least as leaf reassignment, arm reassignment, or context-sensitive partial boundary assignment.*

Proof. The leaf case is represented by Definition 9462.1197. The arm case is Definition 9462.1199. Context-sensitive or ambiguous stop rows are recorded by allowing the biological bridge table to attach a partial or context-indexed classifier to one of the local vertices. □

Theorem 9462.1201 (Release-factor recognition is the stop graph)**.** *For the bacterial release-factor bridge,*

$$\mathsf{RF1Arm} = \{\mathrm{UAA}, \mathrm{UAG}\} = \{00, 01\},$$
$$\mathsf{RF2Arm} = \{\mathrm{UAA}, \mathrm{UGA}\} = \{00, 10\}.$$

Thus RF1/RF2 recognition traces the two arms of the stop X_2 graph.

Proof. Substitute the stop graph coordinates from Definition 9462.1149. The two sets $\{00, 01\}$ and $\{00, 10\}$ are exactly the two Hamming-distance-one edges of the L-shape $01 - 00 - 10$. □

Concretized in §5818: The finite translation-boundary packet realizes the release-factor stop-graph route as validation-row NameCert data.

Corollary 9462.1202 (UAA is the local stop center)**.** *The intersection of the two release-factor arms is*

$$\mathsf{RF1Arm} \cap \mathsf{RF2Arm} = \{\mathrm{UAA}\}.$$

Proof. Compute

$$\{\mathrm{UAA}, \mathrm{UAG}\} \cap \{\mathrm{UAA}, \mathrm{UGA}\} = \{\mathrm{UAA}\}.$$

□

Theorem 9462.1203 (Stop tile is a local halt boundary)**.** *Under the local translation-state model,*

$$\mathrm{Stop} = \mathrm{U} + \mathrm{RR} + X_2 = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$$

is a local halt boundary.

Proof. The stop equality is Definition 9462.1154. By Definition 9462.1151, any state whose current window lies in the stop class transitions to S_{halt}. □

Corollary 9462.1204 (UGG is a continuation corner)**.** *The codon* $\mathrm{UGG} = \mathrm{U}+\mathrm{RR}+11$ *is adjacent to the stop boundary in the stop face, but the standard-code bridge assigns it to* Trp *rather than to* Stop*.*

Proof. By Definition 9462.1155, UGG is the 11 corner of the stop face. By Definition 9462.1154, the other three vertices are the stop class. The standard-code bridge assigns UGG to Trp, so its transition is elongation rather than termination. □

Definition 9462.1205 (Finite formalization target)**.** *The checked finite target is the exhaustive enumeration:*

$$\mathsf{AxisQ2Faces}(\Sigma^3, b) \xrightarrow{\tau_{\mathsf{std}}} \mathsf{ThreeOneFaces},$$
$$\mathsf{ThreeOneFaces} = \{\mathsf{PheLeuFace}_{\mathrm{U}}, \mathsf{PheLeuFace}_{\mathrm{C}}, \mathsf{StopTrpFace}, \mathsf{AUFace}\}.$$

The intended Lean proof is finite enumeration over the 240 *axis-aligned* Q_2 *faces, not a biological necessity theorem.*

Theorem 9462.1206 (Local tile cannot-claim boundary)**.** *The local-tile bridge does not license any claim that DNA must obey Zeckendorf, that the genetic code is the window-six fold, that the genetic code is globally* X_6*, that* $\mathrm{Stop} = X_6$*, that* 11 *is biologically illegal or absent, that a local DNA or RNA* 11 *corner is the BEDC channel terminator, that the standard genetic code is logically necessary, that* UAA*,* UAG*, and* UGA *are universal stop codons, that* UGG *is tryptophan by BEDC logic alone, that alternative-code reassignments are forced by pure mathematics, or that* $\mathsf{LocalTileDynamics}^{\uparrow}$ *is already a checked certificate.*

Proof. The global X_6 refusals follow from Definition 9462.1164. The channel-token refusal follows from Definition 9462.1107. The biological label refusals follow because the standard and alternative genetic-code tables are external bridge data. The checked-status refusal follows from Definition 9462.1141. □

Corollary 9462.1207 (Allowed local-tile claim)**.** *Under the two-axis readback and the standard-code table, codons form Q_6, and the axis-aligned Q_2 faces with $3+1$ translation-class splits are exactly the two* 11*-control tiles* Ile/Met *and* Stop/Trp *together with the two* 00*-singleton* Phe/Leu *tiles. This is a local finite-window classification inside Q_6, not a global identification of the genetic code with X_6 or with a BEDC channel code.*

Definition 9462.1208 (Alternative-code reassignment spectrum)**.** *Let $E_1 : Q_6 \to C_1$ be the standard genetic-code classifier and let $E_t : Q_6 \to C_t$ be another curated genetic-code table on the same codon carrier. The reassignment set is*

$$\Delta_t := \{c \in Q_6 : E_t(c) \neq E_1(c)\}.$$

For a family of tables, the reassignment spectrum is the finite multiset of all codon rows in all Δ_t, grouped by local codon module.

Concretized in §3589: Alternative-code reassignment spectra are realized as finite standard-code comparison, module ledger, sparse-support, transport, provenance, and NameCert rows.

Definition 9462.1209 (Four reassignment modules)**.** *The comparison ledger uses four local modules:*

$$\begin{aligned} M_{\text{Stop/Trp}} &= \{\text{UAA}, \text{UAG}, \text{UGA}, \text{UGG}\}, \\ M_{\text{Ile/Met}} &= \{\text{AUU}, \text{AUC}, \text{AUA}, \text{AUG}\}, \\ M_{\text{Phe/Leu}} &= \{\text{UUU}, \text{UUC}, \text{UUA}, \text{UUG}, \text{CUU}, \text{CUC}, \text{CUA}, \text{CUG}\}, \\ M_{\text{AGA/AGG}} &= \{\text{AGA}, \text{AGG}\}. \end{aligned}$$

The first two are the complete global $3+1$ control tiles of Definition 9462.1167; the third is the unique Phe/Leu $6+2$ cube of Definition 9462.1177; the fourth is a two-codon Arg-side pair that becomes visible in comparative tables.

Theorem 9462.1210 (Alternative-code reassignment concentration)**.** *Across the curated non-standard genetic-code tables compared with the standard table, the reassignment spectrum has* 65 *codon rows. Grouped by the modules of Definition 9462.1209, the counts are*

module	*reassignment rows*	*tables involved*
$M_{\text{Stop/Trp}}$	33	22
$M_{\text{AGA/AGG}}$	16	8
$M_{\text{Phe/Leu}}$	7	4
$M_{\text{Ile/Met}}$	5	5
other codons	4	4.

Proof. For each non-standard table, compare all 64 codon assignments with the standard classifier and record exactly those codons whose label changes. Classifying the resulting 65 rows by Definition 9462.1209 gives the displayed finite table. The enumeration is bridge-side data over curated genetic-code tables; it is not a BEDC derivation of those biological assignments. □

Corollary 9462.1211 (Stop/Trp is the main deformation face)**.** *The Stop/Trp tile contains only four codons, but it accounts for* 33 *of the* 65 *reassignment rows. Thus it is the dominant local deformation face in the comparative spectrum.*

Proof. This is the first row of Definition 9462.1210. □

Theorem 9462.1212 (Sparse reassignment codon support)**.** *Across the comparison family, the codons that are ever reassigned relative to the standard classifier are exactly*

$$\text{UGA, UAG, UAA, AUA, AGA, AGG, AAA,}$$
$$\text{CUG, CUU, CUC, CUA, UCA, UUA.}$$

With multiplicity over tables, the codon counts are

codon	*standard label*	*count*	*observed target labels*
UGA	Stop	15	Trp, Cys, Gly, Stop|Trp
UAG	Stop	10	Gln, Leu, Tyr, Glu, Trp, partial
AGA	Arg	8	Stop, Ser, Gly
AGG	Arg	8	Stop, Ser, Gly, Lys
UAA	Stop	8	Gln, Tyr, Glu, partial
AUA	Ile	5	Met
CUG	Leu	3	Thr, Ser, Ala
AAA	Lys	3	Asn
CUU, CUC, CUA	Leu	1 *each*	Thr
UCA	Ser	1	Stop
UUA	Leu	1	Stop.

Proof. For each non-standard table, compare all 64 rows against the standard classifier, retaining partial labels as distinct target labels when the bridge table records a partial stop/sense assignment. Taking the union of changed codons gives the displayed 13-codon support; keeping table multiplicity gives the displayed counts. □

Corollary 9462.1213 (Comparative variation is sparse)**.** *The comparison changes only* 13 *of the* 64 *codons relative to the standard classifier. Thus the observed family is a sparse reassignment family rather than a global reshuffling of the codon carrier.*

Proof. This is the support size in Definition 9462.1212. □

Theorem 9462.1214 (Control half-cube concentration)**.** *Let*

$$Q_5^{\mathrm{ctrl}} = \{x \in Q_6 : b_1^f(x) = 0\}.$$

Among the 65 *reassignment rows in the comparison family,* 59 *lie in* Q_5^{ctrl} *and* 6 *lie outside it:*

region	*reassignment rows*
$b_1^f = 0$	59
$b_1^f = 1$	6.

Equivalently, 59/65 *of the reassignment rows lie in the same half-cube that contains the dual Ile/Met and Stop/Trp control tiles.*

Proof. For each reassignment row, decode the codon to its six-bit word and read the first-base family bit. The finite count gives 59 rows with $b_1^f = 0$ and 6 rows with $b_1^f = 1$. The identification of this half-cube with the shared dual-control half-cube is Definition 9462.1194. □

Corollary 9462.1215 (The shared half-cube is the comparative working region)**.** *The half-cube selected by the standard-code dual control tiles is also the main region of observed comparative reassignment. In this sense* $b_1^f = 0$ *is both a standard-code control half-cube and the dominant comparative deformation region.*

Proof. The standard-code half-cube is Definition 9462.1194. Its comparative concentration is Definition 9462.1214. □

Theorem 9462.1216 (Refined reassignment module counts)**.** *The* 65 *reassignment rows decompose into the following refined local modules:*

module	*codons*	*rows*
Stop/Trp X_2	UAA, UAG, UGA	33
AGR	AGA, AGG	16
Ile/Met leaf	AUA	5
AAA leaf	AAA	3
rare stop insertions	UCA, UUA	2
CUN Leu	CUU, CUC, CUA, CUG	6.

The first three rows contribute 54 *of the* 65 *reassignment rows.*

Proof. Group the codon counts in Definition 9462.1212 by the displayed codon sets and sum within each set. □

Corollary 9462.1217 (Main comparative axis)**.** *The dominant comparative axis is*

$$\text{Stop/Trp} \;+\; \text{AGR} \;+\; \text{Ile/Met}.$$

It accounts for 54/65 *reassignment rows, while the remaining rows are confined to the AAA leaf, two rare stop insertions, and the CUN Leu module.*

Proof. This is the sum of the first three rows in Definition 9462.1216. □

Theorem 9462.1218 (Connected reassignment support)**.** *Let R be the set of the* 13 *codons that are ever reassigned in the comparison family. The induced Hamming subgraph $Q_6[R]$ is connected and has* 16 *internal edges.*

Proof. Take the support set from Definition 9462.1212. Enumerate all Hamming edges whose two endpoints lie in this set. The finite enumeration gives 16 such edges. A breadth-first search from any vertex reaches all 13 codons. □

Corollary 9462.1219 (Reassignment support is a connected zone)**.** *The reassigned codons are not scattered as isolated vertices of Q_6. They form one connected local deformation zone, whose weighted mass is concentrated in the control half-cube $b_1^f = 0$.*

Proof. Connectivity is Definition 9462.1218. Weighted half-cube concentration is Definition 9462.1214. □

Theorem 9462.1220 (Stop/Trp 11 corner is invariant across the comparison)**.** *In the Stop/Trp tile, all observed reassignments occur in the X_2 side:*

local corner	*codon*	*standard label*	*reassignment rows*
00	UAA	Stop	8
01	UAG	Stop	10
10	UGA	Stop	15
11	UGG	Trp	0.

Proof. Restrict the reassignment spectrum to the four codons UAA, UAG, UGA, and UGG. The finite count gives the displayed rows. In particular, the local 11 corner UGG remains assigned to Trp throughout the comparison. □

Corollary 9462.1221 (The Stop/Trp 11 corner is continuation, not absence)**.** *The comparative spectrum strengthens the reserved-corner reading of Definition 9462.1163: inside the Stop/Trp tile,* 11 *is a stable continuation corner, while the* X_2 *side carries the observed stop-boundary deformations.*

Proof. The standard-code interpretation of UGG is continuation by Definition 9462.1204. Its reassignment count is zero by Definition 9462.1220. □

Theorem 9462.1222 (Coupled 10-to-11 control-tile reassignment)**.** *The only observed Ile/Met tile reassignment is*

$$\mathrm{AUA} : \mathrm{Ile} \to \mathrm{Met}.$$

It occurs in exactly the tables

$$2, \quad 3, \quad 5, \quad 13, \quad 21.$$

Each of these tables also has

$$\mathrm{UGA} : \mathrm{Stop} \to \mathrm{Trp}.$$

In local coordinates, both changes have the form

$$10 \textit{ joins the class containing } 11.$$

Proof. In the Ile/Met tile, AUA = AU + 10 and AUG = AU + 11. In the Stop/Trp tile, UGA = U + RR + 10 and UGG = U + RR + 11. The finite comparison of non-standard tables shows that the AUA-to-Met row occurs exactly in the displayed five table identifiers, and each of those identifiers also contains the UGA-to-Trp row. The local coordinate action is therefore the same in both complete control tiles. □

Corollary 9462.1223 (Dual control tiles are coupled in observed variation)**.** *The Ile/Met and Stop/Trp complete control tiles are not merely parallel standard-code structures. In the comparative spectrum, the observed Ile/Met deformation is always accompanied by the corresponding Stop/Trp* 10-*to*-11 *deformation.*

Proof. This is the inclusion of table identifiers established in Definition 9462.1222. □

Theorem 9462.1224 (Control-tile pattern spectra across comparison tables)**.** *Across the comparison family, the Ile/Met tile has exactly two partial-aware local patterns:*

Ile/Met pattern on (AUU, AUC, AUA, AUG)	*table count*
$I/I/I/M$	22
$I/I/M/M$	5.

The Stop/Trp tile has 14 *partial-aware local patterns. The highest count rows are*

Stop/Trp pattern on (UAA, UAG, UGA, UGG)	*table count*
$*/*/W/W$	8
$*/*/*/W$	5
$Y/*/W/W$	2
$*/L/*/W$	2.

The remaining ten Stop/Trp patterns each occur once:

$$Q/Q/*/W, \quad */Q/*/W, \quad */*/C/W, \quad */*/G/W, \quad Y/Y/*/W,$$
$$E/E/*/W, \quad */W/*/W, \quad Q/Q/*|W/W, \quad Q|*/Q|*/*|W/W, \quad E|*/E|*/W/W.$$

Proof. For each table, read the four tile coordinates in the displayed order. The comparison keeps partial rows such as $*|W$, $Q|*$, and $E|*$ as separate labels. Finite grouping gives the two Ile/Met rows and the fourteen Stop/Trp rows. □

Corollary 9462.1225 (Stop/Trp has richer comparative tile dynamics)**.** *The Ile/Met tile supports one observed nonstandard local operation, the* 10 *leaf joining the* 11 *Met corner. The Stop/Trp tile supports that same* 10*-to-*11 *form and also arm, one-sided, and partial-boundary forms on the* X_2 *side.*

Proof. The Ile/Met patterns in Definition 9462.1224 differ only by the third coordinate. The Stop/Trp patterns include changes in the first two coordinates and partial labels as well as the third coordinate. □

Theorem 9462.1226 (Alternative-code edge smoothness remains local)**.** *Across the standard table together with the curated non-standard genetic-code tables, the total number of same-class Hamming edges lies between* 47 *and* 52*, with mean approximately* 50.07*. The third-base family bit remains the dominant stable direction: its same-class edge count ranges from* 28 *to* 32 *out of* 32*, with mean approximately* 30.04*. The first-base shape bit has zero same-class edges in every table.*

Proof. For each table, enumerate the same 192 Hamming edges used in Definition 9462.1169 and count same-class endpoints, both in total and by bit direction. The displayed range and means are the finite counts over the comparison family. □

Corollary 9462.1227 (Alternative codes are local deformations)**.** *The comparative tables preserve the broad Hamming-local smoothness profile of the standard code while moving a small number of codon assignments, concentrated in the Stop/Trp tile, the Ile/Met tile, the Phe/Leu cube, and the AGA/AGG pair.*

Proof. The edge-count range is narrow by Definition 9462.1226, and the reassignment rows are concentrated by Definition 9462.1210. □

Theorem 9462.1228 (Nucleotide-substitution smoothness across the comparison)**.** *For ordinary single-nucleotide substitution edges, the mean same-class edge count across the comparison family is approximately* 69.04 *out of* 288*. By codon position, the mean same-class counts are approximately*

$$3.59, \qquad 0.67, \qquad 64.78$$

out of 96 *edges per position.*

Proof. For each table and each codon position, fix the other two bases and connect the four choices at the chosen position by the complete graph on four bases. Counting same-class endpoints over the resulting 288 substitution edges gives the displayed means. □

Corollary 9462.1229 (Third-position stability is table-family level)**.** *The third-position stability seen in the standard table is preserved across the comparison family, both for two-axis bit flips and for ordinary single-nucleotide substitution edges.*

Proof. The bit-flip statement is Definition 9462.1226. The nucleotide-substitution statement is Definition 9462.1228. □

Theorem 9462.1230 (Comparative tile-dynamics cannot-claim boundary)**.** *The comparative reassignment spectrum does not license any claim that alternative genetic codes are forced by BEDC, that the observed curated tables exhaust all possible biological translation systems, that codon identity alone determines ribosome dynamics, that reassignment frequency is a mechanistic cause, or that the AGA/AGG pair has already been reduced to a complete local control-tile certificate.*

Proof. The spectrum is a finite bridge-side comparison of curated external tables. It records where assignment rows differ from the standard classifier. It does not supply biochemical mechanism, evolutionary necessity, exhaustive biological coverage, or a checked BEDC certificate for the AGA/AGG pair. □

Corollary 9462.1231 (Allowed comparative tile-dynamics claim)**.** *Under the two-axis codon bridge, comparative genetic-code variation is strongly concentrated in local modules already visible in the standard codon-cube spectra. The Stop/Trp tile is the main deformation face; the shared* $b_1^f = 0$ *half-cube is the dominant reassignment region; the Stop/Trp* 11 *corner remains a stable continuation corner; and the observed Ile/Met deformation is coupled to the corresponding Stop/Trp* 10-*to*-11 *deformation.*

Proof. Combine Definition 9462.1210, Definition 9462.1214, Definition 9462.1220, and Definition 9462.1222. □

Concretized in §6448: Alternative-code reassignment spectra are realized as finite support, reassignment, spectral, transport, replay, provenance, and NameCert rows.

Definition 9462.1232 (Reassignment weight and subcube mass)**.** *For a codon* c*, define its comparative reassignment weight by*

$$w(c) = |\{t : E_t(c) \neq E_1(c)\}|,$$

where E_1 *is the standard classifier and* E_t *ranges over the curated comparison tables. For a subcube* $S \subset Q_6$*, define its reassignment mass by*

$$M(S) = \sum_{c \in S} w(c).$$

Theorem 9462.1233 (Nested maximum-mass subcubes)**.** *Among all axis-aligned subcubes of the indicated dimension, the unique maximum-mass subcubes form the following nested chain:*

dimension	*fixed conditions*	*codon reading*	*mass*	*fraction*
Q_5	$b_3^s = 1$	$c_3 \in \{\mathrm{A}, \mathrm{G}\}$	63	63/65
Q_4	$b_1^f = 0,\ b_3^s = 1$	$c_1 \in \{\mathrm{U}, \mathrm{A}\},\ c_3 \in \{\mathrm{A}, \mathrm{G}\}$	59	59/65
Q_3	$b_1^f = 0,\ b_2^s = 1,\ b_3^s = 1$	$c_1 \in \{\mathrm{U}, \mathrm{A}\},\ c_2, c_3 \in \{\mathrm{A}, \mathrm{G}\}$	52	52/65
Q_2	$\{\mathrm{AAA}, \mathrm{AGA}, \mathrm{UAA}, \mathrm{UGA}\}$	*A-ending purine-core square*	34	34/65.

Proof. Enumerate all axis-aligned Q_d subcubes for $d = 5, 4, 3, 2$ and compute $M(S)$ from Definition 9462.1232. At each dimension, the maximum is attained by exactly one subcube, and the four maximizers are the displayed nested subcubes. □

Corollary 9462.1234 (Purine-ending constraint)**.** *The strongest single-bit constraint on reassignment mass is $b_3^s = 1$: 63 of the 65 reassignment rows have third codon base in $\{\mathrm{A}, \mathrm{G}\}$.*

Proof. This is the Q_5 row of Definition 9462.1233. □

Definition 9462.1235 (Purine-core cube)**.** *The purine-core cube is*

$$Q_3^{\mathrm{pur}} = \{\mathrm{U}, \mathrm{A}\} \times \{\mathrm{A}, \mathrm{G}\} \times \{\mathrm{A}, \mathrm{G}\}.$$

Equivalently,

$$Q_3^{\mathrm{pur}} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}, \mathrm{AAA}, \mathrm{AAG}, \mathrm{AGA}, \mathrm{AGG}\}.$$

Theorem 9462.1236 (Purine-core cube is the maximum-mass Q_3)**.** *The purine-core cube is the unique maximum-mass Q_3 subcube. Its standard labels and reassignment weights are*

codon	*standard label*	$w(c)$
UAA	Stop	8
UAG	Stop	10
UGA	Stop	15
UGG	Trp	0
AAA	Lys	3
AAG	Lys	0
AGA	Arg	8
AGG	Arg	8.

Thus $M(Q_3^{\mathrm{pur}}) = 52$.

Proof. The Q_3 maximum in Definition 9462.1233 is fixed by $b_1^f = 0$, $b_2^s = 1$, and $b_3^s = 1$, which is exactly Definition 9462.1235. Summing the displayed weights gives 52. □

Corollary 9462.1237 (Stop/Trp sits inside the Stop/Lys/Arg/Trp core)**.** *The Stop/Trp tile is not the whole comparative hotspot. It is embedded inside the larger standard-code pattern*

$$\mathrm{Stop}_3 + \mathrm{Lys}_2 + \mathrm{Arg}_2 + \mathrm{Trp}_1$$

on Q_3^{pur}.

Proof. Read the standard labels in Definition 9462.1236. The first four codons are the Stop/Trp tile; the other four codons are the Lys and Arg doubletons. □

Definition 9462.1238 (A-ending purine-core square)**.** *The A-ending purine-core square is*

$$Q_2^{\mathrm{Aend}} = \{\mathrm{AAA}, \mathrm{AGA}, \mathrm{UAA}, \mathrm{UGA}\}.$$

Theorem 9462.1239 (A-ending square is the maximum-mass Q_2)**.** *The square Q_2^{Aend} is the unique maximum-mass Q_2 face. Its weights are*

codon	*standard label*	$w(c)$
AAA	Lys	3
AGA	Arg	8
UAA	Stop	8
UGA	Stop	15.

Thus $M(Q_2^{\mathrm{Aend}}) = 34$.

Proof. Enumerating the 240 axis-aligned Q_2 faces and summing reassignment weights gives a unique maximum of 34, attained at $\{\mathrm{AAA}, \mathrm{AGA}, \mathrm{UAA}, \mathrm{UGA}\}$. □

Corollary 9462.1240 (Static and comparative faces differ)**.** *The static* $3+1$ *control tile is*

$$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\},$$

with reassignment mass 33*. The maximum-mass comparative* Q_2 *face is*

$$\{\mathrm{AAA}, \mathrm{AGA}, \mathrm{UAA}, \mathrm{UGA}\},$$

with reassignment mass 34*. Thus the static coding-control face and the comparative maximum-mass face are adjacent but not identical.*

Proof. The Stop/Trp mass is $8 + 10 + 15 + 0 = 33$ by Definition 9462.1236. The comparative maximum Q_2 mass is Definition 9462.1239. □

Theorem 9462.1241 (Complete reassignment Q_2 faces)**.** *Among the* 240 *axis-aligned* Q_2 *faces, the distribution by number of reassigned vertices is*

reassigned vertices in the face	0	1	2	3	4
face count	123	60	40	13	4.

The four faces whose vertices are all reassigned codons are

face	*mass*	*reading*
$\{\mathrm{AAA}, \mathrm{AGA}, \mathrm{UAA}, \mathrm{UGA}\}$	34	*A-ending purine-core square*
$\{\mathrm{UAA}, \mathrm{UCA}, \mathrm{UGA}, \mathrm{UUA}\}$	25	*U-first A-ending square*
$\{\mathrm{AAA}, \mathrm{AUA}, \mathrm{UAA}, \mathrm{UUA}\}$	17	*A-ending first-position square*
$\{\mathrm{CUA}, \mathrm{CUC}, \mathrm{CUG}, \mathrm{CUU}\}$	6	*CUN Leu square.*

Proof. For each Q_2 face, count how many of its four vertices have positive reassignment weight. The resulting finite distribution and the four complete faces are displayed. □

Corollary 9462.1242 (Reassignment support contains a small surface)**.** *The reassigned codon support contains four complete* Q_2 *faces. Thus the support is not only Hamming-connected; it contains a small local surface made from square faces.*

Proof. Connectivity was established in Definition 9462.1218. The complete square faces are Definition 9462.1241. □

Definition 9462.1243 (Co-reassignment edge weight)**.** *For adjacent codons* $c \sim d$ *in the reassignment support, define*

$$\omega(c, d) = |\{t : E_t(c) \neq E_1(c) \text{ and } E_t(d) \neq E_1(d)\}|.$$

Theorem 9462.1244 (Positive co-reassignment edges)**.** *The positive co-reassignment edges are*

edge	ω
UGA−AGA	8
AGA−AGG	8
UAA−UAG	6
UAA−UGA	5
AGA−AAA	3
AUA−AAA	1
UAA−AAA	1
CUA−CUG	1
CUC−CUG	1
CUU−CUA	1
CUU−CUC	1.

Proof. Restrict the Q_6 Hamming graph to reassigned codons. For each internal edge, intersect the two sets of comparison tables in which its endpoints are reassigned. The positive intersections are exactly the displayed finite table. □

Corollary 9462.1245 (Weighted deformation spine)**.** *The highest-weight co-reassignment path is*

$$\mathrm{UAG} - \mathrm{UAA} - \mathrm{UGA} - \mathrm{AGA} - \mathrm{AGG},$$

with branch

$$\mathrm{AGA} - \mathrm{AAA} - \mathrm{AUA}.$$

In particular, UGA *is not only a Stop/Trp tile leaf; it is also the Hamming bridge from the stop side to the AGR side.*

Proof. Read the positive edge weights in Definition 9462.1244. The edges UGA−AGA and AGA−AGG have weight 8, and the stop-arm edges have weights 6 and 5. □

Theorem 9462.1246 (Positive co-reassignment components)**.** *The graph on reassigned codons using only positive co-reassignment edges has components*

$$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{AAA}, \mathrm{AUA}, \mathrm{AGA}, \mathrm{AGG}\},$$
$$\{\mathrm{CUU}, \mathrm{CUC}, \mathrm{CUA}, \mathrm{CUG}\},$$
$$\{\mathrm{UCA}\}, \qquad \{\mathrm{UUA}\}.$$

Proof. Use the positive edge list of Definition 9462.1244 and compute connected components. The isolated vertices are reassigned codons whose Hamming-neighbor co-reassignment intersections are zero. □

Corollary 9462.1247 (Geometric support and co-reassignment support differ)**.** *The full reassignment support is connected as a Hamming subgraph, but positive co-reassignment separates a Stop/AGR/AUA/AAA component from a CUN component and two isolated low-frequency codons.*

Proof. Hamming connectivity is Definition 9462.1218. Positive co-reassignment connectivity is Definition 9462.1246. □

Theorem 9462.1248 (Nested-core comparative dynamics statement)**.** *The comparative reassignment spectrum is concentrated along a nested subcube core*

$$Q_5 \supset Q_4 \supset Q_3 \supset Q_2,$$

where the Q_3 core is

$$Q_3^{\mathrm{pur}} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}, \mathrm{AAA}, \mathrm{AAG}, \mathrm{AGA}, \mathrm{AGG}\}.$$

The same data define a positive co-reassignment spine

$$\mathrm{UAG} - \mathrm{UAA} - \mathrm{UGA} - \mathrm{AGA} - \mathrm{AGG}$$

with branch $\mathrm{AGA} - \mathrm{AAA} - \mathrm{AUA}$.

Proof. The nested subcube core is Definition 9462.1233. The Q_3 core is identified in Definition 9462.1236. The weighted spine is Definition 9462.1245. □

Concretized in §5869: finite maximum-mass subcube NameCert for reassignment geometry

Definition 9462.1249 (Connected deformation candidate)**.** *Let $R = \{c : w(c) > 0\}$ be the reassigned codon support. A subset $S \subseteq R$ is a connected deformation candidate when the Hamming subgraph $Q_6[S]$ is connected. Its mass is*

$$M(S) = \sum_{c \in S} w(c).$$

For each cardinality k, define a maximum-mass connected candidate by maximizing $M(S)$ over connected $S \subseteq R$ with $|S| = k$.

Theorem 9462.1250 (Maximum-mass connected candidates)**.** *For $k = 1, \ldots, 7$, the maximum-mass connected candidates are*

k	*maximum mass*	*maximizing connected support*
1	15	$\{\mathrm{UGA}\}$
2	23	$\{\mathrm{UGA}, \mathrm{AGA}\}$ *or* $\{\mathrm{UGA}, \mathrm{UAA}\}$
3	33	$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$
4	41	$\{\mathrm{AGA}, \mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$
5	49	$\{\mathrm{AGA}, \mathrm{AGG}, \mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$
6	52	$\{\mathrm{AAA}, \mathrm{AGA}, \mathrm{AGG}, \mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$
7	57	$\{\mathrm{AAA}, \mathrm{AGA}, \mathrm{AGG}, \mathrm{AUA}, \mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$.

From $k = 3$ through $k = 7$, the maximizer is unique and the supports form a nested chain.

Proof. Enumerate all subsets of R of cardinality k, discard those whose induced Hamming subgraph is disconnected, and compute the mass from Definition 9462.1232. The finite enumeration gives the displayed table. The $k = 2$ row has two maximizers; the rows $k = 3, \ldots, 7$ have one maximizer each, and direct inclusion checks give the nested chain. □

Corollary 9462.1251 (Stop triplet is the first stable connected core)**.** *The first unique connected optimum beyond the singleton case is*

$$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\},$$

the standard Stop tripleton.

Proof. This is the $k = 3$ row of Definition 9462.1250. □

Corollary 9462.1252 (UGA is the stop-to-AGR bridge)**.** *The connected optimum grows from the Stop tripleton by adding* AGA *through the Hamming edge*

$$\mathrm{UGA} - \mathrm{AGA}.$$

Thus UGA *is both the* 10 *leaf of the Stop/Trp tile and the bridge from the stop side into the AGR side of the comparative support.*

Proof. The $k = 4$ optimum in Definition 9462.1250 adds AGA to the Stop tripleton. The edge UGA − AGA is a Hamming edge, and it is one of the highest-weight co-reassignment edges in Definition 9462.1244. □

Definition 9462.1253 (Bit majority mass)**.** *For a bit coordinate i, define*

$$M_i(\epsilon) = \sum_{c:b_i(c)=\epsilon} w(c), \qquad \epsilon \in \{0, 1\}.$$

The majority mass at bit i is

$$M_i^{\max} = \max(M_i(0), M_i(1)).$$

Theorem 9462.1254 (Bit-level reassignment concentration)**.** *The six bit coordinates have the following majority masses:*

bit	*majority condition*	*majority mass*	*fraction*
b_1^s	0	41	41/65
b_1^f	0	59	59/65
b_2^s	1	52	52/65
b_2^f	0	33	33/65
b_3^s	1	63	63/65
b_3^f	0	43	43/65.

The strongest single-bit condition is $b_3^s = 1$, the third-position purine condition.

Proof. For each reassigned codon, add its weight to the 0 or 1 bucket of each bit coordinate. Taking the larger bucket at each bit gives the displayed table. □

Corollary 9462.1255 (Third-position dual role)**.** *The third codon position has two distinct roles in the two-axis spectrum: b_3^f is the dominant same-class Hamming direction in Definition 9462.1170, while $b_3^s = 1$ is the dominant single-bit concentration condition for reassignment mass.*

Proof. The same-class edge statement is Definition 9462.1170. The reassignment-mass statement is Definition 9462.1254. □

Theorem 9462.1256 (High-mass core and broad-support core)**.** *Among Q_3 subcubes, the maximum-mass core is the purine-core cube of Definition 9462.1235, with mass* 52 *and six reassigned vertices. The unique Q_3 subcube containing the largest number of reassigned vertices is*

$$\{\mathrm{UUA}, \mathrm{UCA}, \mathrm{UAA}, \mathrm{UGA}, \mathrm{AUA}, \mathrm{ACA}, \mathrm{AAA}, \mathrm{AGA}\}.$$

It is fixed by

$$b_1^f = 0, \qquad b_3^s = 1, \qquad b_3^f = 0,$$

contains seven reassigned vertices, and has mass 41.

Proof. Enumerate the 160 axis-aligned Q_3 subcubes. Sorting by reassignment mass gives the purine-core cube as in Definition 9462.1236. Sorting by the number of vertices with positive reassignment weight gives the displayed A-ending cube, uniquely. □

Corollary 9462.1257 (Two cores in the reassignment zone)**.** *The reassignment zone has a high-mass core*

$$Q_3^{\mathrm{pur}}, \qquad M = 52,$$

and a broad-support A-ending core with seven reassigned vertices and mass 41*.*

Proof. This is a restatement of Definition 9462.1256. □

Theorem 9462.1258 (Three-block low-dimensional cover)**.** *All* 13 *reassigned codons can be covered by three low-dimensional subcubes:*

block	*covered reassigned codons*	*mass*
Q_3^{pur}	{UAA, UAG, UGA, AAA, AGA, AGG}	52
{CUU, CUC, CUA, CUG}	{CUU, CUC, CUA, CUG}	6
{UUA, UCA, AUA, ACA}	{UUA, UCA, AUA}	7.

The minimum number of Q_2 and Q_3 blocks needed to cover all reassigned codons is 3*.*

Proof. Enumerate all Q_2 and Q_3 subcubes and solve the finite set cover problem over the reassigned support. No one-block or two-block cover exists, and the displayed three blocks cover all 13 reassigned codons. □

Corollary 9462.1259 (Three-module compression)**.** *The comparative support admits a three-module compression:*

$$\textit{purine-core } Q_3 \quad + \quad \textit{CUN square} \quad + \quad \textit{A-ending residual square.}$$

Proof. This is the semantic reading of the three blocks in Definition 9462.1258. □

Theorem 9462.1260 (Weighted deformation spine)**.** *The comparative reassignment spectrum is governed by the nested connected spine*

$$\begin{gathered}\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\} \subset \{\mathrm{AGA}, \mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\} \\ \subset \{\mathrm{AGA}, \mathrm{AGG}, \mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\} \subset \{\mathrm{AAA}, \mathrm{AGA}, \mathrm{AGG}, \mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\} \\ \subset \{\mathrm{AAA}, \mathrm{AGA}, \mathrm{AGG}, \mathrm{AUA}, \mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}.\end{gathered}$$

As a Hamming graph, its main path is

$$\mathrm{UAG} - \mathrm{UAA} - \mathrm{UGA} - \mathrm{AGA} - \mathrm{AGG},$$

with branch

$$\mathrm{AGA} - \mathrm{AAA} - \mathrm{AUA}.$$

Proof. The nested connected supports are the unique maximum-mass connected candidates for $k = 3, \ldots, 7$ in Definition 9462.1250. Drawing the Hamming edges among those vertices gives the displayed path and branch. □

Corollary 9462.1261 (Stop, AGR, AAA, and AUA are one comparative spine)**.** *The Stop, AGR, AAA, and AUA reassignment modules are not separated in the weighted Hamming geometry. They lie on a single connected deformation spine.*

Proof. The spine in Definition 9462.1260 contains the Stop triplet, the AGR doublet, AAA, and AUA. □

Theorem 9462.1262 (Weighted-spine comparative dynamics statement)**.** *The comparative genetic-code spectrum has three simultaneous finite geometric descriptions:*

$$\textit{a maximum-mass subcube chain } Q_5 \supset Q_4 \supset Q_3 \supset Q_2,$$
$$\textit{a high-mass purine-core } Q_3 = \mathrm{Stop}_3 + \mathrm{Lys}_2 + \mathrm{Arg}_2 + \mathrm{Trp}_1,$$

and a weighted deformation spine UAG − UAA − UGA − AGA − AGG *with branch* AGA − AAA − AUA.

Proof. The subcube chain is Definition 9462.1233. The purine-core identification is Definition 9462.1236. The spine is Definition 9462.1260. □

Concretized in §5552: The weighted deformation spine is realized as finite trigger-support, weight-ledger, deformation-route, boundary-readback, transport, replay, provenance, and NameCert rows.

Definition 9462.1263 (Walsh spectrum of reassignment weight)**.** *Let $w : Q_6 \to \mathbb{R}_{\geq 0}$ be the reassignment weight function. For $S \subseteq \{1, \ldots, 6\}$, define*

$$\chi_S(x) = (-1)^{\sum_{i \in S} x_i}, \qquad \widehat{w}(S) = 2^{-6} \sum_{x \in Q_6} w(x)\chi_S(x).$$

Theorem 9462.1264 (Dominant Walsh coefficients)**.** *The largest non-constant Walsh coefficients of w are*

rank	S	$\widehat{w}(S)$	*reading*
1	b_3^s	−0.953125	*third base biased to purine*
2	$b_1^f b_3^s$	−0.890625	*first family with third purine*
3	b_1^f	0.828125	*first base biased to* {U, A}
4	$b_1^f b_2^s$	−0.796875	*first family with second purine*
5	$b_1^f b_2^s b_3^s$	0.734375	*purine-core interaction*
6	$b_2^s b_3^s$	0.671875	*second and third purine interaction*
7	b_2^s	−0.609375	*second base biased to purine.*

Proof. Evaluate the finite Walsh transform of Definition 9462.1263 over all 64 codons and sort the non-empty subsets by absolute coefficient. □

Corollary 9462.1265 (Walsh spectrum recovers the purine-core variables)**.** *The dominant spectral variables are exactly the coordinates defining the purine-core cube:*

$$b_1^f = 0, \qquad b_2^s = 1, \qquad b_3^s = 1.$$

Proof. The variables b_3^s, b_1^f, and b_2^s and their low-order interactions occupy the leading rows of Definition 9462.1264. These are exactly the fixed coordinates of Q_3^{pur} in Definition 9462.1235. □

Theorem 9462.1266 (Low-order spectral compressibility)**.** *After removing the constant coefficient, the Walsh energy $\sum_{S \neq \varnothing} \widehat{w}(S)^2$ has degree distribution*

degree	1	2	3	4	5	6
energy share	0.275	0.320	0.194	0.137	0.065	0.009.

Consequently, degrees at most 3 *account for approximately* 0.789 *of the non-constant energy, and degrees at most* 4 *account for approximately* 0.926.

Proof. Compute $\widehat{w}(S)^2$ for each non-empty subset $S \subseteq \{1, \ldots, 6\}$, group by $|S|$, and normalize by the total non-constant energy. □

Corollary 9462.1267 (Reassignment weight is low-order in Q_6)**.** *The reassignment weight function is largely controlled by low-order bit conditions rather than by high-degree oscillation on the full codon cube.*

Proof. This is the cumulative degree statement in Definition 9462.1266. □

Definition 9462.1268 (Weight-permutation null model)**.** *The permutation null model keeps the multiset of reassignment weights fixed and randomly assigns those weights to the* 64 *vertices of* Q_6*. For each randomized weight function and each* d*, record*

$$\max_{Q_d \subset Q_6} M(Q_d).$$

Theorem 9462.1269 (Subcube mass significance under permutation)**.** *Using* 100000 *fixed-seed random permutations of the reassignment weight multiset, the maximum subcube masses have the following null comparison:*

dimension	*observed maximum mass*	*random mean maximum mass*	p
Q_2	34	24.97	0.01415
Q_3	52	31.46	0.00020
Q_4	59	39.82	0.00053
Q_5	63	50.94	0.01003.

Here p *is the fraction of randomized trials whose maximum subcube mass is at least the observed maximum.*

Proof. For each trial in the permutation null model of Definition 9462.1268, enumerate all axis-aligned Q_d subcubes for $d = 2, 3, 4, 5$ and record the maximum mass. The displayed means and tail fractions are the resulting finite Monte Carlo counts with fixed seed. □

Corollary 9462.1270 (The strongest subcube signal is three-dimensional)**.** *Although the* Q_5 *condition captures* 63/65 *of the mass, the strongest permutation-null signal is the purine-core* Q_3*, which captures* 52/65 *of the mass on only eight codons.*

Proof. Compare the p column in Definition 9462.1269 with the subcube identities in Definition 9462.1233. □

Theorem 9462.1271 (Three-module geometric compression)**.** *The reassigned support cannot be covered by two* Q_2/Q_3 *subcubes, but it can be covered by three. One such cover is*

module	*covered reassigned codons*	*mass*
Q_3^{pur}	{UAA, UAG, UGA, AAA, AGA, AGG}	52
CUN square	{CUU, CUC, CUA, CUG}	6
A-ending residual square	{UUA, UCA, AUA}	7.

Proof. This is the finite Q_2/Q_3 set-cover enumeration of Definition 9462.1258. The first nonempty covers occur at size 3; the displayed cover is the canonical three-module reading used there. □

Corollary 9462.1272 (Purine core dominates the minimal compression)**.** *In the three-module compression,* Q_3^{pur} *carries* 52/65 *of the total reassignment mass. The two remaining* Q_2 *modules cover the low-mass residual support.*

Proof. Read the mass column of Definition 9462.1271. □

Theorem 9462.1273 (Spectral compression statement)**.** *The reassignment weight function is recovered by four independent finite signals:*

$$\begin{gathered}\textit{dominant Walsh variables } b_3^s, b_1^f, b_2^s,\\ \textit{low-order spectral energy concentration},\\ \textit{permutation-significant maximum } Q_3^{\mathrm{pur}},\\ \textit{and a three-module } Q_2/Q_3 \textit{ cover.}\end{gathered}$$

Thus the purine-core Q_3 is not an externally chosen block; it is selected by the spectrum, by subcube mass, by the permutation null model, and by geometric compression.

Proof. The Walsh variables are Definition 9462.1264. The energy concentration is Definition 9462.1266. The permutation-null statement is Definition 9462.1269. The geometric cover is Definition 9462.1271. □

Concretized in §3897: The Walsh coefficient and median-closure support rows are realized as a finite NameCert spectrum packet.

Definition 9462.1274 (Reassigned support)**.** *Let*

$$\mathcal{R} = \{c : \exists t,\ E_t(c) \neq E_1(c)\}$$

be the support of codons that are reassigned in at least one comparison table.

Theorem 9462.1275 (Reassigned support)**.** *The reassigned support is the* 13*-codon set*

$$\begin{gathered}\mathcal{R} = \{\mathrm{UGA}, \mathrm{UAG}, \mathrm{UAA}, \mathrm{AUA}, \mathrm{AGA}, \mathrm{AGG}, \mathrm{AAA},\\ \mathrm{CUG}, \mathrm{CUU}, \mathrm{CUC}, \mathrm{CUA}, \mathrm{UCA}, \mathrm{UUA}\}.\end{gathered}$$

Proof. This is the support computed in Definition 9462.1212, ignoring table multiplicity. □

Theorem 9462.1276 (Five-motif support formula)**.** *With IUPAC notation*

$$N = \{\mathrm{U}, \mathrm{C}, \mathrm{A}, \mathrm{G}\}, \qquad R = \{\mathrm{A}, \mathrm{G}\}, \qquad S = \{\mathrm{C}, \mathrm{G}\},$$

and

$$W = \{\mathrm{U}, \mathrm{A}\}, \qquad Y = \{\mathrm{U}, \mathrm{C}\},$$

the reassigned support satisfies the exact formula

$$\mathcal{R} = \mathrm{CUN} \cup \mathrm{AGR} \cup \mathrm{UNA} \cup \mathrm{WWA} \cup \mathrm{UAR}.$$

Proof. Expand the five motifs:

$$\begin{aligned}\mathrm{CUN} &= \{\mathrm{CUU}, \mathrm{CUC}, \mathrm{CUA}, \mathrm{CUG}\},\\ \mathrm{AGR} &= \{\mathrm{AGA}, \mathrm{AGG}\},\\ \mathrm{UNA} &= \{\mathrm{UUA}, \mathrm{UCA}, \mathrm{UAA}, \mathrm{UGA}\},\\ \mathrm{WWA} &= \{\mathrm{UUA}, \mathrm{UAA}, \mathrm{AUA}, \mathrm{AAA}\},\\ \mathrm{UAR} &= \{\mathrm{UAA}, \mathrm{UAG}\}.\end{aligned}$$

Their union is exactly the 13 codons displayed in Definition 9462.1275. □

Corollary 9462.1277 (Support is a union of motifs)**.** *The reassigned support is not merely a list of codons. It is the union of five low-dimensional codon motifs:*

$$\text{CUN}, \quad \text{AGR}, \quad \text{UNA}, \quad \text{WWA}, \quad \text{UAR}.$$

Proof. This is Definition 9462.1276. □

Definition 9462.1278 (Reassignment support function)**.** *The support function of the comparative reassignment set is the Boolean map*

$$F : Q_6 \to \{0,1\}, \qquad F(x) = 1 \iff x \in \mathcal{R}.$$

An exact subcube is an axis-aligned subcube $S \subset Q_6$ satisfying $S \subseteq \mathcal{R}$. A prime implicant is a maximal exact subcube under inclusion.

Theorem 9462.1279 (Boolean DNF form)**.** *Write a codon as*

$$(s_1, f_1, s_2, f_2, s_3, f_3)$$

using $U = 00$, $C = 01$, $A = 10$, and $G = 11$. Then F is the disjunction of the five terms

$$\begin{aligned}
\text{CUN} &: \neg s_1 \wedge f_1 \wedge \neg s_2 \wedge \neg f_2, \\
\text{AGR} &: s_1 \wedge \neg f_1 \wedge s_2 \wedge f_2 \wedge s_3, \\
\text{UNA} &: \neg s_1 \wedge \neg f_1 \wedge s_3 \wedge \neg f_3, \\
\text{WWA} &: \neg f_1 \wedge \neg f_2 \wedge s_3 \wedge \neg f_3, \\
\text{UAR} &: \neg s_1 \wedge \neg f_1 \wedge s_2 \wedge \neg f_2 \wedge s_3.
\end{aligned}$$

Proof. Each displayed Boolean term is exactly the bit condition defining the corresponding IUPAC motif in Definition 9462.1276. Their disjunction therefore defines the same support function F. □

Theorem 9462.1280 (Prime implicants of the reassignment support)**.** *The Boolean support function F has exactly seven prime implicants:*

motif	*codons*	*weight*
CUN	{CUU, CUC, CUA, CUG}	6
UNA	{UUA, UCA, UAA, UGA}	25
WRA	{AAA, AGA, UAA, UGA}	34
WWA	{AAA, AUA, UAA, UUA}	17
AGR	{AGA, AGG}	16
UAR	{UAA, UAG}	18
YUA	{CUA, UUA}	2.

Proof. Enumerate the axis-aligned subcubes of Q_6. Retain those whose vertices lie in $\mathcal{R}$, then delete every retained subcube strictly contained in another retained subcube. The remaining maximal exact subcubes are precisely the seven motifs displayed above. The weights are the table-count reassignment weights summed over the codons in each motif. □

Theorem 9462.1281 (Minimal prime-implicant cover)**.** *Among covers of $\mathcal{R}$ by prime implicants, the minimum cover size is 5, and the cover is unique:*

$$\text{CUN}, \quad \text{WWA}, \quad \text{UNA}, \quad \text{AGR}, \quad \text{UAR}.$$

Proof. Run finite set-cover enumeration over the seven prime implicants of Definition 9462.1280. No subfamily of size less than 5 covers $\mathcal{R}$, and exactly one subfamily of size 5 does. It is the displayed family. □

Theorem 9462.1282 (Exact subcube covers)**.** *If nonmaximal exact subcubes are also allowed, the minimum cover size is still* 5*, but the minimum cover is not unique. There are exactly six minimum covers:*

$$\{\mathrm{UAG}, \mathrm{USA}, \mathrm{AGR}, \mathrm{WWA}, \mathrm{CUN}\},$$
$$\{\mathrm{UAG}, \mathrm{AWA}, \mathrm{AGR}, \mathrm{UNA}, \mathrm{CUN}\},$$
$$\{\mathrm{UAG}, \mathrm{AGR}, \mathrm{WWA}, \mathrm{UNA}, \mathrm{CUN}\},$$
$$\{\mathrm{USA}, \mathrm{UAR}, \mathrm{AGR}, \mathrm{WWA}, \mathrm{CUN}\},$$
$$\{\mathrm{AWA}, \mathrm{UAR}, \mathrm{AGR}, \mathrm{UNA}, \mathrm{CUN}\},$$
$$\{\mathrm{UAR}, \mathrm{AGR}, \mathrm{WWA}, \mathrm{UNA}, \mathrm{CUN}\}.$$

Proof. Enumerate all exact subcubes, including singleton subcubes. There are 33 retained exact subcubes. A finite set-cover search gives no cover of size less than 5 and the six covers displayed above at size 5. □

Corollary 9462.1283 (Forced support motifs)**.** *Across all minimum exact subcube covers, the only common motifs are*

$$\mathrm{CUN} \qquad \textit{and} \qquad \mathrm{AGR}.$$

Proof. Intersect the six minimum covers in Definition 9462.1282. The common terms are exactly CUN and AGR. □

Concretized in §3558: Reassignment support compression is realized as finite support, motif, prime-implicant, minimal-cover, transport, replay, provenance, and NameCert rows.

Theorem 9462.1284 (Envelope versus exact support)**.** *The three-module low-dimensional envelope is*

$$\mathrm{WRR} \cup \mathrm{CUN} \cup \mathrm{WYA},$$

where

$$\mathrm{WRR} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}, \mathrm{AAA}, \mathrm{AAG}, \mathrm{AGA}, \mathrm{AGG}\},$$
$$\mathrm{CUN} = \{\mathrm{CUU}, \mathrm{CUC}, \mathrm{CUA}, \mathrm{CUG}\},$$
$$\mathrm{WYA} = \{\mathrm{UUA}, \mathrm{UCA}, \mathrm{AUA}, \mathrm{ACA}\}.$$

It satisfies

$$\mathrm{WRR} \cup \mathrm{CUN} \cup \mathrm{WYA} = \mathcal{R} \cup \{\mathrm{UGG}, \mathrm{AAG}, \mathrm{ACA}\}.$$

Proof. Expand the three motifs and compare with Definition 9462.1275. The only codons in the three-module envelope that are not in $\mathcal{R}$ are UGG, AAG, and ACA. □

Corollary 9462.1285 (Three-module envelope and five-motif support)**.** *There are two complementary compressions of the reassigned support:*

$$\mathcal{R} \subset \mathrm{WRR} \cup \mathrm{CUN} \cup \mathrm{WYA}$$

with three false-positive codons, and

$$\mathcal{R} = \mathrm{CUN} \cup \mathrm{AGR} \cup \mathrm{UNA} \cup \mathrm{WWA} \cup \mathrm{UAR}$$

with no false positives.

Proof. The envelope equality is Definition 9462.1284. The exact equality is Definition 9462.1276. □

Theorem 9462.1286 (Prime-implicant overlap hub)**.** *In the weighted overlap graph of the seven prime implicants,* WRA *has the largest total overlap weight. Its nonempty overlaps include*

$$\begin{aligned} \mathrm{WRA} \cap \mathrm{UNA} &= \{\mathrm{UAA}, \mathrm{UGA}\}, & \textit{weight} &= 23, \\ \mathrm{WRA} \cap \mathrm{WWA} &= \{\mathrm{AAA}, \mathrm{UAA}\}, & \textit{weight} &= 11, \\ \mathrm{WRA} \cap \mathrm{UAR} &= \{\mathrm{UAA}\}, & \textit{weight} &= 8, \\ \mathrm{WRA} \cap \mathrm{AGR} &= \{\mathrm{AGA}\}, & \textit{weight} &= 8. \end{aligned}$$

The total weighted overlap score of WRA *is* 50*, larger than the corresponding scores for* UNA*,* WWA*,* UAR*,* AGR*,* YUA*, and* CUN*.*

Proof. Take all pairwise intersections among the seven prime implicants in Definition 9462.1280. Weight each intersection by the reassignment weights of the shared codons and sum the incident intersection weights at each prime implicant. The incident score of WRA is $23 + 11 + 8 + 8 = 50$, and the other incident scores are smaller. □

Theorem 9462.1287 (Support compression statement)**.** *The comparative reassignment support admits separate support and mass geometries:*

$$\textit{support geometry: } \mathrm{CUN} \cup \mathrm{AGR} \cup \mathrm{UNA} \cup \mathrm{WWA} \cup \mathrm{UAR},$$
$$\textit{mass geometry: } \mathrm{WRA} \subset \mathrm{WRR}.$$

The support geometry is the unique minimum cover by prime implicants. The mass geometry identifies the highest-weight exact square WRA *inside the purine-core envelope* WRR*.*

Proof. The support-geometry statement is Definition 9462.1281. The mass statement follows from Definition 9462.1280 and Definition 9462.1286, together with the envelope identity in Definition 9462.1284. □

Definition 9462.1288 (Reassignment support graph)**.** *Let $G_{\mathcal{R}} = Q_6[\mathcal{R}]$ be the Hamming graph induced by the reassigned support $\mathcal{R}$. Thus two vertices of $G_{\mathcal{R}}$ are adjacent exactly when the corresponding codons differ in one bit of the two-axis readback.*

Theorem 9462.1289 (Reassignment support graph)**.** *The induced graph $G_{\mathcal{R}}$ is connected and has*

$$|V(G_{\mathcal{R}})| = 13, \qquad |E(G_{\mathcal{R}})| = 16.$$

Its cyclomatic number is therefore

$$|E| - |V| + 1 = 4.$$

Proof. Enumerating one-bit Hamming edges inside $\mathcal{R}$ gives

$$\begin{array}{llll} \mathrm{UUA}{-}\mathrm{AUA}, & \mathrm{UAA}{-}\mathrm{AAA}, & \mathrm{UGA}{-}\mathrm{AGA}, & \mathrm{UUA}{-}\mathrm{CUA}, \\ \mathrm{UUA}{-}\mathrm{UAA}, & \mathrm{UCA}{-}\mathrm{UGA}, & \mathrm{AUA}{-}\mathrm{AAA}, & \mathrm{UUA}{-}\mathrm{UCA}, \\ \mathrm{UAA}{-}\mathrm{UGA}, & \mathrm{AAA}{-}\mathrm{AGA}, & \mathrm{CUU}{-}\mathrm{CUA}, & \mathrm{CUC}{-}\mathrm{CUG}, \\ \mathrm{UAA}{-}\mathrm{UAG}, & \mathrm{CUU}{-}\mathrm{CUC}, & \mathrm{CUA}{-}\mathrm{CUG}, & \mathrm{AGA}{-}\mathrm{AGG}. \end{array}$$

These edges connect all 13 vertices, so the displayed cyclomatic number follows. □

Corollary 9462.1290 (Compact support graph)**.** *The support graph is significantly denser than a random* 13*-vertex subset of* Q_6*. The random-subset expectation is*

$$192 \cdot \frac{13 \cdot 12}{64 \cdot 63} = 7.428571\ldots$$

internal Hamming edges, while $G_{\mathcal{R}}$ *has* 16 *such edges. A* 100000*-trial fixed-seed random-subset test gives exceedance count* 19*, hence* $p = 0.00019$ *for observing at least* 16 *internal edges.*

Proof. The expectation is the number of Hamming edges in Q_6 times the probability that both endpoints of a fixed edge lie in a uniformly chosen 13-element subset. The Monte Carlo count is obtained by the same edge statistic over random supports of size 13. □

Theorem 9462.1291 (Four square cycles)**.** *The four independent cycles of* $G_{\mathcal{R}}$ *are represented by the four complete* Q_2 *faces*

$$\begin{aligned}
\mathrm{CUN} &= \{\mathrm{CUU}, \mathrm{CUC}, \mathrm{CUA}, \mathrm{CUG}\},\\
\mathrm{UNA} &= \{\mathrm{UUA}, \mathrm{UCA}, \mathrm{UAA}, \mathrm{UGA}\},\\
\mathrm{WWA} &= \{\mathrm{UUA}, \mathrm{UAA}, \mathrm{AUA}, \mathrm{AAA}\},\\
\mathrm{WRA} &= \{\mathrm{UAA}, \mathrm{UGA}, \mathrm{AAA}, \mathrm{AGA}\}.
\end{aligned}$$

Their reassignment weights are respectively 6*,* 25*,* 17*, and* 34*.*

Proof. Each displayed motif is an axis-aligned Q_2 face contained in $\mathcal{R}$, hence contributes a four-cycle to $G_{\mathcal{R}}$. Since Definition 9462.1289 gives cyclomatic number 4, these four square cycles account for the full cycle rank. □

Definition 9462.1292 (Punctured A-ending W-family cube)**.** *Let*

$$\mathrm{WNA} = \{\mathrm{U}, \mathrm{A}\} \times \{\mathrm{U}, \mathrm{C}, \mathrm{A}, \mathrm{G}\} \times \{\mathrm{A}\}.$$

Equivalently,

$$\mathrm{WNA} = \{\mathrm{UUA}, \mathrm{UCA}, \mathrm{UAA}, \mathrm{UGA}, \mathrm{AUA}, \mathrm{ACA}, \mathrm{AAA}, \mathrm{AGA}\}.$$

Theorem 9462.1293 (Punctured-cube skeleton formula)**.** *The reassigned support admits the exact cube-complex skeleton formula*

$$\mathcal{R} = (\mathrm{WNA} \setminus \{\mathrm{ACA}\}) \cup \mathrm{CUN} \cup \{\mathrm{UAG}, \mathrm{AGG}\}.$$

Proof. The punctured cube is

$$\mathrm{WNA} \setminus \{\mathrm{ACA}\} = \{\mathrm{UUA}, \mathrm{UCA}, \mathrm{UAA}, \mathrm{UGA}, \mathrm{AUA}, \mathrm{AAA}, \mathrm{AGA}\}.$$

Adding

$$\mathrm{CUN} = \{\mathrm{CUU}, \mathrm{CUC}, \mathrm{CUA}, \mathrm{CUG}\}$$

and the two codons $\mathrm{UAG}, \mathrm{AGG}$ gives exactly the support listed in Definition 9462.1275. □

Theorem 9462.1294 (Cube-complex edge decomposition)**.** *At the graph level,*

$$G_{\mathcal{R}} = G_{\mathrm{WNA}\setminus\{\mathrm{ACA}\}} \cup G_{\mathrm{CUN}} \cup \{\mathrm{UAA}{-}\mathrm{UAG}, \mathrm{AGA}{-}\mathrm{AGG}, \mathrm{UUA}{-}\mathrm{CUA}\}.$$

The punctured cube contributes 7 *vertices and* 9 *edges, the CUN square contributes* 4 *vertices and* 4 *edges, and the three displayed bridges account for the remaining edges.*

Proof. Intersect the edge list of Definition 9462.1289 with $\mathrm{WNA} \setminus \{\mathrm{ACA}\}$ and with CUN. The first induced subgraph has 9 listed edges, the second has 4, and the complement in the 16-edge support graph is precisely the three displayed bridge edges. □

Theorem 9462.1295 (Articulation gates)**.** *The articulation codons of $G_{\mathcal{R}}$ are exactly*

$$\mathrm{UAA}, \quad \mathrm{AGA}, \quad \mathrm{UUA}, \quad \mathrm{CUA}.$$

The leaf codons are exactly

$$\mathrm{UAG}, \quad \mathrm{AGG}.$$

Proof. Delete each vertex of $G_{\mathcal{R}}$ and recompute connected components. Only the four displayed codons disconnect the graph. The same adjacency list shows that UAG and AGG are the only vertices of degree one. □

Theorem 9462.1296 (Largest biconnected block)**.** *The largest biconnected component of $G_{\mathcal{R}}$ is the punctured cube*

$$\mathrm{WNA} \setminus \{\mathrm{ACA}\} = \{\mathrm{UUA}, \mathrm{UCA}, \mathrm{UAA}, \mathrm{UGA}, \mathrm{AUA}, \mathrm{AAA}, \mathrm{AGA}\}.$$

Its reassignment weight is 41*.*

Proof. The biconnected components of the support graph are

$$\{\mathrm{UUA}, \mathrm{UCA}, \mathrm{UAA}, \mathrm{UGA}, \mathrm{AUA}, \mathrm{AAA}, \mathrm{AGA}\},$$
$$\{\mathrm{CUU}, \mathrm{CUC}, \mathrm{CUA}, \mathrm{CUG}\}, \quad \{\mathrm{AGA}, \mathrm{AGG}\}, \quad \{\mathrm{CUA}, \mathrm{UUA}\}, \quad \{\mathrm{UAA}, \mathrm{UAG}\}.$$

The first is largest. Its weight is

$$1 + 1 + 8 + 15 + 5 + 3 + 8 = 41.$$

□

Theorem 9462.1297 (Support skeleton statement)**.** *The reassigned support has three compatible descriptions:*

$$\textit{prime support formula: } \mathrm{CUN} \cup \mathrm{AGR} \cup \mathrm{UNA} \cup \mathrm{WWA} \cup \mathrm{UAR},$$
$$\textit{cube-complex skeleton: } (\mathrm{WNA} \setminus \{\mathrm{ACA}\}) \cup \mathrm{CUN} \cup \{\mathrm{UAG}, \mathrm{AGG}\},$$
$$\textit{mass core: } \mathrm{WRA} \subset \mathrm{WRR}.$$

The first is the prime-implicant support formula, the second is the induced-graph skeleton, and the third is the weighted high-mass core.

Proof. Combine Definition 9462.1281, Definition 9462.1293, and Definition 9462.1287. □

Concretized in §3463: The punctured WNA cube, CUN square, bridge-edge, and articulation-gate support graph is realized as finite NameCert data.

Definition 9462.1298 (Outer reassignment boundary)**.** *The outer boundary of the reassigned support is*

$$\partial\mathcal{R} = \{z \notin \mathcal{R} : \exists r \in \mathcal{R},\ d_H(z, r) = 1\}.$$

For $z \in \partial\mathcal{R}$ define the boundary degree and boundary pressure by

$$d_\partial(z) = |\{r \in \mathcal{R} : d_H(z, r) = 1\}|,$$
$$P_\partial(z) = \sum_{r \in \mathcal{R},\ d_H(z,r)=1} w(r).$$

Theorem 9462.1299 (Outer boundary size)**.** *The reassigned support has* 46 *boundary edges and* 33 *distinct outer boundary codons:*

$$|\mathcal{R}| = 13, \qquad |E(G_{\mathcal{R}})| = 16, \qquad |\partial\mathcal{R}| = 33.$$

Proof. Each vertex of Q_6 has degree 6, so the 13 support vertices have 78 incident half-edges. The 16 internal edges of Definition 9462.1289 consume 32 of these half-edges. The remaining 46 half-edges leave the support. Enumerating their external endpoints gives 33 distinct codons. □

Theorem 9462.1300 (Highest-pressure inactive boundary codons)**.** *The highest-degree inactive boundary codons, ordered by boundary degree and then boundary pressure, begin as follows:*

codon	*class*	d_∂	P_∂	*support neighbors*
UGG	W	3	33	UAG, UGA, AGG
AAG	K	3	21	UAG, AAA, AGG
ACA	T	3	14	UCA, AUA, AGA
UUG	L	3	14	UUA, UAG, CUG
CAG	Q	2	13	UAG, CUG
CAA	Q	2	9	UAA, CUA
GUA	V	2	6	AUA, CUA
CCA	P	2	2	UCA, CUA
UUU	F	2	2	UUA, CUU.

Proof. For every $z \notin \mathcal{R}$, inspect the six Hamming neighbors of z. Retain z when at least one neighbor lies in $\mathcal{R}$, count these neighbors, and sum their reassignment weights. Sorting by boundary degree and pressure gives the displayed rows. □

Corollary 9462.1301 (Inactive envelope corners)**.** *The three false-positive codons in the three-module envelope are exactly*

$$\text{UGG}, \qquad \text{AAG}, \qquad \text{ACA}.$$

They are inactive boundary codons:

$$\text{WRR} \cup \text{CUN} \cup \text{WYA} = \mathcal{R} \cup \{\text{UGG}, \text{AAG}, \text{ACA}\}.$$

Proof. The envelope identity is Definition 9462.1284. The displayed codons also occur in the boundary table of Definition 9462.1300. □

Definition 9462.1302 (Q_2 completion frontier)**.** *The first Q_2-completion frontier is the set of codons $z \notin \mathcal{R}$ for which some Q_2 face contains exactly three vertices of $\mathcal{R}$ and has z as its fourth vertex:*

$$C_1(\mathcal{R}) = \{z \notin \mathcal{R} : \exists Q_2 \text{ face } F,\ |F \cap \mathcal{R}| = 3,\ z \in F \setminus \mathcal{R}\}.$$

Theorem 9462.1303 (First completion frontier)**.** *The first Q_2-completion frontier is*

$$C_1(\mathcal{R}) = \{\text{UGG}, \text{AAG}, \text{ACA}, \text{UUG}, \text{CAA}, \text{CCA}, \text{GUA}, \text{UUU}\}.$$

It is obtained from 13 *three-out-of-four Q_2 faces.*

Proof. Enumerate the 240 axis-aligned Q_2 faces of Q_6 and select those with exactly three vertices in $\mathcal{R}$. There are 13 such faces. Their missing vertices, after removing duplicates, are exactly the eight codons displayed above. □

Theorem 9462.1304 (Q_2 completion percolation)**.** *Starting from $S_0 = \mathcal{R}$ and iterating the rule*

$$S_{n+1} = S_n \cup \{z : \exists Q_2 \text{ face } F,\ |F \cap S_n| \geq 3,\ z \in F\},$$

the process reaches all 64 *codons in five stages. The stage sizes are*

stage	*added*	*codons*
1	8	AAG, ACA, CAA, CCA, GUA, UGG, UUG, UUU
2	16	ACG, AUG, AUU, CAG, CAU, CCG, CCU, CGA, GAA, GCA, GUG, GUU, UAU, UCG, UCU, UUC
3	16	AAU, ACU, AUC, CAC, CCC, CGG, CGU, GAG, GAU, GCG, GCU, GGA, GUC, UAC, UCC, UGU
4	9	AAC, ACC, AGU, CGC, GAC, GCC, GGG, GGU, UGC
5	2	AGC, GGC.

Proof. At each stage enumerate all Q_2 faces and adjoin every missing vertex of each face already containing at least three vertices of the current set. The displayed stage table is the direct finite iteration; after the fifth stage the set has size 64. □

Theorem 9462.1305 (Boundary class pressure)**.** *Aggregating outer-boundary codons by standard-code translation class, the highest-pressure classes are*

class	*boundary edges*	*pressure*	*codons*
W	3	33	UGG
Q	4	22	CAA, CAG
T	4	22	ACA, ACG
K	3	21	AAG
S	4	18	AGC, AGU, UCG, UCU
Y	2	18	UAC, UAU
G	2	16	GGA, GGG
C	1	15	UGU
R	1	15	CGA
L	3	14	UUG.

Proof. For each boundary codon z, take its standard-code class and add $d_\partial(z)$ and $P_\partial(z)$ to that class. Sorting the resulting class rows by pressure gives the displayed table. □

Theorem 9462.1306 (Boundary-closure structure)**.** *The reassigned support is a cubical seed with inactive boundary anchors:*

$$\mathcal{R} \quad + \quad \{\mathrm{UGG}, \mathrm{AAG}, \mathrm{ACA}\} \quad = \quad \textit{the active part of } \mathrm{WRR} \cup \mathrm{CUN} \cup \mathrm{WYA}.$$

The three inactive codons are high-pressure boundary codons, the first Q_2-completion frontier contains eight codons, and repeated Q_2-completion from $\mathcal{R}$ percolates through Q_6.

Proof. Combine Definition 9462.1301, Definition 9462.1303, and Definition 9462.1304. □

Concretized in §3508: finite boundary-trigger closure packet for six-tile DNA window rows

Concretized in §3842: Boundary pressure ledgers are realized as finite support, outer-boundary, degree, pressure, class aggregation, frontier, transport, replay, provenance, and NameCert rows.

Definition 9462.1307 (Inactive-anchor closure)**.** *Let*

$$\mathcal{A} = \{\mathrm{UGG}, \mathrm{AAG}, \mathrm{ACA}\}$$

be the inactive envelope corners from Definition 9462.1301. The inactive-anchor closure of the reassigned support is

$$\overline{\mathcal{R}} = \mathcal{R} \cup \mathcal{A}.$$

Definition 9462.1308 (Cubical support complex)**.** *For a codon set $S \subset Q_6$, let $K(S)$ be the cubical complex whose cells are exactly the axis-aligned subcubes of Q_6 whose vertices all lie in S.*

Concretized in §5852: Inactive-anchor cubical support is realized as finite NameCert rows for codon windows, boundary tiles, inactive anchors, cubical support cells, displayed f-vector data, no-3-cell refusal, transport, replay, provenance, and local naming.

Theorem 9462.1309 (Active cubical f-vector)**.** *The active support complex has*

$$f(K(\mathcal{R})) = (13, 16, 4, 0, \ldots).$$

The four 2-cells are the square faces

$$\mathrm{CUN}, \quad \mathrm{UNA}, \quad \mathrm{WWA}, \quad \mathrm{WRA}.$$

There are no 3-cells.

Proof. Enumerate every axis-aligned subcube of Q_6 and retain those whose vertices lie in $\mathcal{R}$. The retained cells consist of the 13 vertices of $\mathcal{R}$, the 16 internal Hamming edges from Definition 9462.1289, and the four square faces listed in Definition 9462.1291. No retained cube has dimension 3 or higher. □

Theorem 9462.1310 (Active cubical homology)**.** *Over $\mathbb{F}_2$, the cubical homology of $K(\mathcal{R})$ has Betti vector*

$$\beta(K(\mathcal{R})) = (1, 0, 0).$$

Equivalently, the graph cycles in $G_{\mathcal{R}}$ are filled by the four square 2-cells of the cubical complex.

Proof. The cellular boundary ranks over $\mathbb{F}_2$ are

$$\operatorname{rank} \partial_1 = 12, \qquad \operatorname{rank} \partial_2 = 4.$$

Together with $f(K(\mathcal{R})) = (13, 16, 4)$ this gives

$$\begin{aligned} \beta_0 &= 13 - 12 = 1, \\ \beta_1 &= 16 - 12 - 4 = 0, \\ \beta_2 &= 4 - 4 = 0. \end{aligned}$$

□

Theorem 9462.1311 (Inactive-anchor closure formula)**.** *The inactive-anchor closure is exactly*

$$\overline{\mathcal{R}} = \mathrm{WNA} \cup \mathrm{WRR} \cup \mathrm{CUN}.$$

Here

$$\begin{aligned} \mathrm{WNA} &= \{\mathrm{UUA}, \mathrm{UCA}, \mathrm{UAA}, \mathrm{UGA}, \mathrm{AUA}, \mathrm{ACA}, \mathrm{AAA}, \mathrm{AGA}\}, \\ \mathrm{WRR} &= \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}, \mathrm{AAA}, \mathrm{AAG}, \mathrm{AGA}, \mathrm{AGG}\}, \\ \mathrm{CUN} &= \{\mathrm{CUU}, \mathrm{CUC}, \mathrm{CUA}, \mathrm{CUG}\}. \end{aligned}$$

Proof. The only codons in the displayed union that are not in $\mathcal{R}$ are UGG, AAG, and ACA, which are the inactive anchors. Conversely, every codon of $\mathcal{R}$ lies in one of the three displayed motifs by Definition 9462.1293 and Definition 9462.1284. □

Theorem 9462.1312 (Closure cubical f-vector)**.** *The inactive-anchor closure complex has*

$$f(K(\overline{\mathcal{R}})) = (16, 25, 12, 2, 0, \ldots).$$

The two 3*-cells are precisely the cubes* WNA *and* WRR*.*

Proof. Enumerating all internal subcubes of $\overline{\mathcal{R}}$ gives 16 vertices, 25 edges, 12 square faces, and 2 cubes. No retained cube has dimension greater than 3. The two retained 3-cubes are exactly the two eight-vertex motifs WNA and WRR. □

Theorem 9462.1313 (Closure cubical homology)**.** *Over* $\mathbb{F}_2$*, the closure complex has Betti vector*

$$\beta(K(\overline{\mathcal{R}})) = (1, 0, 0, 0).$$

Proof. The cellular boundary ranks are

$$\operatorname{rank} \partial_1 = 15, \qquad \operatorname{rank} \partial_2 = 10, \qquad \operatorname{rank} \partial_3 = 2.$$

Together with $f(K(\overline{\mathcal{R}})) = (16, 25, 12, 2)$, these ranks give

$$\begin{aligned} \beta_0 &= 16 - 15 = 1, \\ \beta_1 &= 25 - 15 - 10 = 0, \\ \beta_2 &= 12 - 10 - 2 = 0, \\ \beta_3 &= 2 - 2 = 0. \end{aligned}$$

□

Theorem 9462.1314 (Hinge square)**.** *The two closure cubes meet in the square*

$$\mathrm{WNA} \cap \mathrm{WRR} = \mathrm{WRA}.$$

Explicitly,

$$\mathrm{WRA} = \{\mathrm{UAA}, \mathrm{UGA}, \mathrm{AAA}, \mathrm{AGA}\},$$

and its reassignment weight is 34*.*

Proof. The first base is constrained to W in both WNA and WRR. The second base is $N \cap R = R$, and the third base is $A \cap R = A$. Hence the intersection is WRA. The weight is

$$w(\mathrm{UAA}) + w(\mathrm{UGA}) + w(\mathrm{AAA}) + w(\mathrm{AGA}) = 8 + 15 + 3 + 8 = 34.$$

□

Theorem 9462.1315 (Inactive anchors eliminate the active leaves)**.** *In* $G_{\mathcal{R}}$*, the codons* UAG *and* AGG *are leaves. In the closure graph on* $\overline{\mathcal{R}}$*, both have degree* 3*:*

$$\begin{aligned} N_{\overline{\mathcal{R}}}(\mathrm{UAG}) &= \{\mathrm{UAA}, \mathrm{UGG}, \mathrm{AAG}\}, \\ N_{\overline{\mathcal{R}}}(\mathrm{AGG}) &= \{\mathrm{AGA}, \mathrm{UGG}, \mathrm{AAG}\}. \end{aligned}$$

Proof. The active graph has leaf set $\{\mathrm{UAG}, \mathrm{AGG}\}$ by Definition 9462.1295. Adding UGG and AAG supplies the two additional Hamming neighbors displayed above for each leaf. □

Theorem 9462.1316 (Boundary edge comparison)**.** *The active support and the inactive-anchor closure have the same number of boundary edges:*

$$|\partial_E \mathcal{R}| = |\partial_E \overline{\mathcal{R}}| = 46.$$

Proof. For the active support,

$$13 \cdot 6 - 2 \cdot 16 = 46.$$

For the closure,

$$16 \cdot 6 - 2 \cdot 25 = 46.$$

Thus the inactive anchors increase internal dimension without reducing the number of external boundary edges. □

Theorem 9462.1317 (Isoperimetric comparison)**.** *In Q_6, the maximum possible number of internal edges among 13 vertices is 22, while $\mathcal{R}$ has 16. The maximum possible number among 16 vertices is 32, while $\overline{\mathcal{R}}$ has 25.*

Proof. Use the hypercube edge-isoperimetric recurrence

$$F(d, n) = \max_k \big(F(d-1, k) + F(d-1, n-k) + \min(k, n-k)\big).$$

The finite computation gives $F(6, 13) = 22$ and $F(6, 16) = 32$. □

Theorem 9462.1318 (Inactive-anchor cubical closure)**.** *The active support is a low-dimensional cubical seed, and the inactive anchors complete it to*

$$\overline{\mathcal{R}} = \mathrm{WNA} \cup \mathrm{WRR} \cup \mathrm{CUN}, \qquad \mathrm{WNA} \cap \mathrm{WRR} = \mathrm{WRA}.$$

Both $K(\mathcal{R})$ and $K(\overline{\mathcal{R}})$ are connected with vanishing higher Betti numbers.

Proof. The closure formula is Definition 9462.1311. The homology claims are Definition 9462.1310 and Definition 9462.1313. The hinge identity is Definition 9462.1314. □

Definition 9462.1319 (Median closure)**.** *For three vertices $x, y, z \in Q_6$, let $m(x, y, z)$ be their coordinatewise majority vertex. The median closure $\mathrm{Med}(S)$ of $S \subset Q_6$ is the least subset of Q_6 containing S and closed under m.*

Theorem 9462.1320 (Median closure of the reassigned support)**.** *The median closure of the reassigned support is*

$$\mathrm{Med}(\mathcal{R}) = \mathrm{WNR} \cup \mathrm{CUN}.$$

Equivalently,

$$\mathrm{Med}(\mathcal{R}) = \{\mathrm{U}, \mathrm{A}\} \times \{\mathrm{U}, \mathrm{C}, \mathrm{A}, \mathrm{G}\} \times \{\mathrm{A}, \mathrm{G}\} \ \cup \ \mathrm{CUN}.$$

It has 20 codons.

Proof. Iterate coordinatewise majority over triples of codons until no new codon appears. The resulting set has the 20 codons

$$\begin{gathered}\mathrm{AAA}, \mathrm{AAG}, \mathrm{ACA}, \mathrm{ACG}, \mathrm{AGA}, \mathrm{AGG}, \mathrm{AUA}, \mathrm{AUG}, \\ \mathrm{CUA}, \mathrm{CUC}, \mathrm{CUG}, \mathrm{CUU}, \mathrm{UAA}, \mathrm{UAG}, \mathrm{UCA}, \mathrm{UCG}, \\ \mathrm{UGA}, \mathrm{UGG}, \mathrm{UUA}, \mathrm{UUG}.\end{gathered}$$

This is exactly $\mathrm{WNR} \cup \mathrm{CUN}$. The displayed union is itself median-closed and contains $\mathcal{R}$, so it is the least such set. □

Concretized in §3545: Median closure packets realize coordinatewise majority saturation, inactive-corner readback, f-vector, and maximal-cell ledgers as finite NameCert data.

Corollary 9462.1321 (Median inactive corners)**.** *The median closure adds seven inactive codons to $\mathcal{R}$:*

$$\mathrm{Med}(\mathcal{R}) \setminus \mathcal{R} = \{\mathrm{AAG}, \mathrm{ACA}, \mathrm{ACG}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}.$$

Relative to the inactive-anchor closure, the additional median codons are

$$\mathrm{Med}(\mathcal{R}) \setminus \overline{\mathcal{R}} = \{\mathrm{UUG}, \mathrm{UCG}, \mathrm{AUG}, \mathrm{ACG}\} = \mathrm{WYG}.$$

Proof. Subtract the support and the inactive-anchor closure from the explicit median closure in Definition 9462.1320. □

Theorem 9462.1322 (Closure chain)**.** *The closure hierarchy is*

$$\mathcal{R} \subset \overline{\mathcal{R}} \subset \mathrm{Med}(\mathcal{R}) \subset \mathrm{Conv}(\mathcal{R}) = Q_6,$$

with sizes

$$13, \qquad 16, \qquad 20, \qquad 64.$$

Proof. The first two sizes are Definition 9462.1307; the median size is Definition 9462.1320. Iterating hypercube intervals over pairs of vertices of $\mathcal{R}$ produces all 64 vertices of Q_6, so the geodesic convex hull is the whole cube. □

Theorem 9462.1323 (Median closure f-vector)**.** *The cubical complex $K(\mathrm{Med}(\mathcal{R}))$ has*

$$f = (20, 38, 26, 8, 1, 0, \ldots).$$

Thus it has 20 *vertices,* 38 *edges,* 26 *square faces,* 8 *cubes, and one* 4*-cube. The unique* 4*-cube is* WNR*.*

Proof. Enumerate every axis-aligned subcube of Q_6 whose vertices lie in $\mathrm{Med}(\mathcal{R})$. The retained cells have the displayed counts. The only retained 4-cube is the 16-vertex motif WNR. □

Theorem 9462.1324 (Maximal cells of the median closure)**.** *The maximal cubical cells of $K(\mathrm{Med}(\mathcal{R}))$ are*

$$\mathrm{WNR} \quad (Q_4), \qquad \mathrm{CUN} \quad (Q_2), \qquad \mathrm{YUR} \quad (Q_2).$$

Here

$$\mathrm{YUR} = \{\mathrm{UUA}, \mathrm{UUG}, \mathrm{CUA}, \mathrm{CUG}\}.$$

Proof. After enumerating all internal subcubes of the median closure, delete every subcube properly contained in another retained subcube. The three remaining maximal cells are exactly WNR, CUN, and YUR. □

Corollary 9462.1325 (Median bridge face)**.** *The square* YUR *bridges the main Q_4 cell and the CUN module:*

$$\mathrm{YUR} \cap \mathrm{WNR} = \{\mathrm{UUA}, \mathrm{UUG}\}, \qquad \mathrm{YUR} \cap \mathrm{CUN} = \{\mathrm{CUA}, \mathrm{CUG}\}.$$

Proof. Intersect the explicit vertex sets in Definition 9462.1324. □

Theorem 9462.1326 (Median closure homology)**.** *Over $\mathbb{F}_2$, the cubical homology of $K(\mathrm{Med}(\mathcal{R}))$ has Betti vector*

$$\beta = (1, 0, 0, 0, 0).$$

Proof. The cellular boundary ranks are

$$\operatorname{rank} \partial_1 = 19, \qquad \operatorname{rank} \partial_2 = 19, \qquad \operatorname{rank} \partial_3 = 7, \qquad \operatorname{rank} \partial_4 = 1.$$

Together with the f-vector $(20, 38, 26, 8, 1)$, these ranks give

$$\begin{aligned}
\beta_0 &= 20 - 19 = 1, \\
\beta_1 &= 38 - 19 - 19 = 0, \\
\beta_2 &= 26 - 19 - 7 = 0, \\
\beta_3 &= 8 - 7 - 1 = 0, \\
\beta_4 &= 1 - 1 = 0.
\end{aligned}$$

□

Theorem 9462.1327 (Median-closure structure)**.** *The natural median-stabilized envelope of the reassigned support is*

$$\mathrm{Med}(\mathcal{R}) = \mathrm{WNR} \cup \mathrm{CUN}.$$

It extends the inactive-anchor closure by the square WYG*, merges the two inactive-anchor cubes into the main Q_4 cell* WNR*, and remains cubically connected with no higher homology.*

Proof. The formula is Definition 9462.1320. The additional codons are Definition 9462.1321. The cubical and homological statements are Definition 9462.1323, Definition 9462.1324, and Definition 9462.1326. □

Definition 9462.1328 (Median iteration layers)**.** *For $S \subset Q_6$, define $\mathrm{Med}_0(S) = S$ and*

$$\mathrm{Med}_{n+1}(S) = \mathrm{Med}_n(S) \cup \{m(x, y, z) : x, y, z \in \mathrm{Med}_n(S)\}.$$

Here $m(x, y, z)$ is the coordinatewise majority vertex of Definition 9462.1319.

Theorem 9462.1329 (Median closure depth of the reassigned support)**.** *The median iteration of the reassigned support stabilizes after two nontrivial layers. The first layer adds*

$$\Delta_1 = \{\mathrm{AAG}, \mathrm{ACA}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\},$$

and the second layer adds

$$\Delta_2 = \{\mathrm{ACG}\}.$$

Thus

$$\begin{aligned}
\mathrm{Med}_1(\mathcal{R}) &= \mathcal{R} \cup \Delta_1, & |\mathrm{Med}_1(\mathcal{R})| &= 19, \\
\mathrm{Med}_2(\mathcal{R}) &= \mathrm{Med}(\mathcal{R}) = \mathrm{Med}_1(\mathcal{R}) \cup \{\mathrm{ACG}\}, & |\mathrm{Med}_2(\mathcal{R})| &= 20.
\end{aligned}$$

Proof. Enumerate all triples in $\mathcal{R}$ and apply coordinatewise majority. The codons outside $\mathcal{R}$ are exactly the six codons in Δ_1. Repeating the same operation on $\mathrm{Med}_1(\mathcal{R})$ produces the single additional codon ACG. A further pass produces no additional vertex, so the second layer is the full median closure. □

Corollary 9462.1330 (Inactive median levels)**.** *The inactive codons in the median closure split into three structural levels:*

$$\textit{anchor inactive codons: } \mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG},$$
$$\textit{first median codons: } \mathrm{AUG}, \mathrm{UCG}, \mathrm{UUG},$$
$$\textit{sealing codon: } \mathrm{ACG}.$$

Proof. The first line is the inactive-anchor set of Definition 9462.1307. The second and third lines are the remaining elements of Δ_1 and Δ_2 in Definition 9462.1329. □

Theorem 9462.1331 (Punctured median Q_4)**.** *The first median layer is*

$$\mathrm{Med}_1(\mathcal{R}) = (\mathrm{WNR} \setminus \{\mathrm{ACG}\}) \cup \mathrm{CUN}.$$

Consequently ACG *is the unique missing vertex of the main* WNR *4-cube at the first median layer.*

Proof. The full median closure is $\mathrm{Med}(\mathcal{R}) = \mathrm{WNR} \cup \mathrm{CUN}$ by Definition 9462.1320. By Definition 9462.1329, the only vertex of this median closure absent from $\mathrm{Med}_1(\mathcal{R})$ is ACG. □

Theorem 9462.1332 (Sealing-corner f-vector transition)**.** *The cubical f-vector changes from*

$$f(K(\mathrm{Med}_1(\mathcal{R}))) = (19, 34, 20, 4, 0, 0, \ldots)$$

to

$$f(K(\mathrm{Med}(\mathcal{R}))) = (20, 38, 26, 8, 1, 0, \ldots).$$

The difference is

$$(1, 4, 6, 4, 1, 0, \ldots).$$

Proof. At the first median layer, the main WNR cell is a 4-cube with one vertex, ACG, removed, together with the unchanged CUN module. Restoring one missing corner of a 4-cube contributes $\binom{4}{k}$ k-cells for $k = 0, 1, 2, 3, 4$, hence the difference vector $(1, 4, 6, 4, 1)$. Direct enumeration of all internal cubical cells gives the two displayed f-vectors. □

Corollary 9462.1333 (Top-dimensional sealing corner)**.** *The codon* ACG *is not an active reassignment codon and is not one of the three inactive-anchor codons. Its median role is top-dimensional: it seals the punctured* WNR *4-cube into a complete Q_4 cell.*

Proof. The codon ACG is absent from $\mathcal{R}$ and from the inactive-anchor set $\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG}\}$. Its cellular contribution is the top-dimensional transition of Definition 9462.1332. □

Theorem 9462.1334 (Median witnesses for the two layers)**.** *The first-layer inactive codons have active median witnesses*

$$\begin{aligned}
\mathrm{ACA} &= m(\mathrm{AGA}, \mathrm{AUA}, \mathrm{UCA}),\\
\mathrm{UGG} &= m(\mathrm{AGG}, \mathrm{UAG}, \mathrm{UGA}),\\
\mathrm{AAG} &= m(\mathrm{AAA}, \mathrm{AGG}, \mathrm{UAG}),\\
\mathrm{AUG} &= m(\mathrm{AGG}, \mathrm{AUA}, \mathrm{CUG}),\\
\mathrm{UCG} &= m(\mathrm{AGG}, \mathrm{UCA}, \mathrm{CUC}),\\
\mathrm{UUG} &= m(\mathrm{AUA}, \mathrm{CUG}, \mathrm{UAG}).
\end{aligned}$$

The sealing codon has a second-layer witness

$$\mathrm{ACG} = m(\mathrm{UGG}, \mathrm{AUG}, \mathrm{ACA}).$$

Moreover, ACG *is not the median of any three active codons from* $\mathcal{R}$.

Proof. Each displayed equality is checked by applying coordinatewise majority in the two-axis coding U = 00, C = 01, A = 10, G = 11. The exhaustive active-triple enumeration over $\mathcal{R}$ produces exactly Δ_1 as the points outside $\mathcal{R}$, and therefore omits ACG. The next enumeration over $\mathrm{Med}_1(\mathcal{R})$ adds only ACG. □

Theorem 9462.1335 (Median depth and sealing corner)**.** *The median-stabilized envelope is obtained through the chain*

$$\mathcal{R} \longrightarrow (\mathrm{WNR} \setminus \{\mathrm{ACG}\}) \cup \mathrm{CUN} \longrightarrow \mathrm{WNR} \cup \mathrm{CUN}.$$

The only strict second-layer median point is ACG*, and its addition converts the punctured main* Q_4 *into the complete* WNR *cell.*

Proof. The chain is Definition 9462.1329 together with Definition 9462.1331. The strict second-layer property is Definition 9462.1334; the cellular sealing statement is Definition 9462.1332. □

Concretized in §3981: finite median-depth sealing packet for two-layer stabilization, sealing-codon exposure, transport, replay, provenance, and local naming

Concretized in §7668: The median-depth sealing corner is realized as finite median-layer, unique-corner, f-vector, witness, transport, replay, provenance, and NameCert rows.

Definition 9462.1336 (Active median leakage)**.** *Let*

$$\mathcal{T}_3(\mathcal{R}) = \{\{x, y, z\} : x, y, z \in \mathcal{R} \text{ distinct}\}.$$

For a triple $T = \{x, y, z\}$ *write* $m(T) = m(x, y, z)$*. A triple is closed when* $m(T) \in \mathcal{R}$ *and leaking when* $m(T) \notin \mathcal{R}$*.*

Theorem 9462.1337 (Median-almost-closed active support)**.** *The reassigned support has* 286 *active triples. Among them,* 264 *triples are closed and* 22 *triples leak to inactive codons:*

$$\frac{264}{286} = 0.923076\ldots, \qquad \frac{22}{286} = 0.076923\ldots.$$

Thus $\mathcal{R}$ *is nearly closed under the median operation on distinct active triples.*

Proof. There are $\binom{13}{3} = 286$ distinct active triples. Enumerating them and applying coordinatewise majority gives 264 outputs in $\mathcal{R}$ and 22 outputs outside $\mathcal{R}$. □

Concretized in §2296: Median leakage spectra are realized as finite NameCert packets over active triples, median outputs, inactive leakage rows, centrality counts, direct-output multiplicities, transport, replay, provenance, and local naming.

Corollary 9462.1338 (Random median comparison)**.** *In* 100000 *random* 13*-point subsets of* Q_6*, using seed* 20260522*, the mean number of closed active triples is* 157.49515*. The mean one-step median closure size is* 43.79654*, and the mean number of one-step leakage outputs is* 30.79654*. The estimated tail probabilities are*

$$\Pr(\textit{closed triples} \geq 264) = 0.00007, \qquad \Pr(\textit{leakage outputs} \leq 6) = 0.00034.$$

Proof. For each random subset, enumerate its distinct triples and apply the same median-output count used in Definition 9462.1337. The displayed means and tail probabilities are the direct Monte Carlo tallies. □

Theorem 9462.1339 (One-step leakage outputs)**.** *The one-step active leakage set is*

$$\{m(T) : T \in \mathcal{T}_3(\mathcal{R})\} \setminus \mathcal{R} = \{\mathrm{AAG}, \mathrm{ACA}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}.$$

Consequently

$$\mathrm{Med}_1(\mathcal{R}) = \mathcal{R} \cup \{\mathrm{AAG}, \mathrm{ACA}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}.$$

Proof. The six displayed codons are the distinct inactive outputs among the 22 leaking triples of Definition 9462.1337. This is the same first median layer as in Definition 9462.1329. □

Corollary 9462.1340 (ACG is not a direct leakage point)**.** *The codon* ACG *is the only inactive codon in* $\mathrm{Med}(\mathcal{R}) \setminus \mathcal{R}$ *that is not produced by any distinct active triple.*

Proof. The full inactive median set is

$$\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{ACG}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}.$$

Subtract the one-step leakage set of Definition 9462.1339. □

Definition 9462.1341 (Median centrality)**.** *For* $p \in Q_6$*, define*

$$\mu_{\mathcal{R}}(p) = |\{T \in \mathcal{T}_3(\mathcal{R}) : m(T) = p\}|.$$

Theorem 9462.1342 (Median centrality ranking)**.** *The nonzero median centralities, together with the sealing value, are:*

codon	*active*	$\mu_{\mathcal{R}}$
UUA	*yes*	61
UAA	*yes*	46
CUA	*yes*	31
AAA	*yes*	19
UGA	*yes*	19
CUG	*yes*	16
UAG	*yes*	16
AGA	*yes*	14
AUA	*yes*	14
UCA	*yes*	14
CUU	*yes*	8
UUG	*no*	8
AAG	*no*	4
UGG	*no*	4
AGG	*yes*	3
CUC	*yes*	3
ACA	*no*	2
AUG	*no*	2
UCG	*no*	2
ACG	*no*	0.

Proof. Count the median outputs of all 286 active triples and group the results by output codon. The codon ACG has zero direct centrality by Definition 9462.1340. □

Corollary 9462.1343 (Mass core and median center differ)**.** *The median center is not the same as the reassignment-mass core. In particular,* UUA *has the largest median centrality* $\mu_{\mathcal{R}}(\mathrm{UUA}) = 61$*, whereas high-weight AGR-side codons such as* AGG *have much smaller direct median centrality.*

Proof. Compare Definition 9462.1342 with the weighted reassignment counts in Definition 9462.1256. □

Theorem 9462.1344 (Direct leakage spectrum)**.** *The inactive one-step leakage multiplicities are*

inactive output	*active triples*
UUG	8
AAG	4
UGG	4
ACA	2
AUG	2
UCG	2.

Proof. Restrict the median centrality count to the six inactive outputs in Definition 9462.1339. □

Theorem 9462.1345 (Direct-leakage catalyst)**.** *Among the* 22 *leaking active triples, active codons occur with the following multiplicities:*

active codon	*leaking triples containing it*
AGG	15
UAG	10
CUC	8
CUG	8
AUA	7
UCA	7
UUA	4
AAA	3
UGA	3
AGA	1.

Thus AGG *is the principal direct-leakage catalyst.*

Proof. Enumerate the 22 leaking triples and count active codon appearances inside those triples. □

Corollary 9462.1346 (Median gate role of AGG)**.** *The codon* AGG *is both median-essential and the leading direct-leakage catalyst. It appears in* 15 *of the* 22 *leaking triples.*

Proof. Median-essentiality is Definition 9462.1771. The leakage catalyst count is Definition 9462.1345. □

Theorem 9462.1347 (Minimum inactive median generators)**.** *The minimum size of an active subset* $G \subseteq \mathcal{R}$ *satisfying*

$$\mathrm{Med}(\mathcal{R}) \setminus \mathcal{R} \subseteq \mathrm{Med}(G)$$

is 5. *The four minimum subsets are*

$$\{\mathrm{AGG}, \mathrm{AUA}, \mathrm{CUC}, \mathrm{UAA}, \mathrm{UCA}\},$$
$$\{\mathrm{AGG}, \mathrm{AUA}, \mathrm{CUC}, \mathrm{UAG}, \mathrm{UCA}\},$$
$$\{\mathrm{AGG}, \mathrm{AUA}, \mathrm{CUG}, \mathrm{UAA}, \mathrm{UCA}\},$$
$$\{\mathrm{AGG}, \mathrm{AUA}, \mathrm{CUG}, \mathrm{UAG}, \mathrm{UCA}\}.$$

Proof. Enumerate all active subsets $G \subseteq \mathcal{R}$ and compute $\mathrm{Med}(G)$. No subset of size at most 4 contains all seven inactive median codons in its closure. Exactly the four displayed subsets of size 5 do. □

Corollary 9462.1348 (Inactive leakage core)**.** *Every minimum inactive median generator contains*

$$\mathrm{AGG}, \qquad \mathrm{AUA}, \qquad \mathrm{UCA}.$$

The remaining choices are one of $\mathrm{CUC}, \mathrm{CUG}$ *and one of* $\mathrm{UAA}, \mathrm{UAG}$.

Proof. Intersect the four generators in Definition 9462.1347. □

Theorem 9462.1349 (ACG has twelve second-layer derivations)**.** *Inside* $\mathrm{Med}_1(\mathcal{R})$*, exactly* 12 *distinct triples have median* ACG.

Proof. Enumerate all distinct triples in $\mathrm{Med}_1(\mathcal{R})$ and retain those whose median is ACG. The count is 12. Examples include

$$\mathrm{ACG} = m(\mathrm{AAG}, \mathrm{ACA}, \mathrm{UCG}), \qquad \mathrm{ACG} = m(\mathrm{ACA}, \mathrm{AUG}, \mathrm{UGG}).$$

□

Theorem 9462.1350 (Controlled median leakage)**.** *The median generation path of the reassigned support is*

$$\mathcal{R} \xrightarrow{\text{22 leaking triples}} \mathcal{R} \cup \{\mathrm{AAG}, \mathrm{ACA}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\} \xrightarrow{\mathrm{ACG}} \mathrm{WNR} \cup \mathrm{CUN}.$$

Thus $\mathcal{R}$ *is a median-almost-closed active support whose inactive median closure is generated by a small controlled leakage spectrum and a single second-layer sealing codon.*

Proof. The first arrow is Definition 9462.1337 and Definition 9462.1339. The second arrow is Definition 9462.1340 together with Definition 9462.1349. The terminal formula is Definition 9462.1320. □

Definition 9462.1351 (Hypercube automorphism stabilizer)**.** *The automorphism group of* Q_6 *is*

$$\mathrm{Aut}(Q_6) \cong C_2^6 \rtimes S_6, \qquad |\mathrm{Aut}(Q_6)| = 2^6 \cdot 6! = 46080.$$

For $S \subseteq Q_6$*, write*

$$\mathrm{Stab}(S) = \{\phi \in \mathrm{Aut}(Q_6) : \phi(S) = S\}.$$

For a weight function $w : Q_6 \to \mathbb{R}_{\geq 0}$*, write*

$$\mathrm{Stab}(w) = \{\phi \in \mathrm{Aut}(Q_6) : w(\phi(x)) = w(x) \text{ for all } x \in Q_6\}.$$

Theorem 9462.1352 (Active-support stabilizer)**.** *The active reassignment support has*

$$|\operatorname{Stab}(\mathcal{R})| = 2.$$

The nonidentity element is the coordinate transposition

$$\tau : s_1 \leftrightarrow f_2,$$

with all other bit coordinates fixed.

Proof. Enumerate all 46080 automorphisms of Q_6 and retain those whose image of $\mathcal{R}$ is exactly $\mathcal{R}$. The retained automorphisms are the identity and the transposition $s_1 \leftrightarrow f_2$. □

Corollary 9462.1353 (Hidden C_2 orbit structure)**.** *Under τ, the nontrivial active-support orbits are*

$$\{\mathrm{AAA}, \mathrm{UGA}\}, \qquad \{\mathrm{AUA}, \mathrm{UCA}\}.$$

The remaining active codons are fixed by τ.

Proof. Apply the bit transposition $s_1 \leftrightarrow f_2$ to each codon of $\mathcal{R}$. □

Theorem 9462.1354 (Persistence of the hidden C_2)**.** *The inactive-anchor closure and the first median layer have the same stabilizer size:*

$$|\operatorname{Stab}(\overline{\mathcal{R}})| = 2, \qquad |\operatorname{Stab}(\operatorname{Med}_1(\mathcal{R}))| = 2.$$

In both cases the nonidentity stabilizer is again $\tau : s_1 \leftrightarrow f_2$.

Proof. Enumerate all automorphisms of Q_6 and test set preservation for $\overline{\mathcal{R}}$ and $\operatorname{Med}_1(\mathcal{R})$. Each stabilizer contains exactly the identity and τ. □

Corollary 9462.1355 (Orbit growth under τ)**.** *The nontrivial τ-orbits grow along the closure chain as*

$$\begin{gathered}\mathcal{R} : \{\mathrm{AAA}, \mathrm{UGA}\}, \quad \{\mathrm{AUA}, \mathrm{UCA}\}, \\ \overline{\mathcal{R}} : \{\mathrm{AAG}, \mathrm{UGG}\} \textit{ also appears}, \\ \operatorname{Med}_1(\mathcal{R}) : \{\mathrm{AUG}, \mathrm{UCG}\} \textit{ also appears.}\end{gathered}$$

Proof. This is the explicit orbit decomposition of τ on $\mathcal{R}$, $\overline{\mathcal{R}}$, and $\operatorname{Med}_1(\mathcal{R})$. □

Theorem 9462.1356 (Median-closure stabilizer)**.** *The full median closure has*

$$\operatorname{Stab}(\operatorname{Med}(\mathcal{R})) \cong S_3 \times C_2, \qquad |\operatorname{Stab}(\operatorname{Med}(\mathcal{R}))| = 12.$$

The S_3 factor permutes the three coordinates

$$s_1, \qquad s_2, \qquad f_2,$$

and the C_2 factor flips f_3.

Proof. The median closure is $\mathrm{WNR} \cup \mathrm{CUN}$. In bit variables

$$a = s_1, \quad b = f_1, \quad c = s_2, \quad d = f_2, \quad e = s_3, \quad g = f_3,$$

this set is described by

$$(\neg b \wedge e) \ \vee \ (b \wedge \neg a \wedge \neg c \wedge \neg d).$$

The coordinates a, c, d are symmetric in this formula, and g is absent. This gives $S_3 \times C_2$. Exhaustive enumeration of all 46080 hypercube automorphisms gives no additional stabilizers. □

Corollary 9462.1357 (Symmetry restoration at the sealing corner)**.** *The stabilizer size changes along the median chain as*

$$|\operatorname{Stab}(\mathcal{R})| = 2, \qquad |\operatorname{Stab}(\operatorname{Med}_1(\mathcal{R}))| = 2, \qquad |\operatorname{Stab}(\operatorname{Med}(\mathcal{R}))| = 12.$$

Thus the sealing codon ACG *raises the set stabilizer from* C_2 *to* $S_3 \times C_2$*.*

Proof. The first two stabilizers are Definition 9462.1352 and Definition 9462.1354. The last stabilizer is Definition 9462.1356. The equality $\operatorname{Med}_1(\mathcal{R}) = \operatorname{Med}(\mathcal{R}) \setminus \{\mathrm{ACG}\}$ is Definition 9462.1331. □

Theorem 9462.1358 (Median-closure orbits)**.** *Under* $\operatorname{Stab}(\operatorname{Med}(\mathcal{R}))$*, the median closure decomposes into the following orbits:*

size	*orbit*
6	$\{\mathrm{AAA}, \mathrm{AAG}, \mathrm{ACA}, \mathrm{ACG}, \mathrm{UGA}, \mathrm{UGG}\}$
6	$\{\mathrm{AUA}, \mathrm{AUG}, \mathrm{UAA}, \mathrm{UAG}, \mathrm{UCA}, \mathrm{UCG}\}$
2	$\{\mathrm{AGA}, \mathrm{AGG}\}$
2	$\{\mathrm{UUA}, \mathrm{UUG}\}$
2	$\{\mathrm{CUA}, \mathrm{CUG}\}$
2	$\{\mathrm{CUC}, \mathrm{CUU}\}$.

Proof. Apply the 12 stabilizing automorphisms of Definition 9462.1356 to the 20 codons of $\operatorname{Med}(\mathcal{R})$ and group codons by orbit. □

Theorem 9462.1359 (Orbit-completion role of ACG)**.** *The codon* ACG *is the unique missing point of the orbit*

$$\{\mathrm{AAA}, \mathrm{AAG}, \mathrm{ACA}, \mathrm{ACG}, \mathrm{UGA}, \mathrm{UGG}\}$$

inside $\operatorname{Med}_1(\mathcal{R})$*. Hence it is both the top-dimensional sealing corner of Definition 9462.1333 and the orbit-completion point for the restored* $S_3 \times C_2$ *symmetry.*

Proof. By Definition 9462.1331, $\operatorname{Med}_1(\mathcal{R})$ is the full median closure with ACG removed. By Definition 9462.1358, ACG lies in the displayed 6-point orbit. The other five points of that orbit are already present in $\operatorname{Med}_1(\mathcal{R})$. □

Theorem 9462.1360 (Weighted symmetry is trivial)**.** *Let* $w(c)$ *be the number of NCBI alternative genetic-code tables in which codon* c *differs from the standard table. Then*

$$|\operatorname{Stab}(w)| = 1.$$

Proof. Enumerate all automorphisms of Q_6 and retain those preserving the weight function on all 64 codons. Only the identity remains. In particular, the support-level symmetry $\tau : s_1 \leftrightarrow f_2$ does not preserve weights: it maps UGA to AAA, while

$$w(\mathrm{UGA}) = 15, \qquad w(\mathrm{AAA}) = 3.$$

□

Corollary 9462.1361 (Geometry and direction)**.** *Support geometry and weight geometry separate. The support and median closure have nontrivial set symmetries, while reassignment frequency breaks all nonidentity hypercube symmetries.*

Proof. Combine Definition 9462.1352, Definition 9462.1356, and Definition 9462.1360. □

Theorem 9462.1362 (Symmetry restoration)**.** *The closure sequence has stabilizer chain*

object	*stabilizer size*	*group*
w	1	*trivial*
$\mathcal{R}$	2	C_2
$\overline{\mathcal{R}}$	2	C_2
$\mathrm{Med}_1(\mathcal{R})$	2	C_2
$\mathrm{Med}(\mathcal{R})$	12	$S_3 \times C_2$.

Thus median closure restores a larger hidden symmetry, while the weighted reassignment function remains fully direction-bearing.

Proof. The table is the collection of Definition 9462.1360, Definition 9462.1352, Definition 9462.1354, and Definition 9462.1356. □

Concretized in §4294: The hidden Q6 stabilizer and orbit-persistence rows are realized as a finite NameCert packet.

Definition 9462.1363 (Median-closure orbit quotient)**.** *Let $M = \mathrm{Med}(\mathcal{R})$ and let $\Gamma = \mathrm{Stab}(M) \cong S_3 \times C_2$. The orbit quotient M/Γ has one state for each Γ-orbit in M. For two orbit states O_i, O_j, define the edge weight*

$$E_{ij} = |\{x \sim y : x \in O_i,\ y \in O_j\}|,$$

where $x \sim y$ means Hamming adjacency in Q_6. For $i = j$, this is the number of internal Hamming edges in the orbit.

Theorem 9462.1364 (Six orbit states of the median closure)**.** *The median closure has the following six orbit states:*

state	*codons*	*size*	*active*	*inactive*	*wei*
Anchor_6	AAA, AAG, ACA, ACG, UGA, UGG	6	AAA, UGA	AAG, ACA, ACG, UGG	
$\mathrm{StopStart}_6$	AUA, AUG, UAA, UAG, UCA, UCG	6	AUA, UAA, UAG, UCA	AUG, UCG	
AGR	AGA, AGG	2	AGA, AGG	$\varnothing$	
UUR	UUA, UUG	2	UUA	UUG	
CUR	CUA, CUG	2	CUA, CUG	$\varnothing$	
CUY	CUC, CUU	2	CUC, CUU	$\varnothing$	

Proof. Apply the 12 automorphisms of $\Gamma = \mathrm{Stab}(\mathrm{Med}(\mathcal{R}))$ to the 20 codons of M. The resulting orbit partition is the one displayed. Weights are sums of NCBI reassignment counts over each orbit. □

Corollary 9462.1365 (Active support as an orbit selector)**.** *The median closure is symmetric, but the active support selects different fractions of different orbit states:*

$$2/6, \quad 4/6, \quad 2/2, \quad 1/2, \quad 2/2, \quad 2/2.$$

Thus $\mathcal{R}$ is a nonuniform active selector inside the symmetric median closure.

Proof. Read off the active columns in Definition 9462.1364. □

Theorem 9462.1366 (Weighted quotient path)**.** *With orbit order*

$$\mathrm{Anchor}_6, \quad \mathrm{StopStart}_6, \quad \mathrm{AGR}, \quad \mathrm{UUR}, \quad \mathrm{CUR}, \quad \mathrm{CUY},$$

the orbit adjacency matrix is

	Anchor_6	$\mathrm{StopStart}_6$	AGR	UUR	CUR	CUY
Anchor_6	3	12	6	0	0	0
$\mathrm{StopStart}_6$	12	3	0	6	0	0
AGR	6	0	1	0	0	0
UUR	0	6	0	1	2	0
CUR	0	0	0	2	1	2
CUY	0	0	0	0	2	1.

After removing internal loops, the quotient graph is the weighted path

$$\mathrm{AGR} - \mathrm{Anchor}_6 - \mathrm{StopStart}_6 - \mathrm{UUR} - \mathrm{CUR} - \mathrm{CUY}.$$

Proof. Enumerate all 38 Hamming edges internal to $\mathrm{Med}(\mathcal{R})$ and group each edge by the two orbit states of its endpoints. The nonzero cross-orbit weights are

$$\mathrm{AGR} - \mathrm{Anchor}_6 : 6, \qquad \mathrm{Anchor}_6 - \mathrm{StopStart}_6 : 12,$$
$$\mathrm{StopStart}_6 - \mathrm{UUR} : 6, \qquad \mathrm{UUR} - \mathrm{CUR} : 2, \qquad \mathrm{CUR} - \mathrm{CUY} : 2.$$

There are no other cross-orbit edges. □

Corollary 9462.1367 (Six-state codon-window automaton)**.** *The* 20*-codon median closure admits a six-state quotient dynamics:*

$$\mathrm{AGR} \longleftrightarrow \mathrm{Anchor}_6 \longleftrightarrow \mathrm{StopStart}_6 \longleftrightarrow \mathrm{UUR} \longleftrightarrow \mathrm{CUR} \longleftrightarrow \mathrm{CUY}.$$

Proof. This is the loop-free quotient graph of Definition 9462.1366. □

Theorem 9462.1368 (Inactive median layer)**.** *Let* $I = M \setminus \mathcal{R}$*. Then*

$$I = \mathrm{WYG} \cup \{\mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG}\}.$$

Here

$$\mathrm{WYG} = \{\mathrm{UUG}, \mathrm{UCG}, \mathrm{AUG}, \mathrm{ACG}\}.$$

The induced Hamming graph on I *is the square* WYG *together with three leaves attached by*

$$\mathrm{AAG} - \mathrm{AUG}, \qquad \mathrm{ACA} - \mathrm{ACG}, \qquad \mathrm{UGG} - \mathrm{UCG}.$$

Proof. The inactive codons are

$$\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{ACG}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}.$$

The codons $\mathrm{UUG}, \mathrm{UCG}, \mathrm{AUG}, \mathrm{ACG}$ form the WYG square. Direct Hamming-edge enumeration gives the three displayed leaf edges and the four square edges. □

Corollary 9462.1369 (Inactive layer is contractible)**.** *The cubical complex induced by* I *has*

$$f = (7, 7, 1, 0, \ldots), \qquad \beta = (1, 0, 0).$$

Thus the inactive layer is a contractible cubical patch.

Proof. The graph has 7 vertices and 7 edges, and the WYG square contributes one 2-cell. The cellular boundary ranks are $\operatorname{rank}\partial_1 = 6$ and $\operatorname{rank}\partial_2 = 1$, giving the displayed Betti vector. □

Definition 9462.1370 (Active-inactive interface)**.** *The active-inactive interface is the set of Hamming edges*

$$\partial_{A/I} = \{x - y : x \in \mathcal{R},\ y \in I,\ d_H(x, y) = 1\}.$$

Theorem 9462.1371 (Active-inactive interface)**.** *The active-inactive interface has* 15 *edges. Grouped by inactive endpoint, the interface degrees are*

inactive codon	*active neighbors*	*degree*
AAG	AAA, AGG, UAG	3
ACA	AGA, AUA, UCA	3
ACG	AGG	1
AUG	AUA	1
UCG	UCA	1
UGG	AGG, UAG, UGA	3
UUG	CUG, UAG, UUA	3.

The active endpoints of maximum interface degree are

$$\text{AGG}, \qquad \text{UAG}.$$

Proof. Enumerate the Hamming edges of M and retain exactly those with one endpoint in $\mathcal{R}$ and the other in I. There are 15 such edges. Sorting by inactive endpoint gives the displayed table. Sorting by active endpoint shows that AGG and UAG each have three inactive neighbors, the largest active-side degree. □

Corollary 9462.1372 (Double gate to the inactive layer)**.** *The codons* AGG *and* UAG *are the two active gates from the reassigned support into the inactive median layer.*

Proof. This is the maximum active-side interface degree statement in Definition 9462.1371. □

Theorem 9462.1373 (ACG as inactive-square contact point)**.** *The codon* ACG *has inactive neighbors*

$$\text{ACA}, \qquad \text{AUG}, \qquad \text{UCG},$$

and active neighbor

$$\text{AGG}.$$

Thus ACG *is the contact point between the inactive* WYG *square and the active gate* AGG*.*

Proof. The inactive-neighbor statement is read from the induced graph on I. The active-neighbor statement is read from the active-inactive interface. Both are direct Hamming-edge enumerations. □

Theorem 9462.1374 (Orbit-interface quotient)**.** *The median closure admits a compact quotient description:*

$$M/\Gamma = \text{AGR} - \text{Anchor}_6 - \text{StopStart}_6 - \text{UUR} - \text{CUR} - \text{CUY},$$

while the inactive layer is the contractible patch

$$\text{WYG} \cup \{\text{AAG}, \text{ACA}, \text{UGG}\}.$$

The active-inactive interface has two active gates, AGG *and* UAG*, and* ACG *is the inactive-square contact point at* AGG*.*

Proof. The quotient path is Definition 9462.1366. The inactive patch is Definition 9462.1368. The interface and contact-point statements are Definition 9462.1371 and Definition 9462.1373. □

Concretized in §5140: The weighted inactive-layer quotient dynamics is realized as a finite orbit-state NameCert packet.

Definition 9462.1375 (One-bit flip dynamics on the median closure)**.** *Let $M = \mathrm{Med}(\mathcal{R})$. From a codon $x \in M$, choose one of the six bit coordinates uniformly and flip it. If the resulting codon remains in M, this is an internal transition. Otherwise it is an outside transition.*

Theorem 9462.1376 (Quotient leakage transition matrix)**.** *On the six orbit states*

$$\mathrm{AGR}, \quad \mathrm{Anchor}_6, \quad \mathrm{StopStart}_6, \quad \mathrm{UUR}, \quad \mathrm{CUR}, \quad \mathrm{CUY},$$

the one-bit flip dynamics has transient transition matrix

	AGR	Anchor_6	$\mathrm{StopStart}_6$	UUR	CUR	CUY	*outside*
AGR	1/6	1/2	0	0	0	0	1/3
Anchor_6	1/6	1/6	1/3	0	0	0	1/3
$\mathrm{StopStart}_6$	0	1/3	1/6	1/6	0	0	1/3
UUR	0	0	1/2	1/6	1/6	0	1/6
CUR	0	0	0	1/6	1/6	1/6	1/2
CUY	0	0	0	0	1/6	1/6	2/3.

Proof. Use the orbit edge counts from Definition 9462.1366. For a state S, the normalizing denominator is $6|S|$. A cross-orbit edge contributes one oriented half-edge from its source state. An internal edge contributes two half-edges within the same state. Dividing these half-edge counts by $6|S|$ gives the displayed matrix and outside column. □

Corollary 9462.1377 (Uniform self-retention)**.** *Every quotient state has the same self-transition probability:*

$$P(S \to S) = 1/6.$$

Proof. Read the diagonal of Definition 9462.1376. The underlying reason is that each orbit has an internal matching coming from the f_3 flip. □

Theorem 9462.1378 (Quotient leakage rates)**.** *The outside probabilities are*

state	*outside probability*
AGR	1/3
Anchor_6	1/3
$\mathrm{StopStart}_6$	1/3
UUR	1/6
CUR	1/2
CUY	2/3.

Proof. For each row of Definition 9462.1376, subtract the internal transition sum from 1. □

Corollary 9462.1379 (CUN tail leakage)**.** *The CUN-side tail has the highest leakage:* CUR *leaks with probability* 1/2*, and* CUY *leaks with probability* 2/3*. The main three-state core* AGR*,* Anchor_6*, and* $\mathrm{StopStart}_6$ *has outside probability* 1/3 *in each state.*

Proof. This is the comparison of the outside probabilities in Definition 9462.1378. □

Theorem 9462.1380 (Expected exit times)**.** *Let T_S be the expected number of one-bit flips before leaving M, starting from quotient state S. Then*

state	T_S
AGR	$1478/487 \approx 3.035$
Anchor_6	$4468/1461 \approx 3.058$
StopStart_6	$4570/1461 \approx 3.128$
UUR	$1716/487 \approx 3.524$
CUR	$1088/487 \approx 2.234$
CUY	$802/487 \approx 1.647.$

Proof. Let Q be the 6×6 transient matrix in Definition 9462.1376. The expected exit vector is

$$T = (I - Q)^{-1}\mathbf{1}.$$

Solving this exact rational linear system gives the displayed values. □

Corollary 9462.1381 (UUR bridge residence)**.** *The state* UUR *has the largest expected exit time, approximately* 3.524 *one-bit flips.*

Proof. Compare the six values in Definition 9462.1380. □

Definition 9462.1382 (One-step retention)**.** *For $S \subseteq Q_6$, define*

$$\rho(S) = \frac{2|E(S)|}{6|S|},$$

where $E(S)$ is the set of Hamming edges internal to S.

Theorem 9462.1383 (Closure-chain retention)**.** *The closure chain has the following one-step retention data:*

set	*vertices*	*internal edges*	*boundary half-edges*	ρ
$\mathcal{R}$	13	16	46	$16/39 \approx 0.410$
$\overline{\mathcal{R}}$	16	25	46	$25/48 \approx 0.521$
$\text{Med}_1(\mathcal{R})$	19	34	46	$34/57 \approx 0.596$
M	20	38	44	$19/30 \approx 0.633.$

Proof. Each codon has degree 6 in Q_6. Internal edges contribute two internal half-edges, so $\rho(S) = 2|E(S)|/(6|S|)$. Boundary half-edges are $6|S| - 2|E(S)|$. Substitute the enumerated vertex and internal-edge counts for the four sets. □

Corollary 9462.1384 (Median closure as local stabilization)**.** *The retention values increase along the chain*

$$0.410 \to 0.521 \to 0.596 \to 0.633.$$

Thus the inactive anchors and median closure raise the one-bit retention probability.

Proof. This is the monotone comparison in Definition 9462.1383. □

Theorem 9462.1385 (ACG boundary seal)**.** *Adding* ACG *to* $\text{Med}_1(\mathcal{R})$ *changes the boundary half-edge count from* 46 *to* 44*.*

Proof. If a vertex p is added to a set S and has k neighbors in S, the boundary half-edge count changes by

$$\Delta\partial = 6 - 2k.$$

For $S = \mathrm{Med}_1(\mathcal{R})$ and $p = \mathrm{ACG}$, the neighbors already in S are

$$\mathrm{ACA}, \qquad \mathrm{AGG}, \qquad \mathrm{AUG}, \qquad \mathrm{UCG}.$$

Thus $k = 4$ and $\Delta\partial = 6 - 8 = -2$. □

Corollary 9462.1386 (Three roles of ACG)**.** *The codon* ACG *has three structural roles: it is the top-dimensional sealing corner, the symmetry-restoring orbit-completion point, and the boundary-reducing dynamical seal.*

Proof. The top-dimensional role is Definition 9462.1333. The orbit-completion role is Definition 9462.1359. The boundary role is Definition 9462.1385. □

Theorem 9462.1387 (Quotient leakage dynamics)**.** *The median closure is a stabilizing envelope for one-bit Hamming dynamics: its orbit quotient is a six-state path with outside leakage, its CUN tail is the highest-leakage region, and the closure chain strictly raises one-step retention from* $16/39$ *to* $19/30$*.*

Proof. The quotient transition matrix is Definition 9462.1376; the tail comparison is Definition 9462.1379; the retention chain is Definition 9462.1383. □

Concretized in §5822: The quotient leakage transition matrix is realized as a finite NameCert packet for six orbit states, outside-probability rows, and expected-exit ledgers.

Definition 9462.1388 (Killed bit-flip walk)**.** *Let $S \subseteq Q_6$. The killed bit-flip walk on S starts at a codon $x \in S$, chooses one of the six bit coordinates uniformly, and flips that coordinate. If the resulting codon remains in S, the walk continues. If the resulting codon lies outside S, the walk is absorbed. The transient matrix is*

$$Q_S(x, y) = \begin{cases} 1/6, & x \sim y \text{ and } y \in S, \\ 0, & \text{otherwise.} \end{cases}$$

Its spectral radius is denoted

$$\lambda(S) = \rho(Q_S).$$

Theorem 9462.1389 (Spectral stabilization along the closure chain)**.** *For the closure chain*

$$\mathcal{R} \subset \overline{\mathcal{R}} \subset \mathrm{Med}_1(\mathcal{R}) \subset M,$$

the killed bit-flip spectral data are

set	*vertices*	*internal edges*	ρ_1	λ	$1/(1-\lambda)$
$\mathcal{R}$	13	16	$16/39 \approx 0.410$	0.4759	1.908
$\overline{\mathcal{R}}$	16	25	$25/48 \approx 0.521$	0.5733	2.344
$\mathrm{Med}_1(\mathcal{R})$	19	34	$34/57 \approx 0.596$	0.6422	2.795
M	20	38	$19/30 \approx 0.633$	0.6752	3.079.

Concretized in §2270: The killed bit-flip closure-chain spectral-radius and survival-potential ledger is realized as a finite NameCert packet.

Proof. For each set S, enumerate the Hamming edges internal to S and form the transient matrix of Definition 9462.1388. The one-step retention ρ_1 is the retention quantity of Definition 9462.1382. Since Q_S is a symmetric nonnegative matrix, its spectral radius is the Perron root. Direct finite enumeration gives the displayed values. □

Corollary 9462.1390 (Spectral meaning of median closure)**.** *The median closure is a spectral stabilization envelope for the reassignment support: along the closure chain, the killed-walk spectral radius rises from approximately* 0.476 *to approximately* 0.675*.*

Proof. This is the monotone comparison of the four spectral radii in Definition 9462.1389. □

Definition 9462.1391 (Quasi-stationary distribution and survival potential)**.** *For $M = \mathrm{Med}(\mathcal{R})$, let λ_M be the Perron root of Q_M. The quasi-stationary distribution is the normalized left Perron vector*

$$\pi Q_M = \lambda_M \pi, \qquad \sum_{x \in M} \pi(x) = 1.$$

The survival potential is the right Perron vector

$$Q_M h = \lambda_M h,$$

normalized so that the largest orbit-average value is 1*.*

Theorem 9462.1392 (Quasi-stationary mass on the quotient path)**.** *Aggregated over the six quotient states of Definition 9462.1364, the quasi-stationary distribution of the killed walk on M is*

state	*quasi-stationary mass*
AGR	0.1117
Anchor_6	0.3407
$\mathrm{StopStart}_6$	0.3524
UUR	0.1313
CUR	0.0482
CUY	0.0158.

Hence

$$\pi(\mathrm{Anchor}_6 \cup \mathrm{StopStart}_6) = 0.6931.$$

Proof. Compute the Perron vector of Q_M and sum its entries over the six orbits of $\mathrm{Stab}(M)$. The two central orbit states Anchor_6 and $\mathrm{StopStart}_6$ have combined mass $0.3407 + 0.3524 = 0.6931$ after normalization. □

Corollary 9462.1393 (Quasi-stationary core)**.** *Conditioned on long survival inside M, the walk is concentrated on the anchor and stop-start core*

$$\mathrm{Anchor}_6 \cup \mathrm{StopStart}_6.$$

Proof. The combined quasi-stationary mass of these two states is 0.6931 by Definition 9462.1392. □

Theorem 9462.1394 (Survival potential on the quotient path)**.** *The orbit-averaged survival potential is*

state	*survival potential*
AGR	0.8506
Anchor_6	0.8652
StopStart_6	0.8948
UUR	1.0000
CUR	0.3671
CUY	0.1203.

Proof. Take the Perron vector h satisfying $Q_M h = \lambda_M h$, average it on each quotient orbit, and divide by the largest orbit average. The largest average occurs on UUR. □

Corollary 9462.1395 (UUR as survival bridge)**.** *The state* UUR *has the highest survival potential, even though the quasi-stationary mass is concentrated mainly on* $\text{Anchor}_6 \cup \text{StopStart}_6$*.*

Proof. Compare Definition 9462.1392 with Definition 9462.1394. □

Theorem 9462.1396 (Quasi-stationary escape source)**.** *Conditioned on the next step escaping from M, the pre-escape quotient state has distribution*

state	*conditional probability*
AGR	0.1146
Anchor_6	0.3497
StopStart_6	0.3617
UUR	0.0674
CUR	0.0742
CUY	0.0324.

Thus

$$P(\text{Anchor}_6 \cup \text{StopStart}_6 \mid \textit{escape}) = 0.7114.$$

Proof. In quasi-stationarity the probability of escape in one step is $1 - \lambda_M$. The conditional contribution of a quotient state S is

$$\frac{\pi(S)P(S \to \text{outside})}{1 - \lambda_M}.$$

Use the quasi-stationary masses from Definition 9462.1392 and the leakage probabilities from Definition 9462.1378. □

Corollary 9462.1397 (Escape mass versus pointwise leakage)**.** *The CUN tail has high pointwise leakage, but the dominant quasi-stationary escape contribution comes from the anchor and stop-start core.*

Proof. The tail leakage comparison is Definition 9462.1379. The conditional escape source distribution is Definition 9462.1396. □

Theorem 9462.1398 (Outside target classes)**.** *Starting from quasi-stationarity and conditioning on a one-step escape, the outside target codons aggregate by standard-code class as*

class	*probability*
Ser	0.1176
Pro	0.0931
Val	0.0931
Gln	0.0850
Phe	0.0755
Ile	0.0603
Tyr	0.0603
Ala	0.0583
Cys	0.0583
Glu	0.0583
Asn	0.0583
Arg	0.0583
Thr	0.0583
Gly	0.0573
His	0.0081.

Proof. For each $x \in M$ and each one-bit outside neighbor $y \notin M$, add the weight

$$\frac{\pi(x)}{6(1-\lambda_M)}$$

to the standard-code class of y. Summing over all outside neighbors gives the displayed distribution. □

Corollary 9462.1399 (Sense-class escape boundary)**.** *The outside escape distribution is spread over ordinary sense classes; it is not concentrated on stop-like targets.*

Proof. The target table in Definition 9462.1398 contains no dominant stop-class entry. □

Theorem 9462.1400 (ACG as spectral sealing corner)**.** *Adding* ACG *to* $\mathrm{Med}_1(\mathcal{R})$ *raises the killed-walk spectral radius from* 0.6422 *to* 0.6752*, raises one-step retention from approximately* 0.596 *to approximately* 0.633*, and lowers the boundary half-edge count from* 46 *to* 44*.*

Proof. The spectral radii are the last two rows of Definition 9462.1389. The retention and boundary values are the last two rows of Definition 9462.1383. □

Corollary 9462.1401 (Four roles of ACG)**.** *The codon* ACG *is simultaneously a strict second-order median point, a top-dimensional sealing corner, an orbit-completion point for* $S_3 \times C_2$ *symmetry, and a spectral stabilization point.*

Proof. The median-depth role is Definition 9462.1334. The top-dimensional role is Definition 9462.1333. The orbit-completion role is Definition 9462.1359. The spectral role is Definition 9462.1400. □

Theorem 9462.1402 (Spectral stabilization theorem)**.** *The median closure* $M = WNR \cup CUN$ *is the spectral stabilization envelope of the active reassignment support under killed one-bit Hamming dynamics: the closure chain increases the Perron root, the quasi-stationary mass concentrates on the anchor and stop-start core, the strongest survival potential lies at the* UUR *bridge, and* ACG *completes the spectral seal.*

Proof. Combine Definition 9462.1389, Definition 9462.1392, Definition 9462.1394, and Definition 9462.1400. □

Definition 9462.1403 (Fixed-budget spectral expansion)**.** *For $S \subseteq Q_6$ and $m \geq 1$, the fixed-budget spectral expansion problem asks for subsets*

$$B \subseteq Q_6 \setminus S, \qquad |B| = m,$$

maximizing

$$\lambda(S \cup B),$$

where λ is the killed bit-flip spectral radius of Definition 9462.1388.

Theorem 9462.1404 (Fixed-budget spectral frontier from the active support)**.** *For $m = 1, 2, 3, 4$, exhaustive finite enumeration from $\mathcal{R}$ gives the following spectral optima:*

m	*optimal adjoined set*	$\lambda(\mathcal{R} \cup B)$	*multiplicity*
1	$\{\mathrm{ACA}\}$	0.5237258	1
2	$\{\mathrm{ACA}, \mathrm{UUG}\}$	0.5465038	1
3	$\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG}\}$	0.5733331	1
4	$\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{AUG}, \mathrm{UUG}\}$	0.5970778	2
4	$\{\mathrm{ACA}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}$	0.5970778	2.

Proof. For each m, enumerate all $\binom{51}{m}$ subsets of the inactive complement of $\mathcal{R}$ and compute the Perron root of the killed bit-flip transition matrix on $\mathcal{R} \cup B$. The candidate counts are 51, 1275, 20825, and 249900 for $m = 1, 2, 3, 4$, respectively. The displayed rows are the maximizers. □

Corollary 9462.1405 (Fixed-budget non-nesting)**.** *The fixed-budget spectral optima from $\mathcal{R}$ do not form a nested chain. In particular,*

$$\{\mathrm{ACA}, \mathrm{UUG}\} \not\subseteq \{\mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG}\}.$$

Proof. The two displayed sets are the unique optima for budgets $m = 2$ and $m = 3$ in Definition 9462.1404. □

Corollary 9462.1406 (Spectral budget frustration)**.** *The codon* UUG *is selected by the optimal two-point expansion from $\mathcal{R}$, but is absent from the optimal three-point anchor block. Thus small-budget spectral optimization can select a point that is not part of the next optimal closure block.*

Proof. This is the comparison between the $m = 2$ and $m = 3$ rows of Definition 9462.1404. □

Definition 9462.1407 (Layered block spectral optimality)**.** *A closure chain is layered block spectral-optimal when each prescribed layer size is a spectral maximizer from the previous layer, without requiring the fixed-budget optima from the initial set to be nested.*

Theorem 9462.1408 (Anchor triple optimality)**.** *Among all 3-point subsets $B \subseteq Q_6 \setminus \mathcal{R}$, the unique maximizer of $\lambda(\mathcal{R} \cup B)$ is*

$$B = \{\mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG}\}.$$

The search has $\binom{51}{3} = 20825$ candidates, and

$$\lambda(\mathcal{R}) = 0.475879, \qquad \lambda(\mathcal{R} \cup B) = 0.573333.$$

Proof. This is the $m = 3$ row of Definition 9462.1404. □

Theorem 9462.1409 (Anchor-layer spectral frontier)**.** *From*

$$\overline{\mathcal{R}} = \mathcal{R} \cup \{\mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG}\},$$

the first three fixed-budget spectral optima are

m	*optimal adjoined set*	$\lambda(\overline{\mathcal{R}} \cup B)$	*multiplicity*
1	$\{\mathrm{UUG}\}$	0.5929439	1
2	$\{\mathrm{AUG}, \mathrm{UUG}\}$	0.6183868	2
2	$\{\mathrm{UCG}, \mathrm{UUG}\}$	0.6183868	2
3	$\{\mathrm{AUG}, \mathrm{UCG}, \mathrm{UUG}\}$	0.6421817	1.

Proof. Enumerate all m-point subsets of $Q_6 \setminus \overline{\mathcal{R}}$ for $m = 1, 2, 3$ and compute the killed-walk Perron root for each expanded set. The displayed rows are the maximizers. □

Theorem 9462.1410 (First-median triple optimality)**.** *Among all* 3*-point subsets* $B \subseteq Q_6 \setminus \overline{\mathcal{R}}$*, the unique maximizer of* $\lambda(\overline{\mathcal{R}} \cup B)$ *is*

$$B = \{\mathrm{AUG}, \mathrm{UCG}, \mathrm{UUG}\}.$$

Equivalently,

$$\mathrm{Med}_1(\mathcal{R}) = \overline{\mathcal{R}} \cup B$$

is the unique optimal three-point spectral stabilization of the anchor closure.

Proof. This is the $m = 3$ row of Definition 9462.1409, together with Definition 9462.1329. □

Theorem 9462.1411 (ACG single-point optimality)**.** *Among all single codons* $p \in Q_6 \setminus \mathrm{Med}_1(\mathcal{R})$*, the unique maximizer of*

$$\lambda(\mathrm{Med}_1(\mathcal{R}) \cup \{p\})$$

is

$$p = \mathrm{ACG}.$$

There are 45 *candidates, and*

$$\lambda(\mathrm{Med}_1(\mathcal{R})) = 0.642182, \qquad \lambda(\mathrm{Med}_1(\mathcal{R}) \cup \{\mathrm{ACG}\}) = 0.675248.$$

Proof. Enumerate the 45 codons outside $\mathrm{Med}_1(\mathcal{R})$ and compute the killed-walk Perron root after adjoining each one. The unique maximum is attained at ACG. □

Theorem 9462.1412 (Layered block spectral closure chain)**.** *The chain*

$$\mathcal{R} \xrightarrow{\text{best } +3} \overline{\mathcal{R}} \xrightarrow{\text{best } +3} \mathrm{Med}_1(\mathcal{R}) \xrightarrow{\text{best } +1} M$$

is layered block spectral-optimal. The adjoined blocks are

$$\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG}\}, \qquad \{\mathrm{AUG}, \mathrm{UCG}, \mathrm{UUG}\}, \qquad \{\mathrm{ACG}\}.$$

The corresponding spectral radii are

set	*adjoined codons*	*vertices*	λ
$\mathcal{R}$	$\varnothing$	13	0.475879
$\overline{\mathcal{R}}$	AAG, ACA, UGG	16	0.573333
$\mathrm{Med}_1(\mathcal{R})$	AUG, UCG, UUG	19	0.642182
M	ACG	20	0.675248.

Proof. The three steps are respectively Definition 9462.1408, Definition 9462.1410, and Definition 9462.1411. □

Definition 9462.1413 (Spectral gain)**.** *For $S \subseteq S' \subseteq Q_6$, define*

$$\Delta\lambda(S, S') = \lambda(S') - \lambda(S).$$

Corollary 9462.1414 (Diminishing block gain)**.** *The layered block gains are*

$$0.097454, \qquad 0.068849, \qquad 0.033066,$$

and therefore strictly decrease.

Proof. Subtract consecutive spectral radii in Definition 9462.1412. □

Theorem 9462.1415 (Budget-four spectral branching)**.** *At budget $m = 4$ from $\mathcal{R}$, the two optimal adjoined sets are*

$$B_4^{(1)} = \{\mathrm{AAG}, \mathrm{ACA}, \mathrm{AUG}, \mathrm{UUG}\},$$

and

$$B_4^{(2)} = \{\mathrm{ACA}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}.$$

They have the same spectral radius 0.5970778 *and are exchanged by the support symmetry $\tau : s_1 \leftrightarrow f_2$.*

Proof. The two optimal sets are the $m = 4$ rows of Definition 9462.1404. Under τ, AAG is exchanged with UGG, AUG is exchanged with UCG, while ACA and UUG are fixed. □

Corollary 9462.1416 (Anchor layer is a block stabilizer)**.** *The anchor triple* $\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG}\}$ *is a joint spectral optimizer, not the result of nested fixed-budget optimization from $\mathcal{R}$.*

Proof. The non-nesting statement is Definition 9462.1405. The triple optimality is Definition 9462.1408. □

Theorem 9462.1417 (τ-invariant inactive frontier)**.** *If the adjoined inactive set $B \subseteq Q_6 \setminus \mathcal{R}$ is required to satisfy $\tau(B) = B$, the optimal symmetric frontier includes the following representatives:*

$\lvert B\rvert$	*optimal τ-invariant adjoined set*
1	$\{\mathrm{ACA}\}$
2	$\{\mathrm{ACA}, \mathrm{UUG}\}$
3	$\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG}\}$
4	$\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{UGG}, \mathrm{UUG}\}$
5	$\{\mathrm{AAG}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}$
6	$\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}$
6	$\{\mathrm{AAG}, \mathrm{ACG}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}$
7	$\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{ACG}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}$.

Proof. Take the τ-orbits in $Q_6 \setminus \mathcal{R}$ and enumerate orbit unions of the prescribed cardinality. For each orbit union, compute the killed-walk Perron root after adjoining it to $\mathcal{R}$. The displayed sets are the maximizing orbit unions. □

Corollary 9462.1418 (Symmetric completion recovers the inactive median layer)**.** *At cardinality* 7*, the optimal τ-invariant inactive completion is*

$$\{\mathrm{AAG}, \mathrm{ACA}, \mathrm{ACG}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\} = M \setminus \mathcal{R}.$$

Proof. The $|B| = 7$ row of Definition 9462.1417 is exactly the inactive layer of Definition 9462.1368. □

Theorem 9462.1419 (Block-optimal budget-frustrated spectral closure)**.** *The median closure chain is not a nested fixed-budget optimum from $\mathcal{R}$. It is instead a layered block spectral-optimal chain, with a symmetric seven-point inactive completion equal to $M \setminus \mathcal{R}$.*

Proof. Non-nesting is Definition 9462.1405. The layered block optimality is Definition 9462.1412. The symmetric completion statement is Definition 9462.1418. □

Concretized in §3753: finite trigger-spectrum closure packet

Definition 9462.1420 (Directional saturation)**.** *For $S \subseteq Q_6$ and a bit coordinate i, let $x^{(i)}$ denote the codon obtained from x by flipping the ith bit. The directional saturation of S in direction i is*

$$\mathrm{Sat}_i(S) = S \cup \{x^{(i)} : x \in S\}.$$

For the coordinate order

$$(s_1, f_1, s_2, f_2, s_3, f_3),$$

the direction f_3 flips the family bit of the third codon position, so it exchanges $\mathrm{U} \leftrightarrow \mathrm{C}$ *and* $\mathrm{A} \leftrightarrow \mathrm{G}$ *at that position.*

Theorem 9462.1421 (Unique non-leaking saturation direction)**.** *Among the six one-bit saturation directions, f_3 is the unique direction for which the saturation of the active support remains inside the median closure:*

$$\mathrm{Sat}_{f_3}(\mathcal{R}) \subseteq M.$$

The six saturation rows are

direction	*added codons*	*added set*	$\subseteq M$
s_1	7	AAG, ACA, GUA, GUC, GUG, GUU, UGG	*no*
f_1	11	CAA, CAG, CCA, CGA, GAA, GGA, GGG, GUA, UUC, UUG, UUU	*no*
s_2	7	ACA, ACG, CAA, CAC, CAG, CAU, UUG	*no*
f_2	7	AAG, ACA, CCA, CCC, CCG, CCU, UGG	*no*
s_3	9	AAU, AGC, AGU, AUU, UAC, UAU, UCU, UGU, UUU	*no*
f_3	5	AAG, AUG, UCG, UGG, UUG	*yes.*

Proof. For each coordinate i, compute $\mathrm{Sat}_i(\mathcal{R})$ by flipping the ith bit of each codon in $\mathcal{R}$ and compare the result with $M = \mathrm{Med}(\mathcal{R})$. The displayed finite enumeration shows that only the f_3 row has no point outside M. □

Theorem 9462.1422 (f_3 saturation misses exactly the Thr pair)**.** *The f_3 saturation of the active support is*

$$\mathrm{Sat}_{f_3}(\mathcal{R}) = M \setminus \{\mathrm{ACA}, \mathrm{ACG}\}.$$

Equivalently,

$$\mathrm{Sat}_{f_3}(\mathcal{R}) \setminus \mathcal{R} = \{\mathrm{AAG}, \mathrm{AUG}, \mathrm{UCG}, \mathrm{UGG}, \mathrm{UUG}\}.$$

Proof. The five added codons are the f_3 partners of active codons:

$$\mathrm{AAA} \leftrightarrow \mathrm{AAG}, \qquad \mathrm{AUA} \leftrightarrow \mathrm{AUG},$$
$$\mathrm{UCA} \leftrightarrow \mathrm{UCG}, \qquad \mathrm{UGA} \leftrightarrow \mathrm{UGG}, \qquad \mathrm{UUA} \leftrightarrow \mathrm{UUG}.$$

Comparing with the median closure $M = \mathrm{WNR} \cup \mathrm{CUN}$ leaves exactly ACA and ACG outside the saturation. □

Theorem 9462.1423 (Wobble saturation presentation of median closure)**.** *The full median closure is obtained by adjoining either member of the missing Thr pair and saturating in the f_3 direction:*

$$M = \mathrm{Sat}_{f_3}(\mathcal{R} \cup \{\mathrm{ACA}\}) = \mathrm{Sat}_{f_3}(\mathcal{R} \cup \{\mathrm{ACG}\}).$$

Moreover, ACA *and* ACG *are the only codons outside $\mathcal{R}$ with this property.*

Proof. By Definition 9462.1422, $\mathrm{Sat}_{f_3}(\mathcal{R}) = M \setminus \{\mathrm{ACA}, \mathrm{ACG}\}$. Since $\mathrm{ACA}^{(f_3)} = \mathrm{ACG}$ and $\mathrm{ACG}^{(f_3)} = \mathrm{ACA}$, adjoining either one supplies both missing vertices after f_3 saturation. Exhaustive comparison over the inactive complement of $\mathcal{R}$ shows that no other single codon has saturation equal to M. □

Definition 9462.1424 (Directional boundary)**.** *For $S \subseteq Q_6$, the directional boundary in bit coordinate i is*

$$\partial_i(S) = |\{x \in S : x^{(i)} \notin S\}|.$$

The normalized Boolean influence is

$$I_i(S) = \partial_i(S)/32.$$

Theorem 9462.1425 (Directional boundary profile of the closure chain)**.** *For the closure chain*

$$\mathcal{R} \subset \overline{\mathcal{R}} \subset \mathrm{Med}_1(\mathcal{R}) \subset M,$$

the directional boundary counts in the coordinate order $(s_1, f_1, s_2, f_2, s_3, f_3)$ are

set	s_1	f_1	s_2	f_2	s_3	f_3	*total*
$\mathcal{R}$	7	11	7	7	9	5	46
$\overline{\mathcal{R}}$	4	14	8	4	12	4	46
$\mathrm{Med}_1(\mathcal{R})$	5	15	5	5	15	1	46
M	4	16	4	4	16	0	44.

Proof. For each set S in the displayed chain and each bit coordinate i, count the codons $x \in S$ for which $x^{(i)} \notin S$. This direct enumeration gives the table. □

Corollary 9462.1426 (Final f_3 boundary seal)**.** *The unique f_3 boundary edge at the first median layer is*

$$\mathrm{ACA} \leftrightarrow \mathrm{ACG}.$$

Adjoining ACG *changes ∂_{f_3} from* 1 *to* 0.

Proof. The row for $\mathrm{Med}_1(\mathcal{R})$ in Definition 9462.1425 has $\partial_{f_3} = 1$, and finite enumeration identifies the single edge as $\mathrm{ACA} \leftrightarrow \mathrm{ACG}$. The row for M has $\partial_{f_3} = 0$. □

Theorem 9462.1427 (f_3-silent Boolean form)**.** *In bit variables*

$$(s_1, f_1, s_2, f_2, s_3, f_3),$$

the median closure has the Boolean description

$$M = (\neg f_1 \wedge s_3) \vee (f_1 \wedge \neg s_1 \wedge \neg s_2 \wedge \neg f_2).$$

In particular, membership in M is independent of f_3.

Proof. The identity $M = \mathrm{WNR} \cup \mathrm{CUN}$ gives $\mathrm{WNR} = \{\neg f_1 \wedge s_3\}$, because the first codon position is U or A and the third position is A or G. It also gives

$$\mathrm{CUN} = \{f_1 \wedge \neg s_1 \wedge \neg s_2 \wedge \neg f_2\},$$

with the third position free. The displayed formula is their union and contains no occurrence of f_3. □

Corollary 9462.1428 (Gate and silent axes)**.** *For M, the directional boundary vector is*

$$(4, 16, 4, 4, 16, 0).$$

Thus f_1 and s_3 are the two main gate axes, s_1, s_2, and f_2 are low-boundary axes, and f_3 is a silent axis.

Proof. This is the M row of Definition 9462.1425, together with the absence of f_3 from Definition 9462.1427. □

Concretized in §3941: Finite NameCert seal for the unique f3 directional saturation route.

Theorem 9462.1429 (Wobble-saturation closure)**.** *The median closure of the reassigned support is the third-position family-bit saturation envelope*

$$M = \mathrm{Sat}_{f_3}(\mathcal{R} \cup \{\mathrm{ACA}\}) = \mathrm{Sat}_{f_3}(\mathcal{R} \cup \{\mathrm{ACG}\}),$$

and f_3 is the unique active-support saturation direction that does not leave M. The codon ACG *is simultaneously the median sealing corner, the symmetry-restoring corner, the spectral sealing corner, and the final f_3 saturation seal.*

Proof. The saturation identity is Definition 9462.1423. The uniqueness of the non-leaking direction is Definition 9462.1421. The median sealing role is Definition 9462.1329; the symmetry role is Definition 9462.1362; the spectral role is Definition 9462.1411; and the final f_3 boundary seal is Definition 9462.1426. □

Definition 9462.1430 (f_3 quotient)**.** *Let*

$$\pi : Q_6 \to Q_5$$

delete the third-position family bit:

$$\pi(s_1, f_1, s_2, f_2, s_3, f_3) = (s_1, f_1, s_2, f_2, s_3).$$

Thus the third codon position retains only its shape class. A quotient symbol such as UUR *denotes the pair*

$$\mathrm{UUR} = \{\mathrm{UUA}, \mathrm{UUG}\},$$

and ACR *denotes*

$$\mathrm{ACR} = \{\mathrm{ACA}, \mathrm{ACG}\}.$$

Theorem 9462.1431 (Median closure quotient)**.** *For $M = \mathrm{Med}(\mathcal{R})$, the f_3 quotient has ten vertices:*

$$\pi(M) = \{\mathrm{UUR}, \mathrm{UCR}, \mathrm{UAR}, \mathrm{UGR}, \mathrm{AUR}, \mathrm{ACR}, \mathrm{AAR}, \mathrm{AGR}, \mathrm{CUR}, \mathrm{CUY}\}.$$

Equivalently, $\pi(M)$ is the image of $\mathrm{WNR} \cup \mathrm{CUN}$ *after deleting f_3.*

Proof. By Definition 9462.1320, $M = \mathrm{WNR} \cup \mathrm{CUN}$. The image of WNR is the eight-point quotient block with first position in $\{\mathrm{U}, \mathrm{A}\}$, arbitrary second position, and third-position shape R. The image of CUN contributes CUY and CUR. These ten vertices are exactly the displayed set. □

Theorem 9462.1432 (Active quotient as a one-hole closure)**.** *The active reassignment support projects to the quotient median closure with exactly one missing vertex:*

$$\pi(\mathcal{R}) = \pi(M) \setminus \{\mathrm{ACR}\}.$$

Thus

$$\pi(\mathcal{R}) = \{\mathrm{UUR}, \mathrm{UCR}, \mathrm{UAR}, \mathrm{UGR}, \mathrm{AUR}, \mathrm{AAR}, \mathrm{AGR}, \mathrm{CUR}, \mathrm{CUY}\}.$$

Proof. Project each active codon by deleting f_3. The pairs AAA/AAG, AGA/AGG, AUA/AUG, and similarly for the U and CU rows, give all vertices of $\pi(M)$ except ACR. The support contains neither ACA nor ACG, so ACR is absent. □

Corollary 9462.1433 (The Thr pair as a quotient hole)**.** *The two codons* ACA *and* ACG *are the two lifts of the single quotient vertex* ACR*. Hence the first-layer point* ACA *and the sealing point* ACG *in Q_6 become one missing vertex after quotienting by f_3.*

Proof. Both codons have the same first five coordinates and differ only in f_3. □

Theorem 9462.1434 (One-step quotient median closure)**.** *In Q_5,*

$$\mathrm{Med}_{Q_5}(\pi(\mathcal{R})) = \pi(M),$$

and the unique added quotient vertex is ACR*. One median witness is*

$$\mathrm{ACR} = m(\mathrm{AGR}, \mathrm{AUR}, \mathrm{UCR}).$$

Proof. By finite enumeration of coordinatewise medians in Q_5, the first median pass on $\pi(\mathcal{R})$ adds exactly ACR and then stabilizes. The displayed witness verifies that ACR is forced by the quotient support. □

Theorem 9462.1435 (Quotient cubical skeleton)**.** *The cubical complex $K(\pi(M))$ has f-vector*

$$(f_0, f_1, f_2, f_3) = (10, 14, 6, 1).$$

Its maximal cells are one Q_3 core

$$\{\mathrm{UUR}, \mathrm{UCR}, \mathrm{UAR}, \mathrm{UGR}, \mathrm{AUR}, \mathrm{ACR}, \mathrm{AAR}, \mathrm{AGR}\},$$

and two edges

$$\mathrm{UUR} - \mathrm{CUR}, \qquad \mathrm{CUY} - \mathrm{CUR}.$$

Proof. Enumerate all subcubes of Q_5 contained in $\pi(M)$. The unique maximal three-cell is the quotient of WNR, and the quotient of the CUN tail contributes CUY − CUR. The bridge UUR − CUR attaches the tail to the core. The resulting cell counts are $(10, 14, 6, 1)$. □

Theorem 9462.1436 (Punctured quotient skeleton)**.** *The active quotient $K(\pi(\mathcal{R}))$ has f-vector*

$$(f_0, f_1, f_2) = (9, 11, 3).$$

It is the punctured Q_3 core

$$\pi(\mathrm{WNR}) \setminus \{\mathrm{ACR}\}$$

together with the same two-edge tail

$$\mathrm{UUR} - \mathrm{CUR} - \mathrm{CUY}.$$

Proof. Deleting one vertex from a Q_3 leaves seven vertices, nine edges, and three squares. The quotient tail contributes two vertices and two edges, giving $(9, 11, 3)$. □

Theorem 9462.1437 (Wobble product decomposition)**.** *The median closure complex is the product of the quotient complex with the f_3 edge:*

$$K(M) = K(\pi(M)) \times Q_1^{f_3}.$$

Consequently the f-vector of $K(M)$ is recovered from $f(K(\pi(M))) = (10, 14, 6, 1)$ by

$$f_k(K \times Q_1) = 2f_k(K) + f_{k-1}(K),$$

giving

$$f(K(M)) = (20, 38, 26, 8, 1).$$

Proof. By Definition 9462.1429, M is saturated in the f_3 direction, so every quotient vertex of $\pi(M)$ has both f_3 lifts in M. This is exactly the cubical product with the f_3 edge. Applying the displayed product formula gives the stated f-vector, matching Definition 9462.1332. □

Theorem 9462.1438 (Quotient spectral reconstruction)**.** *Let $G_{\pi(M)}$ be the Hamming graph on the quotient skeleton. Its largest adjacency eigenvalue is*

$$\mu_{\max}(G_{\pi(M)}) = 3.051487585\ldots.$$

Since $G_M = G_{\pi(M)} \square K_2$, the killed bit-flip spectral radius of M is

$$\lambda(M) = \frac{\mu_{\max}(G_{\pi(M)}) + 1}{6} = 0.675247931\ldots.$$

Proof. The adjacency spectrum of a Cartesian product satisfies

$$\mathrm{Spec}(G \square H) = \{\mu + \nu : \mu \in \mathrm{Spec}(G), \nu \in \mathrm{Spec}(H)\}.$$

For $H = K_2$ the eigenvalues are 1 and -1. The largest adjacency eigenvalue of G_M is therefore $\mu_{\max}(G_{\pi(M)}) + 1$, and the killed bit-flip matrix is $A_M/6$. □

Theorem 9462.1439 (Wobble-pair occupancy)**.** *The active support occupies quotient fibers as follows:*

quotient vertex	*fiber*	*active occupancy*
UUR	UUA/UUG	1
UCR	UCA/UCG	1
UAR	UAA/UAG	2
UGR	UGA/UGG	1
AUR	AUA/AUG	1
ACR	ACA/ACG	0
AAR	AAA/AAG	1
AGR	AGA/AGG	2
CUR	CUA/CUG	2
CUY	CUC/CUU	2.

Thus the full active fibers are

$$\mathrm{UAR}, \mathrm{AGR}, \mathrm{CUR}, \mathrm{CUY},$$

the half-active fibers are

$$\mathrm{UUR}, \mathrm{UCR}, \mathrm{UGR}, \mathrm{AUR}, \mathrm{AAR},$$

and the empty fiber is ACR*.*

Proof. For each quotient vertex, count the two f_3 lifts that lie in $\mathcal{R}$. The displayed table is the resulting finite count. □

Theorem 9462.1440 (Wobble quotient closure)**.** *The full median closure is recovered by taking median closure after the f_3 quotient and then lifting all f_3 fibers:*

$$M = \pi^{-1}(\mathrm{Med}_{Q_5}(\pi(\mathcal{R}))) \,.$$

Equivalently,

$$M = (Q_3 \text{ core plus a two-edge tail}) \times Q_1^{f_3}.$$

Proof. By Definition 9462.1434, $\mathrm{Med}_{Q_5}(\pi(\mathcal{R})) = \pi(M)$. By Definition 9462.1437, $M = \pi^{-1}(\pi(M))$. Combining the two identities gives the displayed formula. □

Concretized in §2317: finite quotient-trigger rows for wobble spectral geometry

Definition 9462.1441 (Radial quotient states)**.** *In the f_3 quotient $P = \pi(M)$ of Definition 9462.1430, the Q_3 core has coordinates s_1, s_2, and f_2. The S_3 action permuting these three coordinates gives the six radial states*

state	*quotient codons*	*lift in M*
X_3	AGR	AGA, AGG
X_2	AAR, ACR, UGR	AAA/AAG, ACA/ACG, UGA/UGG
X_1	AUR, UAR, UCR	AUA/AUG, UAA/UAG, UCA/UCG
X_0	UUR	UUA, UUG
Y_R	CUR	CUA, CUG
Y_Y	CUY	CUC, CUU.

Theorem 9462.1442 (Radial adjacency matrix)**.** *For the Hamming graph of P, the equitable radial quotient in the state order*

$$X_3, X_2, X_1, X_0, Y_R, Y_Y$$

has adjacency matrix

$$A_{\mathrm{rad}} = \begin{pmatrix} 0 & 3 & 0 & 0 & 0 & 0 \\ 1 & 0 & 2 & 0 & 0 & 0 \\ 0 & 2 & 0 & 1 & 0 & 0 \\ 0 & 0 & 3 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}.$$

Equivalently, the Perron equations are

$$\mu h_3 = 3h_2, \qquad \mu h_2 = h_3 + 2h_1,$$
$$\mu h_1 = 2h_2 + h_0, \qquad \mu h_0 = 3h_1 + h_R,$$
$$\mu h_R = h_0 + h_Y, \qquad \mu h_Y = h_R.$$

Proof. Inside the Q_3 core, a vertex of weight k has k neighbors in weight $k-1$ and $3-k$ neighbors in weight $k+1$. The tail contributes the additional edges $X_0 - Y_R$ and $Y_R - Y_Y$. These local neighbor counts give the displayed matrix. □

Theorem 9462.1443 (Radial spectral equation)**.** *The characteristic polynomial of A_{rad} is*

$$\mu^6 - 12\mu^4 + 26\mu^2 - 9.$$

Equivalently, with $r = \mu^2$,

$$r^3 - 12r^2 + 26r - 9 = 0.$$

The largest root satisfies

$$r_{\max} = 9.311576483\ldots, \qquad \mu_{\max} = 3.051487585\ldots.$$

Since $M = P \times Q_1^{f_3}$, the killed bit-flip spectral radius is

$$\lambda(M) = \frac{\mu_{\max} + 1}{6} = 0.675247931\ldots.$$

Proof. Compute $\det(\mu I - A_{\mathrm{rad}})$ from the matrix of Definition 9462.1442. The polynomial is even, so substituting $r = \mu^2$ gives the cubic equation. The product decomposition of Definition 9462.1437 adds the K_2 eigenvalue 1 to the largest quotient eigenvalue, and the killed walk divides adjacency eigenvalues by 6. □

Corollary 9462.1444 (Analytic compression of the killed-walk spectrum)**.** *The killed-walk spectral radius of the 20-codon median closure is determined by the largest root of the cubic*

$$r^3 - 12r^2 + 26r - 9 = 0.$$

Thus the spectral computation compresses as

$$20 \textit{ codons} \longrightarrow 10 \textit{ quotient vertices} \longrightarrow 6 \textit{ radial states} \longrightarrow 1 \textit{ cubic equation.}$$

Proof. This is the combination of Definition 9462.1431, Definition 9462.1442, and Definition 9462.1443. □

Theorem 9462.1445 (Radial quasi-stationary data)**.** *Normalize the positive Perron vector of* A_{rad} *so that* X_0 *has survival potential* 1*. The radial survival potentials are*

state	*survival potential*
$X_3 = \mathrm{AGR}$	0.8506
$X_2 = \mathrm{Anchor}_6$	0.8652
$X_1 = \mathrm{StopStart}_6$	0.8948
$X_0 = \mathrm{UUR}$	1.0000
$Y_R = \mathrm{CUR}$	0.3671
$Y_Y = \mathrm{CUY}$	0.1203.

After weighting by the lift sizes in M*, the quasi-stationary masses are*

state	*lift size*	*quasi-stationary mass*
$X_3 = \mathrm{AGR}$	2	0.1117
$X_2 = \mathrm{Anchor}_6$	6	0.3407
$X_1 = \mathrm{StopStart}_6$	6	0.3524
$X_0 = \mathrm{UUR}$	2	0.1313
$Y_R = \mathrm{CUR}$	2	0.0482
$Y_Y = \mathrm{CUY}$	2	0.0158.

Proof. Solve $A_{\mathrm{rad}}h = \mu_{\max}h$ for the positive Perron vector. The displayed survival potentials are the entries normalized by the X_0 entry. The quasi-stationary mass of a radial state is its lift size times the Perron entry, divided by the corresponding total over all six states. □

Corollary 9462.1446 (Radial mass core and survival bridge)**.** *The radial quasi-stationary mass on* $X_2 \cup X_1$ *is*

$$0.3407 + 0.3524 = 0.6931.$$

Thus $\mathrm{Anchor}_6 \cup \mathrm{StopStart}_6$ *is the mass core, whereas* $X_0 = \mathrm{UUR}$ *is the highest-potential survival bridge.*

Proof. The mass statement and the maximum survival potential are read directly from Definition 9462.1445. □

Theorem 9462.1447 (f_3 self-loop contribution)**.** *In the six-state killed-walk quotient on* M*, every radial state has self-retention probability*

$$1/6$$

coming from the f_3 *edge. Without the wobble edge the normalized spectral value would be*

$$\mu_{\max}/6 = 0.508581264\ldots,$$

whereas the saturated median closure has

$$(\mu_{\max} + 1)/6 = 0.675247931\ldots.$$

The wobble edge contributes the additive term 1/6*.*

Proof. Every codon of M has its f_3 neighbor still in M by Definition 9462.1429. In the quotient state model this direction is a self-loop. The product spectrum adds the K_2 eigenvalue 1, and division by the six available bit-flip directions gives the contribution 1/6. □

Theorem 9462.1448 (Radial wobble spectrum)**.** *The killed bit-flip spectrum, quasi-stationary mass, and survival potential of M are determined by the six-state radial matrix A_{rad} together with the f_3 wobble edge. In particular,*

$$\lambda(M) = \frac{1+\sqrt{r_{\max}}}{6},$$

where $r_{\max}$ is the largest root of

$$r^3 - 12r^2 + 26r - 9 = 0.$$

Proof. The quotient geometry is $M = P \times Q_1^{f_3}$ by Definition 9462.1437. The S_3 radial quotient of P is Definition 9462.1442. The Perron equation and the product spectral shift are Definition 9462.1443. □

Concretized in §3681: The radial wobble spectrum is realized as finite boundary-tile, radial-shell, spectral-hinge, and trigger-ledger NameCert rows.

Definition 9462.1449 (Core and CUN tail)**.** *Let*

$$C = \mathrm{WNR} \subset M.$$

Then C is the main core of the median closure. The remaining quotient geometry is the two-edge tail

$$\mathrm{UUR} - \mathrm{CUR} - \mathrm{CUY},$$

whose lift is the CUN *contribution to $M = \mathrm{WNR} \cup \mathrm{CUN}$.*

Theorem 9462.1450 (The WNR core is a killed-walk Q_4)**.** *The core $C = \mathrm{WNR}$ is a Q_4 subcube. Hence*

$$|C| = 16, \qquad |E(C)| = 32,$$

and for the killed one-bit walk in Q_6,

$$\rho(C) = \lambda(C) = \frac{2}{3}.$$

Proof. The motif WNR fixes $f_1 = 0$ and $s_3 = 1$, leaving four free bits. Thus $C \cong Q_4$ and has $4 \cdot 2^3 = 32$ internal edges. A Q_4 has largest adjacency eigenvalue 4, so the killed transition matrix $A/6$ has spectral radius $4/6 = 2/3$. The uniform one-step retention is also

$$\rho(C) = \frac{2|E(C)|}{6|C|} = \frac{64}{96} = \frac{2}{3}.$$

□

Theorem 9462.1451 (Tail-induced separation of retention and spectrum)**.** *For the full median closure $M = \mathrm{WNR} \cup \mathrm{CUN}$,*

$$|M| = 20, \qquad |E(M)| = 38,$$

so

$$\rho(M) = \frac{2|E(M)|}{6|M|} = \frac{19}{30} < \frac{2}{3}.$$

However

$$\lambda(M) = 0.675247931\ldots > \frac{2}{3}.$$

Proof. The retention formula gives $2 \cdot 38/(6 \cdot 20) = 19/30$. The spectral radius is the value of Definition 9462.1443, namely $(3.051487585\ldots + 1)/6 = 0.675247931\ldots$. Comparing with Definition 9462.1450 gives the strict inequalities. □

Corollary 9462.1452 (Spectral antenna behavior)**.** *The* CUN *tail is not a uniform stabilizer: it lowers average one-step retention. It is a spectral antenna: it raises the Perron survival rate of the killed walk.*

Proof. This is exactly the sign difference in Definition 9462.1451. □

Definition 9462.1453 (Tail self-energy)**.** *For the radial equations of Definition 9462.1442, eliminate the two tail variables h_R and h_Y from*

$$\mu h_R = h_0 + h_Y, \qquad \mu h_Y = h_R.$$

The resulting tail self-energy is

$$\sigma_2(\mu) = \frac{\mu}{\mu^2 - 1}.$$

Theorem 9462.1454 (Positive self-energy perturbation)**.** *The root equation at X_0 becomes*

$$\left(\mu - \frac{\mu}{\mu^2 - 1}\right) h_0 = 3h_1.$$

Thus the two-edge tail supplies a positive self-energy term at the attachment vertex. At the Perron root,

$$\sigma_2(\mu_{\max}) = 0.367137\ldots.$$

Proof. From $\mu h_Y = h_R$, obtain $h_Y = h_R/\mu$. Substitute into $\mu h_R = h_0 + h_Y$ to get

$$h_R = \frac{\mu}{\mu^2 - 1} h_0.$$

The X_0 equation $\mu h_0 = 3h_1 + h_R$ then becomes the displayed self-energy equation. □

Theorem 9462.1455 (Tail length spectral response)**.** *Attach a path of length L to the X_0 vertex of the quotient Q_3 core. The Perron values for $L = 0, \ldots, 5$ are*

L	$\mu_{\max}$	$(\mu_{\max} + 1)/6$
0	3.000000	0.666667
1	3.045475	0.674246
2	3.051488	0.675248
3	3.052315	0.675386
4	3.052430	0.675405
5	3.052446	0.675408.

The biological quotient tail has $L = 2$ and captures

$$0.9817$$

of the spectral gain visible by $L = 5$.

Proof. For each L, form the radial quotient matrix of a Q_3 core with a path of length L attached at X_0 and compute its Perron root. The gain capture ratio is

$$\frac{3.051487585\ldots - 3}{3.052445591\ldots - 3} = 0.9817\ldots.$$

□

Theorem 9462.1456 (Small mass, spectral effect)**.** *In the radial quasi-stationary distribution of Definition 9462.1445, the CUN tail states Y_R and Y_Y have total mass*

$$0.0482 + 0.0158 = 0.0640.$$

Nevertheless they raise the spectral radius from $2/3$ *to* $0.675247931\ldots$.

Proof. The masses are those of Y_R and Y_Y in Definition 9462.1445. The spectral increase is

$$0.675247931\ldots - \frac{2}{3} = 0.008581264\ldots.$$

□

Theorem 9462.1457 (CUN spectral antenna)**.** *The CUN tail separates uniform stability from quasi-stationary spectral stability:*

$$\rho(M) = \frac{19}{30} < \frac{2}{3} = \rho(\mathrm{WNR}),$$

but

$$\lambda(M) = 0.675247931\ldots > \frac{2}{3} = \lambda(\mathrm{WNR}).$$

The tail has small quasi-stationary mass, but acts as a positive self-energy perturbation of the radial Perron mode.

Proof. The retention and spectral inequalities are Definition 9462.1451. The self-energy mechanism is Definition 9462.1454, and the small tail mass is Definition 9462.1456. □

Concretized in §3771: finite CUN tail spectral antenna packet for retention, Perron response, self-energy, and small-mass rows

Definition 9462.1458 (Spectral ablation)**.** *Let $\lambda(M)$ be the killed bit-flip spectral radius of the median closure. If a vertex set, edge set, or quotient module is removed and the resulting killed-walk matrix has spectral radius λ', define the spectral loss by*

$$\Delta\lambda = \lambda(M) - \lambda'.$$

Theorem 9462.1459 (Single-codon ablation)**.** *Single-codon deletion has the following orbit-level losses:*

state	*codons*	$\Delta\lambda$
UUR	UUA, UUG	0.041994
$\mathrm{StopStart}_6$	AUA, AUG, UAA, UAG, UCA, UCG	0.035931
Anchor_6	AAA, AAG, ACA, ACG, UGA, UGG	0.033066
AGR	AGA, AGG	0.031505
CUR	CUA, CUG	0.005593
CUY	CUC, CUU	0.000643.

Proof. For each codon $c \in M$, compute the spectral radius of $M \setminus \{c\}$. The symmetry orbits of Definition 9462.1364 make the loss constant within each displayed row. □

Corollary 9462.1460 (UUR as point-level spectral hinge)**.** *The largest single-codon loss occurs at the* UUR *pair* $\{\mathrm{UUA}, \mathrm{UUG}\}$.

Proof. This is the first row of Definition 9462.1459. □

Theorem 9462.1461 (Orbit-module ablation)**.** *Deleting entire quotient modules gives*

module	*size*	$\lambda(M \setminus S)$	$\Delta\lambda$
$\mathrm{StopStart}_6$	6	0.455342	0.219906
Anchor_6	6	0.512386	0.162862
UUR	2	0.607625	0.067623
AGR	2	0.624360	0.050888
CUR	2	0.666667	0.008581
CUY	2	0.674246	0.001002.

Proof. For each module S, remove all codons in S from M and compute the Perron root of the resulting killed transition matrix. □

Corollary 9462.1462 (Point and module sensitivity differ)**.** *The most sensitive single-codon module is* UUR*, whereas the largest module-level loss comes from* $\mathrm{StopStart}_6$.

Proof. Compare Definition 9462.1459 and Definition 9462.1461. □

Theorem 9462.1463 (Tail-coupling ablation)**.** *Deleting the two interface edges*

$$\mathrm{UUA} - \mathrm{CUA}, \qquad \mathrm{UUG} - \mathrm{CUG}$$

between UUR *and* CUR *gives spectral radius*

$$\frac{2}{3}.$$

The spectral loss is

$$0.008581264\ldots.$$

Proof. Removing these two edges disconnects the CUN tail from the WNR core. The core has spectral radius 2/3 by Definition 9462.1450, and the detached tail has smaller spectral radius. Therefore the largest component spectral radius is 2/3. □

Corollary 9462.1464 (Antenna input port)**.** *The spectral gain of the* CUN *antenna enters the core through the* $\mathrm{UUR} - \mathrm{CUR}$ *interface.*

Proof. By Definition 9462.1457, the total gain over the WNR core is $0.008581264\ldots$. By Definition 9462.1463, removing the $\mathrm{UUR} - \mathrm{CUR}$ interface loses exactly this amount. □

Theorem 9462.1465 (Edge-group ablation)**.** *Deleting internal edge groups by radial module gives*

edge group	*edges*	λ'	$\Delta\lambda$
$\mathrm{Anchor}_6 - \mathrm{StopStart}_6$	12	0.512386	0.162862
$\mathrm{StopStart}_6 - \mathrm{UUR}$	6	0.607625	0.067623
$\mathrm{StopStart}_6$ *internal*	3	0.622672	0.052576
$\mathrm{AGR} - \mathrm{Anchor}_6$	6	0.624360	0.050888
Anchor_6 *internal*	3	0.627825	0.047423
UUR *internal*	1	0.655912	0.019336
AGR *internal*	1	0.661306	0.013942
$\mathrm{UUR} - \mathrm{CUR}$	2	0.666667	0.008581
CUR *internal*	1	0.672777	0.002471
$\mathrm{CUR} - \mathrm{CUY}$	2	0.674246	0.001002
CUY *internal*	1	0.674978	0.000270.

Proof. For each displayed group, remove exactly those Hamming edges from the killed-walk adjacency matrix and compute the Perron root of the remaining matrix. □

Corollary 9462.1466 (Central load-bearing interface)**.** *The largest edge-group loss comes from the* $\mathrm{Anchor}_6 - \mathrm{StopStart}_6$ *interface. This central interface is the load-bearing interface of the median closure.*

Proof. It is the first row of Definition 9462.1465. □

Theorem 9462.1467 (Single-edge ablation)**.** *Among the* 38 *internal Hamming edges of* M*, the largest single-edge loss occurs at the wobble edge*

$$\mathrm{UUA} - \mathrm{UUG},$$

with

$$\Delta\lambda = 0.019336.$$

The next six edge losses are the six $\mathrm{StopStart}_6 - \mathrm{UUR}$ *edges, each with*

$$\Delta\lambda = 0.017432.$$

Proof. Remove one internal Hamming edge at a time and compute the Perron root of the resulting killed-walk matrix. The edge $\mathrm{UUA} - \mathrm{UUG}$ gives the largest loss; the next six are the six edges between $\mathrm{StopStart}_6$ and UUR. □

Theorem 9462.1468 (Spectral hinges and load-bearing interfaces)**.** *The spectral stability of* M *separates into distinct critical structures:*

level	*critical object*
single codon	UUR
module	$\mathrm{StopStart}_6$
edge group	$\mathrm{Anchor}_6 - \mathrm{StopStart}_6$
antenna input	$\mathrm{UUR} - \mathrm{CUR}$
single edge	$\mathrm{UUA} - \mathrm{UUG}$.

Proof. The five entries are respectively Definition 9462.1460, Definition 9462.1461, Definition 9462.1466, Definition 9462.1464, and Definition 9462.1467. □

Concretized in §8792: DNA-window trigger frontiers realize boundary-tile hinge and ablation rows as finite trigger, support, reliability, refusal, transport, replay, provenance, and NameCert data.

Concretized in §3959: The spectral ablation hinge is realized as finite deletion, killed-walk, spectral-loss, orbit-module, transport, replay, provenance, and local naming rows.

Concretized in §3961: Spectral ablation hinges are realized as finite killed-walk matrix, orbit-module, point-ablation, edge-ablation, hinge-ranking, transport, replay, provenance, and NameCert rows.

Definition 9462.1469 (Doob-conditioned survival dynamics)**.** *Let Q_M be the killed one-bit transition matrix on $M = \mathrm{Med}(\mathcal{R})$, and let*

$$Q_M h = \lambda(M) h$$

be its positive Perron eigenvector. The Doob-conditioned survival chain on M is

$$P^h(x, y) = \frac{Q_M(x, y)h(y)}{\lambda(M)h(x)}.$$

It is the Markov chain obtained from the killed walk by conditioning on asymptotic survival inside the median closure.

Theorem 9462.1470 (Six-state Doob transition matrix)**.** *In the radial state order*

$$S_0 = \mathrm{AGR}, \quad S_1 = \mathrm{Anchor}_6, \quad S_2 = \mathrm{StopStart}_6, \quad S_3 = \mathrm{UUR}, \quad S_4 = \mathrm{CUR}, \quad S_5 = \mathrm{CUY},$$

the Doob-conditioned chain has transition matrix

	S_0	S_1	S_2	S_3	S_4	S_5
S_0	0.2468	0.7532	0	0	0	0
S_1	0.2427	0.2468	0.5105	0	0	0
S_2	0	0.4773	0.2468	0.2758	0	0
S_3	0	0	0.6626	0.2468	0.0906	0
S_4	0	0	0	0.6723	0.2468	0.0809
S_5	0	0	0	0	0.7532	0.2468.

Proof. The radial quotient of $P = \pi(M)$ has neighbor matrix A_{rad} from Definition 9462.1442. The f_3 wobble edge adds one self-loop to every radial state, so the neighbor-count matrix for the six-state conditioned chain is

$$\begin{pmatrix} 1 & 3 & 0 & 0 & 0 & 0 \\ 1 & 1 & 2 & 0 & 0 & 0 \\ 0 & 2 & 1 & 1 & 0 & 0 \\ 0 & 0 & 3 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 \end{pmatrix}.$$

If $\mu = 6\lambda(M) = 4.051487585\ldots$, then the radial Doob formula is

$$P^h_{ij} = \frac{N_{ij} h_j}{\mu h_i}.$$

Substituting the Perron vector of Definition 9462.1445 gives the displayed matrix; each row sums to 1. □

Concretized in §??: finite Doob-conditioned survival-chain NameCert data

Corollary 9462.1471 (Central drift of conditioned survival)**.** *The mean radial drift of the Doob chain is*

state	*drift*
S_0	0.7532
S_1	0.2679
S_2	−0.2015
S_3	−0.5719
S_4	−0.5914
S_5	−0.7532.

Thus the drift reverses at the Anchor_6–$\mathrm{StopStart}_6$ *interface.*

Proof. Assign positions $0, \ldots, 5$ to $S_0, \ldots, S_5$ and compute the expected one-step displacement from the rows of Definition 9462.1470. □

Theorem 9462.1472 (Doob stationary distribution)**.** *The stationary distribution of the Doob-conditioned chain satisfies*

$$\pi_i^h \propto |S_i| h_i^2.$$

Numerically,

state	π^h
$S_0 = \mathrm{AGR}$	0.1110
$S_1 = \mathrm{Anchor}_6$	0.3444
$S_2 = \mathrm{StopStart}_6$	0.3684
$S_3 = \mathrm{UUR}$	0.1534
$S_4 = \mathrm{CUR}$	0.0207
$S_5 = \mathrm{CUY}$	0.0022.

In particular,

$$\pi^h(\mathrm{Anchor}_6 \cup \mathrm{StopStart}_6) = 0.7128\ldots,$$

and including the UUR *bridge gives about* 86.6% *of the conditioned stationary mass.*

Proof. For a symmetric killed matrix, the Doob transform is reversible with stationary weights proportional to $h(x)^2$. Collapsing over a radial state multiplies by its lift size $|S_i|$. The displayed values are obtained from the Perron vector of Definition 9462.1445. □

Theorem 9462.1473 (QSD and Doob residence differ)**.** *The quasi-stationary radial mass and the Doob stationary radial mass are*

state	*QSD*	π^h
$S_0 = \mathrm{AGR}$	0.1117	0.1110
$S_1 = \mathrm{Anchor}_6$	0.3407	0.3444
$S_2 = \mathrm{StopStart}_6$	0.3524	0.3684
$S_3 = \mathrm{UUR}$	0.1313	0.1534
$S_4 = \mathrm{CUR}$	0.0482	0.0207
$S_5 = \mathrm{CUY}$	0.0158	0.0022.

The Doob chain suppresses the terminal CUN states more strongly than the quasi-stationary distribution.

Proof. The quasi-stationary radial mass is proportional to $|S_i|h_i$, as in Definition 9462.1445. The Doob stationary mass is proportional to $|S_i|h_i^2$ by Definition 9462.1472. Squaring the small tail potentials lowers the CUR and CUY masses. □

Definition 9462.1474 (Perron edge flux)**.** *For adjacent radial states S_i and S_j, define the stationary Perron flux of the Doob chain by*

$$\Phi_{ij} = \pi_i^h P_{ij}^h.$$

The reversibility of the Doob chain gives

$$\pi_i^h P_{ij}^h = \pi_j^h P_{ji}^h.$$

Theorem 9462.1475 (Perron flux concentration)**.** *The radial edge fluxes are*

edge group	Φ
$S_0 - S_1$	0.0836
$S_1 - S_2$	0.1758
$S_2 - S_3$	0.1016
$S_3 - S_4$	0.0139
$S_4 - S_5$	0.0017.

The largest Perron flux crosses the Anchor_6–$\mathrm{StopStart}_6$ *interface.*

Proof. Multiply the stationary masses from Definition 9462.1472 by the transition probabilities of Definition 9462.1470. The maximum entry is the $S_1 - S_2$ flux. □

Corollary 9462.1476 (The CUN tail is not a residence core)**.** *The CUN input flux $S_3 - S_4$ is only* 0.0139*, and the terminal tail flux $S_4 - S_5$ is only* 0.0017*. Thus the CUN tail is a spectral antenna in the sense of Definition 9462.1457, but not a residence core for the conditioned survival chain.*

Proof. These are the final two rows of Definition 9462.1475. They are much smaller than the central flux 0.1758. □

Definition 9462.1477 (Prefix conductance)**.** *For the prefix*

$$A_k = \{S_0, \dots, S_{k-1}\}$$

of the radial path, define the Doob-chain conductance by

$$\phi(A_k) = \frac{\Phi(A_k, A_k^c)}{\min(\pi^h(A_k), 1 - \pi^h(A_k))}.$$

Theorem 9462.1478 (Balanced central bottleneck)**.** *The prefix cuts have conductance*

cut	$\pi^h(A)$	$\Phi(A, A^c)$	$\phi(A)$
$S_0 \mid S_1 \cdots S_5$	0.1110	0.0836	0.7532
$S_0S_1 \mid S_2 \cdots S_5$	0.4554	0.1758	0.3861
$S_0S_1S_2 \mid S_3 \cdots S_5$	0.8237	0.1016	0.5765
$S_0 \cdots S_3 \mid S_4S_5$	0.9771	0.0139	0.6071
$S_0 \cdots S_4 \mid S_5$	0.9978	0.0017	0.7532.

The minimum occurs at the central cut through $S_1 - S_2$.

Proof. For each prefix, the boundary flux is the corresponding path flux from Definition 9462.1475. Dividing by the smaller side mass gives the displayed conductance values. □

Theorem 9462.1479 (Doob-conditioned median-closure dynamics)**.** *The conditioned survival dynamics of the median closure concentrates its stationary mass, Perron flux, and balanced bottleneck at the* Anchor_6–$\mathrm{StopStart}_6$ *interface. The* UUR *state acts as the adjacent survival bridge, while the CUN tail has low conditioned residence and low conditioned flux.*

Proof. Mass concentration is Definition 9462.1472; drift reversal is Definition 9462.1471; flux concentration is Definition 9462.1475; and the balanced bottleneck is Definition 9462.1478. The low-tail claim is Definition 9462.1476. □

Definition 9462.1480 (First-exit channel)**.** *For the killed bit-flip walk on* $M = \mathrm{Med}(\mathcal{R})$*, a first-exit step is a transition*

$$x \in M, \qquad x^{(i)} \notin M.$$

The associated channel records the origin state of x*, the flipped bit* i*, and the outside target codon* $x^{(i)}$ *together with its standard genetic-code class.*

Theorem 9462.1481 (Quasi-stationary exit origins)**.** *Under the quasi-stationary distribution of the killed walk on* M*, the pre-exit origin state has distribution*

origin state	*conditional probability*
$\mathrm{StopStart}_6$	0.3617
Anchor_6	0.3497
AGR	0.1146
CUR	0.0742
UUR	0.0674
CUY	0.0324.

Thus

$$\Pr(\mathrm{Anchor}_6 \cup \mathrm{StopStart}_6 \mid \textit{first exit}) = 0.7114\ldots.$$

Proof. For each boundary half-edge $x \in M$, $x^{(i)} \notin M$, add $q(x)/6$, where q is the quasi-stationary distribution. Normalizing by the total exit probability $1 - \lambda(M)$ and grouping by the six radial states gives the table. □

Corollary 9462.1482 (Tail leakage is not the dominant exit source)**.** *The two CUN tail states* CUR *and* CUY *contribute only*

$$0.0742 + 0.0324 = 0.1066$$

of quasi-stationary first exits.

Proof. This is the sum of the CUR and CUY rows of Definition 9462.1481. □

Theorem 9462.1483 (Quasi-stationary exit bits)**.** *The bit direction of a quasi-stationary first exit has distribution*

bit	*reading*	*conditional probability*
s_3	*third-position shape*	0.4804
f_1	*first-position family*	0.4211
f_2	*second-position family*	0.0328
s_1	*first-position shape*	0.0328
s_2	*second-position shape*	0.0328
f_3	*third-position family*	0.

Consequently,

$$\Pr(s_3 \text{ or } f_1 \mid \textit{first exit}) = 0.9015\ldots.$$

Proof. Sum the quasi-stationary boundary weights $q(x)/6$ over all boundary half-edges with the same flipped bit. The f_3 row is zero because M is f_3-saturated by Definition 9462.1429. □

Corollary 9462.1484 (Silent escape axis)**.** *The third-position family bit is a silent escape axis:*

$$\Pr(f_3 \textit{ exit}) = 0.$$

Proof. This is the final row of Definition 9462.1483, equivalently the f_3 saturation statement of Definition 9462.1429. □

Theorem 9462.1485 (Eventual first-exit bit by start state)**.** *Let $u_i(x)$ be the probability that the eventual first exit from M, starting at x, occurs through bit i. Averaged over the six radial states, the probabilities are*

start state	s_1	f_1	s_2	f_2	s_3	f_3
AGR	0.0041	0.4860	0.0041	0.0041	0.5017	0
Anchor_6	0.0068	0.4766	0.0068	0.0068	0.5029	0
StopStart_6	0.0151	0.4486	0.0151	0.0151	0.5063	0
UUR	0.0616	0.2895	0.0616	0.0616	0.5257	0
CUR	0.2628	0.1020	0.2628	0.2628	0.1095	0
CUY	0.2526	0.2204	0.2526	0.2526	0.0219	0.

Proof. For each bit i, solve the harmonic first-exit equation

$$u_i(x) = \frac{1}{6}\mathbf{1}[x^{(i)} \notin M] + \sum_{\substack{y \in M \\ y \sim x}} \frac{1}{6} u_i(y).$$

Equivalently,

$$(I - Q_M)u_i = r_i,$$

where $r_i(x) = 1/6$ exactly when the i-flip leaves M. Averaging the solution over each radial state gives the displayed table. □

Corollary 9462.1486 (Core and tail exit mechanisms)**.** *The core states* AGR*,* Anchor_6*, and* StopStart_6 *exit almost entirely through f_1 and s_3. The CUN tail states* CUR *and* CUY *instead place most eventual exit probability on s_1, s_2, and f_2.*

Proof. In Definition 9462.1485, the $f_1 + s_3$ sums for the three core states are respectively 0.9877, 0.9795, and 0.9549. For CUR and CUY, the sums over s_1, s_2, and f_2 are 0.7884 and 0.7577. □

Theorem 9462.1487 (Outside target classes)**.** *Quasi-stationary first exits land in the following standard-code classes:*

outside class	*conditional probability*
S	0.1176
P	0.0931
V	0.0931
Q	0.0850
F	0.0755
I	0.0603
Y	0.0603
A	0.0583
C	0.0583
E	0.0583
N	0.0583
R	0.0583
T	0.0583
G	0.0573
H	0.0081.

No first-exit target lies in the standard Stop class.

Proof. For each boundary half-edge $x \in M$, $y = x^{(i)} \notin M$, add the quasi-stationary boundary weight $q(x)/6$ to the standard-code class of y, then normalize by $1 - \lambda(M)$. The absence of a Stop target follows because UAA, UAG, and UGA lie inside M. □

Theorem 9462.1488 (Outside codon targets)**.** *The largest quasi-stationary outside codon targets are*

outside codon	*class*	*conditional probability*
CAA, CAG	Q	0.0425
CCA, CCG	P	0.0425
GUA, GUG	V	0.0425
UUC, UUU	F	0.0377
AUC, AUU	I	0.0301
UAC, UAU	Y	0.0301
UCC, UCU	S	0.0301.

Proof. The same boundary half-edge weights as in Definition 9462.1487 are aggregated by outside codon rather than by standard-code class. Equal-probability targets are grouped in the table. □

Theorem 9462.1489 (First-exit channel geometry)**.** *The first-exit geometry of the wobble-saturated median closure is controlled by two gate axes, s_3 and f_1, while the f_3 wobble axis is internally closed. Quasi-stationary exits mostly originate from* $\mathrm{Anchor}_6 \cup \mathrm{StopStart}_6$ *and land in ordinary sense classes outside M, not in the Stop class.*

Proof. The origin statement is Definition 9462.1481. The gate-axis statement is Definition 9462.1483; the silent-axis statement is Definition 9462.1484. The target-class statement is Definition 9462.1487. □

Concretized in §3677: The first-exit channel geometry is realized as finite origin, bit, outside-target, target-class, transition-ledger, transport, replay, provenance, and NameCert rows.

Concretized in §3678: The boundary-shadow trigger packet realizes first-exit half-edge, bit, outside target, and class rows as finite NameCert data.

Definition 9462.1490 (Post-median gate shell)**.** *Let*

$$M = \mathrm{Med}(\mathcal{R}).$$

The first post-median gate shell is the external f_3-saturated set

$$\mathcal{G}_1 = \{\mathrm{CAA}, \mathrm{CAG}, \mathrm{CCA}, \mathrm{CCG}, \mathrm{GUA}, \mathrm{GUG}\}.$$

Equivalently,

$$\mathcal{G}_1 = \mathrm{CAR} \cup \mathrm{CCR} \cup \mathrm{GUR}.$$

Write

$$M^+ = M \cup \mathcal{G}_1.$$

Theorem 9462.1491 (Post-median single-point spectral optimum)**.** *Among all single codons $p \in Q_6 \setminus M$, the maximum of*

$$\lambda(M \cup \{p\})$$

is attained exactly at

$$\mathrm{CAA}, \mathrm{CAG}, \mathrm{CCA}, \mathrm{CCG}, \mathrm{GUA}, \mathrm{GUG}.$$

For each of these six codons,

$$\lambda(M \cup \{p\}) = 0.681004866\ldots,$$

so the single-point gain over M is

$$0.005756935\ldots.$$

Proof. Enumerate the 44 codons in $Q_6 \setminus M$ and compute the Perron root of the killed transition matrix on $M \cup \{p\}$. The six displayed codons are the complete maximizer set. □

Corollary 9462.1492 (Gate shell and first-exit targets)**.** *The codons of $\mathcal{G}_1$ are exactly the highest-probability outside codon targets of Definition 9462.1488.*

Proof. Definition 9462.1488 lists the same six codons at probability 0.0425 each. By Definition 9462.1491, the same six codons are the post-median single-point spectral maximizers. □

Theorem 9462.1493 (Boolean form of the gate shell)**.** *In the two-axis bit coordinates, $\mathcal{G}_1$ is the set*

$$f_1 = 1, \qquad s_3 = 1, \qquad \mathrm{wt}(s_1, s_2, f_2) = 1,$$

with f_3 free.

Proof. The three quotient fibers are

$$\mathrm{CAR}, \qquad \mathrm{CCR}, \qquad \mathrm{GUR}.$$

They all have first-position family bit $f_1 = 1$ and third-position shape bit $s_3 = 1$. Among the three symmetric coordinates s_1, s_2, f_2, exactly one is 1 for each of the three quotient fibers. The third-position family bit f_3 distinguishes the two lifts inside each fiber. □

Theorem 9462.1494 (Gate shell as a full external orbit)**.** *Under*

$$\Gamma = \mathrm{Stab}(M) \cong S_3 \times C_2,$$

the set $\mathcal{G}_1$ is a full orbit in $Q_6 \setminus M$.

Proof. The S_3 factor permutes the three coordinates s_1, s_2, f_2, and the condition

$$\mathrm{wt}(s_1, s_2, f_2) = 1$$

is a single S_3 orbit. The C_2 factor flips f_3, making each quotient point into its full f_3 pair. Hence the orbit has $3 \cdot 2 = 6$ codons, namely $\mathcal{G}_1$. □

Theorem 9462.1495 (Best symmetric post-median orbit)**.** *Among the* 10 *external* Γ*-orbits in* $Q_6 \setminus M$*, adjoining* $\mathcal{G}_1$ *gives the largest spectral radius:*

$$\lambda(M \cup \mathcal{G}_1) = 0.727773877\ldots.$$

Proof. Enumerate the external orbits of the action of $\Gamma = \mathrm{Stab}(M)$ on $Q_6 \setminus M$. For each orbit O, compute $\lambda(M \cup O)$. The maximum is attained by the orbit of Definition 9462.1494. □

Theorem 9462.1496 (Geometry of the post-median shell)**.** *The extension*

$$M^+ = M \cup \mathcal{G}_1$$

has

$$|M^+| = 26, \qquad |E(M^+)| = 53.$$

Thus its uniform one-step retention is

$$\rho(M^+) = \frac{2|E(M^+)|}{6|M^+|} = \frac{53}{78} = 0.679487\ldots.$$

Its killed-walk spectral radius is

$$\lambda(M^+) = 0.727773877\ldots.$$

Proof. Directly count the induced Hamming edges after adjoining the six codons of $\mathcal{G}_1$. The retention formula is $2|E|/(6|V|)$, and the spectral value is the Perron root of the killed transition matrix on M^+. □

Theorem 9462.1497 (CUR exit closure)**.** *In M^+, the state*

$$\mathrm{CUR} = \{\mathrm{CUA}, \mathrm{CUG}\}$$

has no one-bit exit:

$$P_{\mathrm{out}}(\mathrm{CUR}; M^+) = 0.$$

Proof. The six one-bit neighbors of CUA are

$$\mathrm{UUA}, \mathrm{CUG}, \mathrm{CCA}, \mathrm{CAA}, \mathrm{GUA}, \mathrm{CUU}.$$

The codons UUA, CUG, CUU lie in M, while CCA, CAA, GUA lie in $\mathcal{G}_1$. The six one-bit neighbors of CUG are handled identically, with the outside neighbors CCG, CAG, GUG supplied by $\mathcal{G}_1$. □

Corollary 9462.1498 (CUN tail exit shell)**.** *The set $\mathcal{G}_1$ is the first exit-closing shell for the* CUR *part of the CUN tail.*

Proof. By Definition 9462.1497, adjoining $\mathcal{G}_1$ changes the CUR leakage probability from 1/2 in M to 0 in M^+. □

Theorem 9462.1499 (Gate-shell bypass)**.** *In the state graph of M^+, the gate shell supplies a two-step bypass*

$$\mathrm{StopStart}_6 - \mathcal{G}_1 - \mathrm{CUR}.$$

There are 6 *edges from* $\mathrm{StopStart}_6$ *to* $\mathcal{G}_1$ *and* 6 *edges from* $\mathcal{G}_1$ *to* CUR*.*

Proof. Group the Hamming edges of M^+ by the six original radial states and the added shell state $\mathcal{G}_1$. The cross-edge counts are exactly 6 for $\mathrm{StopStart}_6$–$\mathcal{G}_1$ and 6 for $\mathcal{G}_1$–CUR. □

Theorem 9462.1500 (Best wobble-pair expansion)**.** *If the added set must be a full f_3 pair outside M, the spectral maximizers are exactly*

$$\mathrm{CAR}, \qquad \mathrm{CCR}, \qquad \mathrm{GUR}.$$

Each gives

$$\lambda(M \cup \mathit{pair}) = 0.691331504\ldots.$$

Their union is $\mathcal{G}_1$.

Proof. Enumerate the external f_3 pairs and compute the killed-walk Perron root after adjoining each pair. The three displayed pairs are the complete maximizer set; their union is the shell of Definition 9462.1490. □

Theorem 9462.1501 (Post-median gate shell)**.** *The set*

$$\mathcal{G}_1 = \mathrm{CAR} \cup \mathrm{CCR} \cup \mathrm{GUR}$$

is simultaneously the top first-exit target layer, the complete post-median external orbit selected by Γ, the best symmetric spectral extension of M, and the exit-closing shell for CUR*.*

Proof. The first-exit identification is Definition 9462.1492. The orbit statement is Definition 9462.1494. The symmetric spectral optimality is Definition 9462.1495. The exit closure is Definition 9462.1498. □

Concretized in §3625: Post-median gate shells are realized as finite codon-shell, Boolean-coordinate, spectral-optimum, first-exit, transport, replay, provenance, and NameCert rows.

Definition 9462.1502 (Radial shell closure beyond the gate shell)**.** *Let*

$$M^\star = \mathrm{NNR} \cup \mathrm{CUY}.$$

Thus $M^\star$ contains every codon whose third position is purine, together with the two codons CUU *and* CUC*. Hence*

$$|M^\star| = 34.$$

Definition 9462.1503 (Y-halfspace shells around CUY)**.** *In the third-position Y halfspace, define H_k to be the set of codons whose first two positions have Hamming distance k from* CU*. Then*

shell	*size*	*description*
H_0	2	CUY
H_1	8	UUY ∪ CCY ∪ CAY ∪ GUY
H_2	12	*six two-flip Y-pairs*
H_3	8	*four three-flip Y-pairs*
H_4	2	AGY.

Thus

$$M^\star = \mathrm{NNR} \cup H_0.$$

Theorem 9462.1504 (Median-closed halfspace anchor)**.** *The set $M^\star$ is median-closed:*

$$\mathrm{Med}(M^\star) = M^\star.$$

Proof. After quotienting by the saturated f_3 direction, the set is the complete halfspace $s_3 = 1$ together with the single Y-side point CUY. A three-point median of quotient points either has at least two entries in the halfspace, in which case it remains in the halfspace, or has at least two entries at CUY, in which case it remains at CUY or at an already present halfspace point. Lifting back along f_3 preserves median closure. □

Theorem 9462.1505 (Shell-triggered median percolation)**.** *For every $k = 1, 2, 3, 4$,*

$$\mathrm{Med}(M^\star \cup H_k) = Q_6.$$

The finite stage counts are

added shell	*start size*	*closure size*	*stage additions*
H_1	42	64	12, 10
H_2	46	64	18
H_3	42	64	22
H_4	36	64	28.

Proof. Compute the coordinatewise median closure from each starting set $M^\star \cup H_k$. Each closure is all 64 codons. The stage additions in the table record the number of codons first generated at each median-closure pass. □

Theorem 9462.1506 (Antipodal single trigger)**.** *The two codons in*

$$H_4 = \mathrm{AGY} = \{\mathrm{AGU}, \mathrm{AGC}\}$$

are single-codon median triggers:

$$\mathrm{Med}(M^\star \cup \{\mathrm{AGU}\}) = Q_6, \qquad \mathrm{Med}(M^\star \cup \{\mathrm{AGC}\}) = Q_6.$$

In both cases the closure reaches Q_6 in one median pass.

Proof. In the f_3 quotient, CUY and AGY are antipodal points in the four coordinates of the third-position Y halfspace. For any target point b in that Y halfspace, take the point t_b in the already present R halfspace with the same first-four-bit coordinates as b. The median of CUY, AGY, and t_b has the first four coordinates of t_b and third-position shape Y, hence is b. Thus the whole Y halfspace is generated in one pass; the R halfspace was already present. □

Corollary 9462.1507 (CUY anchor and AGY antipode)**.** *The set $M^\star$ is a complete R halfspace with a Y-side anchor* CUY*, and* AGY *is the antipodal median trigger for that anchor.*

Proof. This is the geometric content of Definition 9462.1506. □

Theorem 9462.1508 (Single-point spectrum and median triggering differ)**.** *From $M^\star$, single-codon spectral stabilization and median percolation select different shells:*

single-codon shell	Med *-closure size*	$\lambda(M^\star \cup \{p\})$
H_1	36	0.837956
H_2	40	0.837179
H_3	48	0.837165
$H_4 = \mathrm{AGY}$	64	0.837156.

Thus the best single-point spectral stabilizer lies in H_1, while the strongest median trigger lies in H_4.

Proof. For a representative codon in each shell, compute both $\lambda(M^\star \cup \{p\})$ and the size of the median closure. The spectral values are largest in the nearest shell H_1, whereas Definition 9462.1506 gives full-cube median generation from the antipodal shell H_4. □

Theorem 9462.1509 (Radial shell filling spectrum)**.** *Let*

$$S_j = \mathrm{NNR} \cup \bigcup_{k=0}^{j} H_k.$$

Then

level	*size*	*structure*	λ	ρ
S_0	34	$\mathrm{NNR} \cup H_0$	0.836111	0.813725
S_1	42	$+H_1$	0.859128	0.817460
S_2	54	$+H_2$	0.921172	0.895062
S_3	62	$+H_3$	0.978349	0.973118
S_4	64	$+H_4 = Q_6$	1.000000	1.000000.

Proof. For each S_j, count induced Hamming edges to compute $\rho = 2|E(S_j)|/(6|S_j|)$, and compute the Perron root of the killed transition matrix on S_j. At $j = 4$ the set is all of Q_6. □

Theorem 9462.1510 (Antipodal triggering beyond the radial shell)**.** *The set $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$ is median-closed, but adjoining either codon of* AGY *generates the whole codon cube by median closure:*

$$M^\star \quad \textit{is closed}, \qquad M^\star \cup \{\mathrm{AGU}\} \textit{ or } M^\star \cup \{\mathrm{AGC}\} \Longrightarrow Q_6.$$

Proof. The closedness is Definition 9462.1504. The single-codon full-cube generation is Definition 9462.1506. □

Concretized in §3694: The antipodal AGY trigger is realized as finite median-closure, shell, trigger-ledger, transport, replay, provenance, and NameCert rows.

Definition 9462.1511 (Anchor subcube span)**.** *Let*

$$M^\star = \mathrm{NNR} \cup \mathrm{CUY}.$$

Every codon outside $M^\star$ lies in the third-position Y halfspace. For a set $B \subseteq Q_6 \setminus M^\star$, let $\rho(B)$ be the projection of B to the four bits of the first two codon positions, and let $D(B)$ be the smallest axis-aligned subcube of that Q_4 which contains the anchor CU *and $\rho(B)$. Write*

$$d(B) = \dim D(B).$$

Theorem 9462.1512 (Anchor-subcube closure formula)**.** *For every $B \subseteq Q_6 \setminus M^\star$,*

$$\mathrm{Med}(M^\star \cup B) = \mathrm{NNR} \cup (D(B) \times Y).$$

Proof. The set $M^\star$ contains the full third-position R halfspace. Take two points x, y in the Y halfspace and a point t in the R halfspace. In the third-position shape coordinate, the median of x, y, t remains in the Y halfspace. In any one of the first-four coordinates, if x and y agree, the median is forced to that common value; if they disagree, the corresponding coordinate of t chooses the median value. Since the R halfspace is complete, all choices of t are available. Iterating this interval operation generates exactly the smallest axis-aligned subcube containing the anchor CU and $\rho(B)$, and no coordinate outside that subcube can be introduced. □

Corollary 9462.1513 (Closure size by span dimension)**.** *The closure size depends only on $d(B)$:*

$$|\,\mathrm{Med}(M^\star \cup B)| = 32 + 2^{d(B)+1}.$$

Thus

$d(B)$	*closure size*
0	34
1	36
2	40
3	48
4	64.

Proof. The R halfspace NNR has 32 codons. A $d(B)$-dimensional subcube in the first-four coordinates has $2^{d(B)}$ vertices, and lifting across the two third-position Y codons contributes the factor 2. □

Theorem 9462.1514 (Single-codon span classification)**.** *If $p \in Q_6 \setminus M^\star$ lies in the shell H_d around* CUY*, then*

$$|\,\mathrm{Med}(M^\star \cup \{p\})| = 32 + 2^{d+1}.$$

Equivalently,

shell	*codons*	*closure size*
H_1	8	36
H_2	12	40
H_3	8	48
$H_4 = \mathrm{AGY}$	2	64.

Proof. For a single codon, the subcube spanned by its projection and the anchor CU is exactly their interval in the first-four-bit Q_4. Its dimension is their Hamming distance, namely the shell index d. □

Theorem 9462.1515 (External subset trigger counts)**.** *Among the* 30 *codons of* $Q_6 \setminus M^\star$*, the distribution of median-closure sizes for* m *adjoined codons is*

m	*candidate sets*	36	40	48	64
1	30	8	12	8	2
2	435	4	78	196	157
3	4060	0	120	1216	2724
4	27405	0	90	3824	23491.

Proof. For each m-element subset B of $Q_6 \setminus M^\star$, compute the union of first-four-coordinate supports relative to the anchor CU, then apply Definition 9462.1513. The same table is checked against representative median closures for every nonempty support pattern. □

Definition 9462.1516 (Anchor-relative support)**.** *For* $p \in Q_6 \setminus M^\star$*, define*

$$\mathrm{supp}(p) = \{i \in \{s_1, f_1, s_2, f_2\} : \rho(p)_i \neq \mathrm{CU}_i\}.$$

Theorem 9462.1517 (Full-cube trigger criterion)**.** *For* $B \subseteq Q_6 \setminus M^\star$*,*

$$\mathrm{Med}(M^\star \cup B) = Q_6$$

if and only if

$$\bigcup_{p \in B} \mathrm{supp}(p) = \{s_1, f_1, s_2, f_2\}.$$

Proof. By Definition 9462.1512, the closure is the whole cube exactly when $D(B)$ is the full first-two-position Q_4. This is equivalent to every one of the four coordinates being freed by at least one anchor-relative support. □

Corollary 9462.1518 (AGY as the full-support point)**.** *The codons* AGU *and* AGC *have anchor-relative support*

$$\{s_1, f_1, s_2, f_2\}.$$

Hence either one is a full-cube trigger for $M^\star$*.*

Proof. The first two positions AG are antipodal to CU in the four-bit coordinate system. The claim follows from Definition 9462.1517. □

Theorem 9462.1519 (Anchor-subcube trigger theorem)**.** *The median dynamics beyond* $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$ *are completely determined by the subcube span of the outside* Y*-halfspace points relative to the anchor* CUY*. In particular, the antipodal trigger* AGY *is the single-codon case with* $d(B) = 4$*.*

Proof. The exact closure formula is Definition 9462.1512. The size and full-cube criteria are Definition 9462.1513 and Definition 9462.1517. The antipodal case is Definition 9462.1518. □

Concretized in §3651: Anchor subcube triggers are realized as finite anchor, boundary-tile, coverage-rank, trigger-algebra, blocker, transport, replay, provenance, and NameCert rows.

Definition 9462.1520 (Boolean trigger closure)**.** *Let $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$, and let the first-two-position coordinates be ordered as*

$$s_1, f_1, s_2, f_2.$$

For $p \in Q_6 \setminus M^\star$, define the anchor support

$$\sigma(p) = \{i \in \{s_1, f_1, s_2, f_2\} : p_i \neq \mathrm{CU}_i\}.$$

For $B \subseteq Q_6 \setminus M^\star$, put

$$J(B) = \bigcup_{p \in B} \sigma(p), \qquad r(B) = |J(B)|.$$

For $J \subseteq \{s_1, f_1, s_2, f_2\}$, let $Q_J(\mathrm{CU})$ be the first-two-position subcube based at CU with exactly the coordinates in J free, and set

$$C_J = \mathrm{NNR} \cup (Q_J(\mathrm{CU}) \times Y).$$

Theorem 9462.1521 (Trigger lattice)**.** *For every $B \subseteq Q_6 \setminus M^\star$,*

$$\mathrm{Med}(M^\star \cup B) = C_{J(B)}.$$

Consequently the post-$M^\star$ median closures are exactly the sixteen sets C_J indexed by $J \subseteq \{s_1, f_1, s_2, f_2\}$.

Proof. This is Definition 9462.1512 with the subcube $D(B)$ written by its free-coordinate set. The free coordinates are exactly the union of the anchor-relative supports of the adjoined codons. □

Corollary 9462.1522 (Rank size and full triggering)**.** *If $|J| = r$, then*

$$|C_J| = 32 + 2^{r+1}.$$

Thus

r	$\lvert C_J \rvert$
0	34
1	36
2	40
3	48
4	64.

In particular, $\mathrm{Med}(M^\star \cup B) = Q_6$ *if and only if* $J(B) = \{s_1, f_1, s_2, f_2\}$.

Proof. The R halfspace contributes 32 codons. The Y-side trigger subcube has 2^r first-two-position vertices and two third-position Y-lifts. Full-cube triggering is the case in which all four first-two-position coordinates are free. □

Theorem 9462.1523 (Boolean lattice operations)**.** *For all $I, J \subseteq \{s_1, f_1, s_2, f_2\}$,*

$$C_I \cap C_J = C_{I \cap J},$$

and

$$\mathrm{Med}(C_I \cup C_J) = C_{I \cup J}.$$

Proof. On the Y side, intersection fixes exactly the coordinates fixed by both subcubes, hence leaves the free set $I \cap J$. Median closure of the union is governed by the free-coordinate support of the union, so the free set is $I \cup J$. The common R halfspace NNR is present in every C_J and is unchanged by both operations. □

Theorem 9462.1524 (Cubical and spectral rank table)**.** *The cubical f-vector and killed-walk spectral radius of C_J depend only on $r = |J|$:*

r	$\lvert C_J\rvert$	$f(C_J)$	$\lambda(C_J)$
0	34	$(34, 83, 81, 40, 10, 1)$	0.836111
1	36	$(36, 88, 85, 41, 10, 1)$	0.840912
2	40	$(40, 100, 98, 47, 11, 1)$	0.855963
3	48	$(48, 128, 136, 72, 19, 2)$	0.902369
4	64	$(64, 192, 240, 160, 60, 12, 1)$	1.000000.

The cubical formula is

$$f_k(C_J) = f_k(Q_5) + f_k(Q_{r+2}) - f_k(Q_{r+1}), \qquad f_k(Q_n) = 2^{n-k}\binom{n}{k}.$$

Proof. The complex is the union of the complete R halfspace Q_5 and the trigger slab $Q_J(\mathrm{CU}) \times N \cong Q_{r+2}$. Their intersection is Q_{r+1}, giving the displayed inclusion-exclusion formula. The spectral radii are obtained by the finite killed-walk adjacency computation on each rank representative. □

Theorem 9462.1525 (Quotient spectral equations)**.** *Since every C_J is saturated in the f_3 direction, its killed-walk radius has the form*

$$\lambda_r = \frac{\mu_r + 1}{6}, \qquad r = |J|.$$

The quotient spectral roots are

r	*equation for* μ_r	μ_r
0	$\mu^6 - 21\mu^4 + 80\mu^2 - 24 = 0$	4.016667
1	$\mu^4 - 4\mu^3 - 5\mu^2 + 18\mu + 6 = 0$	4.045475
2	$\mu^4 - 8\mu^3 + 19\mu^2 - 12\mu - 2 = 0$	4.135779
3	$\mu^2 - 6\mu + 7 = 0$	4.414214
4	$\mu - 5 = 0$	5.000000.

Proof. The f_3-wobble edge contributes one uniform self-neighbor in the quotient dynamics, so the six-bit killed-walk eigenvalue is $(\mu_r+1)/6$. The displayed equations are the characteristic equations of the finite quotient adjacency matrices for rank $r = 0, 1, 2, 3, 4$, with the largest positive root selected in each case. □

Corollary 9462.1526 (Near-global rank)**.** *At rank* 3*, the closure has* 48 *codons and spectral radius*

$$\lambda_3 = 0.902369.$$

Thus a trigger set covering any three of the four first-two-position coordinates already lies in a high-survival regime, while covering the last coordinate gives $C_{\{s_1,f_1,s_2,f_2\}} = Q_6$.

Proof. This is the $r = 3$ row of Definition 9462.1524 and Definition 9462.1525. □

Theorem 9462.1527 (Rank distribution for external codons)**.** *Among m adjoined codons from $Q_6 \setminus M^\star$, the number whose final trigger rank is d is*

$$N(m, d) = \binom{4}{d} \sum_{j=0}^{d} (-1)^j \binom{d}{j} \binom{2(2^{d-j} - 1)}{m}.$$

For $m \leq 6$ this gives

m	$r=1$	$r=2$	$r=3$	$r=4$	$\binom{30}{m}$
1	8	12	8	2	30
2	4	78	196	157	435
3	0	120	1216	2724	4060
4	0	90	3824	23491	27405
5	0	36	7936	134534	142506
6	0	6	12000	581769	593775.

Proof. Choose the d coordinates that appear in the final support. Inside those coordinates there are $2(2^d - 1)$ codon lifts with nonempty support. Inclusion-exclusion removes the selections that miss at least one of the d chosen coordinates, giving the stated formula. □

Corollary 9462.1528 (Full-trigger probabilities)**.** *For uniformly chosen m-codon subsets of $Q_6 \setminus M^\star$, the full-cube trigger probabilities for $m = 1, \ldots, 6$ are*

m	$\Pr(\mathrm{Med}(M^\star \cup B) = Q_6)$
1	0.0667
2	0.3609
3	0.6709
4	0.8572
5	0.9441
6	0.9798.

Proof. Divide the $r = 4$ column of Definition 9462.1527 by $\binom{30}{m}$. □

Theorem 9462.1529 (Maximum non-trigger blockers)**.** *The largest external subsets that do not trigger the full cube have cardinality*

$$2(2^3 - 1) = 14.$$

There are four such maximal blockers, one for each omitted coordinate in $\{s_1, f_1, s_2, f_2\}$. Consequently every $B \subseteq Q_6 \setminus M^\star$ with $|B| \geq 15$ satisfies

$$\mathrm{Med}(M^\star \cup B) = Q_6.$$

Proof. A non-trigger set has rank at most 3. For fixed three-coordinate support J, the largest such set contains every nonempty quotient support contained in J, and each quotient support has two f_3-lifts. This gives $2(2^3 - 1) = 14$ codons. There are four choices of the missing coordinate. Any subset of size at least 15 cannot be contained in one of these blockers, so its support rank is 4. □

Theorem 9462.1530 (Minimal full triggers)**.** *At quotient level, the minimal full triggers have counts*

trigger size	*quotient count*
1	1
2	25
3	22
4	1
total	49.

At codon level, where each quotient support has two f_3-lifts, the corresponding counts are

trigger size	*codon count*
1	2
2	100
3	176
4	16
total	294.

Proof. A quotient-level minimal full trigger is a minimal set cover of the four coordinate set $\{s_1, f_1, s_2, f_2\}$ by nonempty supports. Enumerating the minimal covers of a four-element set gives $1, 25, 22, 1$ by trigger size. A codon-level trigger of size m has 2^m choices of f_3-lifts, giving the second table. □

Corollary 9462.1531 (Antipodal singleton)**.** *The only quotient-level one-point full trigger is* AGY*. Its two codon-level lifts are* AGU *and* AGC*.*

Proof. A one-point full trigger must have support $\{s_1, f_1, s_2, f_2\}$. The unique first-two-position quotient point with that support relative to CU is AG. □

Theorem 9462.1532 (Rank-spectral trigger lattice theorem)**.** *After $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$, every median closure, closure size, cubical f-vector, killed-walk spectral radius, and full-cube threshold is controlled by the Boolean trigger rank on $\{s_1, f_1, s_2, f_2\}$. The full cube appears exactly at rank 4, the largest non-trigger external set has size 14, and* AGY *is the unique quotient-level singleton full trigger.*

Proof. The closure classification is Definition 9462.1521. The rank size and full-cube criterion are Definition 9462.1522. The cubical and spectral rank data are Definition 9462.1524 and Definition 9462.1525. The forced threshold is Definition 9462.1529, and the singleton classification is Definition 9462.1531. □

Concretized in §3704: BooleanTriggerLatticeUp realizes the Boolean trigger rank, meet, join, observed table, and support rows as a finite NameCert packet.

Definition 9462.1533 (Random trigger time)**.** *Let $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$. Draw codons without replacement from the 30 codons of $Q_6 \setminus M^\star$, and write*

$$B_m = \{p_1, \ldots, p_m\}.$$

The full-cube trigger time is

$$T = \min\{m : \mathrm{Med}(M^\star \cup B_m) = Q_6\}.$$

Equivalently, T is the first time at which the anchor supports of B_m cover all four coordinates s_1, f_1, s_2, f_2.

Theorem 9462.1534 (Random rank distribution)**.** *For m external codons and trigger rank d, the number of m-element subsets with rank exactly d is*

$$N(m, d) = \binom{4}{d} \sum_{j=0}^{d} (-1)^j \binom{d}{j} \binom{2(2^{d-j} - 1)}{m}.$$

Thus

$$\Pr(r(B_m) = d) = \frac{N(m, d)}{\binom{30}{m}}.$$

Proof. This is the set-cover count of Definition 9462.1527, normalized by the number of m-codon subsets of the external set. □

Theorem 9462.1535 (Full-trigger distribution)**.** *The cumulative full-trigger probabilities are*

$$\Pr(T \le m) = \Pr(r(B_m) = 4) = \frac{N(m,4)}{\binom{30}{m}}.$$

For $m \le 10$:

m	$\Pr(T \le m)$
1	0.0667
2	0.3609
3	0.6709
4	0.8572
5	0.9441
6	0.9798
7	0.9933
8	0.9979
9	0.9994
10	0.9999.

Proof. Full triggering is the rank-four event by Definition 9462.1522. Substitute $d = 4$ into Definition 9462.1534. □

Concretized in §4217: Random trigger thresholds are realized as finite trigger-rank NameCert data.

Theorem 9462.1536 (Trigger time law)**.** *The trigger time satisfies*

$$\Pr(T = m) = \Pr(T \le m) - \Pr(T \le m - 1).$$

Its first values, together with the conditional trigger rate $h_m = \Pr(T = m \mid T \ge m)$, are

m	$\Pr(T = m)$	h_m
1	0.0667	0.0667
2	0.2943	0.3153
3	0.3100	0.4851
4	0.1862	0.5660
5	0.0869	0.6083
6	0.0357	0.6386
7	0.0135	0.6665
8	0.0047	0.6957
9	0.0015	0.7273
10	0.0004	0.7619.

The mode is $T = 3$.

Proof. The probability mass formula follows by differencing the cumulative distribution in Definition 9462.1535. The hazard is the same mass divided by survival before the mth draw. □

Corollary 9462.1537 (Mean and quantiles)**.** *The expected full-cube trigger time is*

$$\mathbb{E}[T] = 3.12998.$$

The median, 90%*,* 95%*, and* 99% *thresholds are*

quantile	*codons*
50%	3
90%	5
95%	6
99%	7.

Proof. Use the finite identity

$$\mathbb{E}[T] = \sum_{m \geq 0} \Pr(T > m),$$

with the deterministic cutoff supplied by Definition 9462.1529. The quantiles are read from the cumulative distribution. □

Theorem 9462.1538 (Expected rank, closure size, and spectrum)**.** *After m random external codons, the expected trigger rank is*

$$\mathbb{E}[r_m] = 4\left(1 - \frac{\binom{14}{m}}{\binom{30}{m}}\right).$$

For $m \leq 7$:

m	$\mathbb{E}[r_m]$
1	2.1333
2	3.1632
3	3.6414
4	3.8539
5	3.9438
6	3.9798
7	3.9933.

The corresponding expected closure sizes and expected spectral radii are

m	$\mathbb{E}\lvert \mathrm{Med}(M^\star \cup B_m)\rvert$	$\mathbb{E}[\lambda]$
0	34.000	0.836111
1	42.667	0.873927
2	52.230	0.928720
3	58.499	0.966502
4	61.689	0.985904
5	63.103	0.994527
6	63.676	0.998025
7	63.892	0.999342
8	63.967	0.999800
9	63.991	0.999945
10	63.998	0.999987.

Proof. A fixed coordinate is absent precisely when all m codons lie in the fourteen external codons whose supports do not contain that coordinate. Linearity of expectation gives the displayed rank formula. The expected closure size and spectral radius are obtained by summing the rank-size and rank-spectral tables against the rank distribution. □

Theorem 9462.1539 (Random trigger threshold theorem)**.** *For the random external process beyond $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$, the average full-cube trigger time is* 3.12998 *codons. The deterministic worst-case threshold is* 15 *codons, while the median and* 99% *random thresholds are* 3 *and* 7 *codons respectively.*

Proof. The mean and quantiles are Definition 9462.1537. The deterministic threshold is Definition 9462.1529. □

Definition 9462.1540 (Rank Markov state)**.** *Let $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$, and draw external codons without replacement from $Q_6 \setminus M^\star$. For $B_m = \{p_1, \ldots, p_m\}$, put*

$$J_m = \bigcup_{p \in B_m} \sigma(p), \qquad r_m = |J_m|.$$

The state of the random trigger process is the pair (m, r_m).

Theorem 9462.1541 (Rank Markov transition)**.** *If the current state is (m, r) with $r < 4$, then the next rank change $\ell = r_{m+1} - r_m$ has probabilities*

$$\Pr(\ell = 0 \mid m, r) = \frac{2(2^r - 1) - m}{30 - m},$$

and, for $1 \le \ell \le 4 - r$,

$$\Pr(\ell \mid m, r) = \frac{2 \cdot 2^r \binom{4-r}{\ell}}{30 - m}.$$

Thus (m, r_m) is a finite Markov process.

Proof. Given a covered coordinate set J of size r, the external codons whose support is contained in J number $2(2^r - 1)$. Since all m drawn codons are already contained in this class when the rank does not increase, the remaining non-increasing codons number $2(2^r - 1) - m$. If exactly ℓ fresh coordinates are added, choose those ℓ from the $4 - r$ uncovered coordinates, choose any subset of the r covered coordinates, and choose one of the two f_3-lifts. Dividing by the $30 - m$ remaining external codons gives the formula. □

Corollary 9462.1542 (Rank drift)**.** *The one-step expected rank change is*

$$\mathbb{E}[r_{m+1} - r_m \mid m, r] = \frac{16(4 - r)}{30 - m}.$$

Proof. Using Definition 9462.1541,

$$\mathbb{E}[\Delta r \mid m, r] = \sum_{\ell=1}^{4-r} \ell \frac{2 \cdot 2^r \binom{4-r}{\ell}}{30 - m}.$$

The binomial identity

$$\sum_{\ell=1}^{n} \ell \binom{n}{\ell} = n 2^{n-1}$$

with $n = 4 - r$ gives the result. □

Corollary 9462.1543 (Direct trigger probability)**.** *For $r < 4$,*

$$\Pr(r_{m+1} = 4 \mid m, r) = \frac{2^{r+1}}{30 - m}.$$

In particular, from state $(3, 3)$ the next draw triggers the full cube with probability $16/27 = 0.5926$.

Proof. Direct triggering is the change $\ell = 4 - r$ in Definition 9462.1541. □

Theorem 9462.1544 (Markov trigger moments)**.** *Let* $T = \min\{m : r_m = 4\}$*. The Markov recursion gives*

$$\mathbb{E}[T] = 3.12998, \qquad \mathrm{Var}(T) = 1.81588, \qquad \mathrm{sd}(T) = 1.34755.$$

The first trigger-time probabilities are the same as in Definition 9462.1536; in particular, the mode is $T = 3$*.*

Proof. Let $E(m, r)$ be the expected remaining number of draws until rank 4. Then $E(m, 4) = 0$ and

$$E(m, r) = 1 + \sum_{r'} \Pr(r' \mid m, r) E(m + 1, r').$$

The second moment satisfies the analogous recursion for $(1+T')^2$. Applying these finite recursions from $(0, 0)$ gives the displayed values. □

Theorem 9462.1545 (Conditional remaining trigger time)**.** *The expected remaining draw counts at representative states are*

state	$E(m, r)$
$(0, 0)$	3.130
$(1, 1)$	2.729
$(1, 2)$	2.329
$(1, 3)$	1.765
$(2, 1)$	2.638
$(2, 2)$	2.252
$(2, 3)$	1.706
$(3, 2)$	2.174
$(3, 3)$	1.647
$(6, 2)$	1.941
$(6, 3)$	1.471.

Proof. These are the values of the finite recursion in Definition 9462.1544. They depend on both the number of consumed external codons and the currently covered coordinate rank. □

Theorem 9462.1546 (Markov trigger theorem)**.** *Beyond* $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$*, random median percolation is exactly the four-coordinate set-cover Markov process on states* (m, r)*. Its transition law is Definition 9462.1541, its drift is Definition 9462.1542, and its full-trigger time has mean* 3.12998 *with deterministic worst-case threshold* 15*.*

Proof. The equivalence between full median closure and rank 4 is Definition 9462.1522. The transition law follows from support counting, and the threshold 15 is Definition 9462.1529. □

Concretized in §5792: Finite rank-trigger Markov dynamics are realized as BHist transition-count and trigger-time NameCert rows.

Concretized in §2245: The finite codon-transition matrix packet realizes the Markov-trigger transition surface as BEDC NameCert data.

Definition 9462.1547 (Blocker complex)**.** *Let* $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$ *and let*

$$\Omega = \{s_1, f_1, s_2, f_2\}.$$

For an external set $B \subseteq Q_6 \setminus M^\star$*, define* $J(B) = \bigcup_{p \in B} \sigma(p)$*. The blocker complex is*

$$\mathcal{B} = \{B \subseteq Q_6 \setminus M^\star : J(B) \subsetneq \Omega\}.$$

It is a simplicial complex because every subset of a non-trigger set is again non-trigger.

Theorem 9462.1548 (Maximal blockers)**.** *The maximal faces of* $\mathcal{B}$ *are the four blockers obtained by omitting one trigger coordinate:*

$$B_{\neg s_1}, \quad B_{\neg f_1}, \quad B_{\neg s_2}, \quad B_{\neg f_2}.$$

Each has 14 *vertices. In IUPAC notation they are*

$$\mathrm{YNY} \setminus \mathrm{CUY}, \quad \mathrm{SNY} \setminus \mathrm{CUY}, \quad \mathrm{NYY} \setminus \mathrm{CUY}, \quad \mathrm{NWY} \setminus \mathrm{CUY}.$$

Proof. If coordinate i is absent, every support lies in $\Omega \setminus \{i\}$. The nonempty supports inside the remaining three coordinates number $2^3 - 1$, and each has two f_3-lifts. Thus each maximal blocker has $2(2^3 - 1) = 14$ codons. The four displayed motifs express the four possible missing coordinates relative to the anchor CUY. □

Corollary 9462.1549 (Forcing threshold)**.** *The largest non-trigger external sets have size* 14*. Hence every external set* B *with* $|B| \geq 15$ *satisfies*

$$\mathrm{Med}(M^\star \cup B) = Q_6.$$

Proof. Every blocker is contained in one of the four maximal blockers of Definition 9462.1548. □

Theorem 9462.1550 (Blocker intersections)**.** *If* ℓ *trigger coordinates are simultaneously omitted, then the corresponding maximal-blocker intersection has size*

$$2(2^{4-\ell} - 1).$$

Consequently the intersection sizes are

ℓ	*intersection size*
1	14
2	6
3	2
4	0.

Proof. After omitting a set L of ℓ coordinates, the allowed nonempty supports are precisely the nonempty subsets of $\Omega \setminus L$. There are $2^{4-\ell} - 1$ such supports, each with two f_3-lifts. □

Theorem 9462.1551 (Blocker nerve)**.** *The nerve of the four-simplex cover of* $\mathcal{B}$ *by its maximal blockers is the tetrahedron boundary* $\partial\Delta^3$*.*

Proof. Every one-, two-, and three-fold intersection of maximal blockers is nonempty by Definition 9462.1550, while the four-fold intersection is empty. The nerve therefore has four vertices, six edges, four triangular faces, and no three-simplex. □

Corollary 9462.1552 (Blocker homotopy type)**.** *The blocker complex satisfies*

$$\mathcal{B} \simeq S^2.$$

Hence its only nonzero reduced homology is

$$\widetilde{H}_2(\mathcal{B}) \cong \mathbb{Z}.$$

Proof. Each maximal blocker and every nonempty intersection of maximal blockers is a simplex, hence contractible. The nerve theorem applies, and the nerve is $\partial\Delta^3 \cong S^2$ by Definition 9462.1551. □

Theorem 9462.1553 (Blocker f-vector)**.** *For $m \geq 1$, the number of m-codon blocker faces is*

$$F_m = 4\binom{14}{m} - 6\binom{6}{m} + 4\binom{2}{m}.$$

Thus the blocker-complex f-vector is

$$(28, 278, 1336, 3914, 7972, 12006, 13728, 12012, 8008, 4004, 1456, 364, 56, 4),$$

and its Euler characteristic is 2*.*

Proof. Use inclusion-exclusion over the four maximal blockers. Single maximal blockers have size 14, pairwise intersections have size 6, triple intersections have size 2, and the four-fold intersection is empty. The alternating sum of the displayed f-vector is 2. □

Corollary 9462.1554 (Probability tail from blockers)**.** *For a uniformly chosen m-codon external subset,*

$$\Pr(T > m) = \frac{F_m}{\binom{30}{m}},$$

and hence

$$\Pr(T \leq m) = 1 - \frac{4\binom{14}{m} - 6\binom{6}{m} + 4\binom{2}{m}}{\binom{30}{m}}.$$

Proof. The event $T > m$ is exactly the event that the chosen subset is a face of $\mathcal{B}$. Count those faces by Definition 9462.1553. □

Theorem 9462.1555 (Trigger-blocker duality theorem)**.** *Beyond $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$, full triggering is the set-cover condition $J(B) = \Omega$, while non-triggering is the blocker complex $\mathcal{B} \simeq S^2$. The minimal full triggers are the minimal nonfaces of $\mathcal{B}$, and there are* 294 *such nonfaces at codon level.*

Proof. The trigger criterion is Definition 9462.1522. The blocker homotopy type is Definition 9462.1552. Minimal full triggers are precisely minimal subsets not belonging to $\mathcal{B}$, and their codon-level count is Definition 9462.1530. □

Concretized in §3801: The trigger-blocker duality reading is realized as finite blocker-complex, maximal-blocker, intersection, nerve, transport, provenance, and NameCert rows.

Definition 9462.1556 (Trigger hypergraph)**.** *Let* $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$ *and let*

$$E = Q_6 \setminus M^\star, \qquad \Omega = \{s_1, f_1, s_2, f_2\}.$$

The post-$M^\star$ *trigger hypergraph has vertex set* E *and edge set*

$$\mathcal{T} = \{T \subseteq E : T \text{ is minimal with } J(T) = \Omega\}.$$

Equivalently, its edges are the minimal full triggers of Definition 9462.1530.

Theorem 9462.1557 (Trigger hypergraph as nonface data)**.** *The trigger hypergraph* $\mathcal{T}$ *is the set of minimal nonfaces of the blocker complex* $\mathcal{B}$*.*

Proof. By Definition 9462.1547, a subset $B \subseteq E$ is a face of $\mathcal{B}$ exactly when $J(B) \subsetneq \Omega$. Thus a minimal subset not belonging to $\mathcal{B}$ is exactly a minimal subset with $J(B) = \Omega$, which is the defining condition for an edge of $\mathcal{T}$. □

Theorem 9462.1558 (Minimal-trigger polynomials)**.** *The quotient-level minimal-trigger generating polynomial is*

$$T_q(z) = z + 25z^2 + 22z^3 + z^4.$$

At codon level it is

$$T_c(z) = 2z + 100z^2 + 176z^3 + 16z^4.$$

Proof. The quotient coefficients are the four rows of Definition 9462.1530. At codon level, each quotient support has two f_3-lifts, so a trigger of size m contributes a factor 2^m. □

Theorem 9462.1559 (Minimal-trigger support types)**.** *At quotient level, the minimal full triggers have the following support-size types:*

trigger size	*support-size type*	*quotient count*	*codon count*
1	(4)	1	2
2	$(1,3)$	4	16
2	$(2,2)$	3	12
2	$(2,3)$	12	48
2	$(3,3)$	6	24
3	$(1,1,2)$	6	48
3	$(1,2,2)$	12	96
3	$(2,2,2)$	4	32
4	$(1,1,1,1)$	1	16.

Proof. Enumerate all minimal set covers of the four-coordinate set Ω by nonempty supports and sort each cover by the cardinalities of its members. The codon counts again multiply the quotient counts by 2^m for trigger size m. □

Theorem 9462.1560 (Bernoulli reliability polynomial)**.** *Suppose each external codon in* E *is independently adjoined with probability* p*, and put* $q = 1 - p$*. The probability of full-cube triggering is*

$$R(p) = 1 - 4q^{16} + 6q^{24} - 4q^{28} + q^{30}.$$

Proof. Failure to trigger is the event that at least one coordinate of Ω is absent. For one fixed coordinate, the 16 codons whose support contains that coordinate must all be omitted, giving q^{16}. For two fixed coordinates to be absent, the 24 codons containing at least one of them must be omitted, giving q^{24}. For three fixed coordinates, the exponent is 28, and for all four it is 30. Inclusion-exclusion over the four missing-coordinate events therefore gives

$$\Pr(\text{non-trigger}) = 4q^{16} - 6q^{24} + 4q^{28} - q^{30},$$

and $R(p)$ is its complement. □

Corollary 9462.1561 (Reliability thresholds)**.** *Solving $R(p) = \alpha$ gives*

α	p_α	$30p_\alpha$
0.50	0.08779	2.63
0.90	0.19455	5.84
0.95	0.23206	6.96
0.99	0.30934	9.28.

Thus an independent activation rate of about 8.779% *already gives a half-probability full trigger.*

Proof. The entries are the unique roots in $[0, 1]$ of the equation in Definition 9462.1560. The final column is the expected number of selected external codons. □

Corollary 9462.1562 (Fixed-size and Bernoulli blocker probabilities)**.** *The fixed-size non-trigger probability and the Bernoulli non-trigger probability are two evaluations of the same blocker complex:*

$$\Pr(\textit{non-trigger after } m \textit{ external codons}) = \frac{4\binom{14}{m} - 6\binom{6}{m} + 4\binom{2}{m} - \binom{0}{m}}{\binom{30}{m}},$$

with the final term only affecting $m = 0$, while

$$\Pr(\textit{Bernoulli non-trigger}) = 4q^{16} - 6q^{24} + 4q^{28} - q^{30}.$$

Proof. The first formula is the blocker f-vector count of Definition 9462.1553 divided by the total number of m-subsets, with the empty four-fold intersection included for the empty face. The second is the missing-coordinate inclusion-exclusion used in Definition 9462.1560. □

Theorem 9462.1563 (Stanley-Reisner trigger ideal)**.** *Let x_p be a squarefree variable for each $p \in E$. The Stanley-Reisner ideal of $\mathcal{B}$ is*

$$I_{\mathcal{B}} = \left\langle \prod_{p \in T} x_p : T \in \mathcal{T} \right\rangle.$$

It has 294 *minimal squarefree monomial generators, with degree distribution*

degree	*minimal generators*
1	2
2	100
3	176
4	16.

The degree-one generators are x_{AGU} and x_{AGC}.

Proof. The Stanley-Reisner ideal is generated by the minimal nonfaces of the complex. By Definition 9462.1557, these are precisely the minimal full triggers. The degree distribution is the codon-level table in Definition 9462.1558, and the degree-one generators are the two codon lifts of the quotient support AGY from Definition 9462.1531. □

Theorem 9462.1564 (Trigger hypergraph and reliability theorem)**.** *Beyond $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$, the full-cube trigger problem is equivalently a four-coordinate set-cover hypergraph, an S^2 blocker complex, a 294-edge minimal-nonface system, and the Bernoulli reliability polynomial*

$$R(p) = 1 - 4(1-p)^{16} + 6(1-p)^{24} - 4(1-p)^{28} + (1-p)^{30}.$$

Proof. The set-cover criterion is Definition 9462.1522. The blocker homotopy type is Definition 9462.1552. The minimal nonface identification is Definition 9462.1557, with the codon-level count from Definition 9462.1558. The reliability polynomial is Definition 9462.1560. □

Concretized in §3657: Finite trigger-edge reliability rows are realized as a NameCert packet.

Definition 9462.1565 (Coverage rank)**.** *Let $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$ and $E = Q_6 \setminus M^\star$. For $p \in E$, let $\sigma(p) \subseteq \Omega$ be its anchor support, where*

$$\Omega = \{s_1, f_1, s_2, f_2\}.$$

For $B \subseteq E$, put

$$J(B) = \bigcup_{p \in B} \sigma(p), \qquad r(B) = |J(B)|.$$

The function r is the coverage rank of the external set B.

Theorem 9462.1566 (Coverage-closure formula)**.** *For every $B \subseteq E$,*

$$\mathrm{Med}(M^\star \cup B) = M^\star \cup \{p \in E : \sigma(p) \subseteq J(B)\}.$$

Equivalently,

$$\mathrm{Med}(M^\star \cup B) = \mathrm{NNR} \cup (Q_{J(B)}(\mathrm{CU}) \times Y).$$

Proof. This is the anchor-subcube formula of Definition 9462.1521 written on the external vertex set E. The complete R halfspace supplies every coordinate choice needed to median-generate the Y-side subcube based at CU with free coordinate set $J(B)$. The external vertices in that subcube are exactly those whose supports are contained in $J(B)$. □

Concretized in §3734: Coverage-rank algebra is realized as finite boundary-tile coverage, rank, trigger, classifier, and NameCert rows.

Corollary 9462.1567 (Rank size formula)**.** *If $r(B) = r$, then*

$$|\mathrm{Med}(M^\star \cup B)| = 34 + 2(2^r - 1) = 32 + 2^{r+1}.$$

Thus

r	$\lvert \mathrm{cl}_E(B) \rvert$	$\lvert \mathrm{Med}(M^\star \cup B) \rvert$
0	0	34
1	2	36
2	6	40
3	14	48
4	30	64.

Proof. For fixed $J \subseteq \Omega$ with $|J| = r$, the external codons closed under J have nonempty supports contained in J. There are $2^r - 1$ such quotient supports and two f_3-lifts for each. Adding the 34 codons already in $M^\star$ gives the displayed formula. □

Definition 9462.1568 (External trigger closure)**.** *For $B \subseteq E$, define*

$$\mathrm{cl}_E(B) = \{p \in E : \sigma(p) \subseteq J(B)\}.$$

Then

$$\mathrm{Med}(M^\star \cup B) = M^\star \cup \mathrm{cl}_E(B).$$

Theorem 9462.1569 (Closed-set lattice)**.** *The closed sets of cl_E are exactly*

$$E_J = \{p \in E : \sigma(p) \subseteq J\}, \qquad J \subseteq \Omega.$$

There are 16 closed sets, and

$$E_I \cap E_J = E_{I \cap J}, \qquad \mathrm{cl}_E(E_I \cup E_J) = E_{I \cup J}.$$

Thus the closed-set lattice is isomorphic to 2^Ω.

Proof. The operator cl_E depends on a subset only through the union support $J(B)$. If C is closed, then $C = \mathrm{cl}_E(C) = E_{J(C)}$. Conversely each E_J is fixed by cl_E. The two displayed identities follow directly from support containment. □

Theorem 9462.1570 (Coverage polymatroid rank)**.** *The function $r(B) = |J(B)|$ is monotone and submodular:*

$$A \subseteq B \Longrightarrow r(A) \leq r(B),$$

and

$$r(A) + r(B) \geq r(A \cup B) + r(A \cap B).$$

It is a coverage polymatroid rank rather than a matroid rank.

Proof. Write

$$r(B) = \sum_{i \in \Omega} \mathbf{1}[i \in J(B)].$$

Each coordinate indicator is monotone and submodular as a set function on E, and finite sums preserve these two properties. However AGU and AGC each have support Ω, so $r(\{\mathrm{AGU}\}) = r(\{\mathrm{AGC}\}) = 4$. A matroid rank function has singleton rank at most 1. □

Definition 9462.1571 (Rank enumerator)**.** *The coverage-rank enumerator is*

$$Z(t, u) = \sum_{B \subseteq E} t^{|B|} u^{r(B)}.$$

Theorem 9462.1572 (Rank-enumerator formula)**.** *The rank enumerator has the closed form*

$$Z(t, u) = \sum_{d=0}^{4} \binom{4}{d} u^d \sum_{k=0}^{d} (-1)^{d-k} \binom{d}{k} (1 + t)^{2(2^k - 1)}.$$

Proof. Fix a coordinate set J with $|J| = d$. The choices with $J(B) \subseteq J$ form a simplex on $2(2^d - 1)$ external codons, so their ordinary generating function is $(1+t)^{2(2^d-1)}$. Inclusion-exclusion over the coordinates of J extracts the choices with $J(B) = J$. Multiplying by $\binom{4}{d}$ and u^d gives the formula. □

Corollary 9462.1573 (Fixed-size rank counts)**.** *The coefficient of $t^m u^d$ in $Z(t,u)$ is*

$$N(m,d) = \binom{4}{d} \sum_{j=0}^{d} (-1)^j \binom{d}{j} \binom{2(2^{d-j}-1)}{m}.$$

For $m \leq 4$ this gives

m	$r=1$	$r=2$	$r=3$	$r=4$
1	8	12	8	2
2	4	78	196	157
3	0	120	1216	2724
4	0	90	3824	23491.

Proof. Extract the coefficient of $t^m u^d$ in Definition 9462.1572 and substitute $j = d - k$. □

Theorem 9462.1574 (Blocker independence polynomial)**.** *The independence polynomial of the non-trigger complex*

$$\mathcal{B} = \{B \subseteq E : r(B) < 4\}$$

is

$$I_{\mathcal{B}}(t) = 4(1+t)^{14} - 6(1+t)^6 + 4(1+t)^2 - 1.$$

Proof. The complex $\mathcal{B}$ is the union of four maximal blocker simplices, one for each omitted coordinate. Their one-, two-, and three-fold intersections have 14, 6, and 2 vertices respectively, while the four-fold intersection contains only the empty face. Applying inclusion-exclusion to the face generating functions gives the displayed polynomial. □

Corollary 9462.1575 (Reliability from blocker independence)**.** *For independent external activation probability p and $q = 1 - p$,*

$$\Pr(\textit{non-trigger}) = q^{30} I_{\mathcal{B}}\left(\frac{p}{q}\right) = 4q^{16} - 6q^{24} + 4q^{28} - q^{30}.$$

Hence

$$R(p) = 1 - 4q^{16} + 6q^{24} - 4q^{28} + q^{30}.$$

Proof. Weighting a blocker face of size m by $p^m q^{30-m}$ gives $q^{30} I_{\mathcal{B}}(p/q)$. Substituting the polynomial from Definition 9462.1574 and simplifying recovers the reliability polynomial of Definition 9462.1560. □

Theorem 9462.1576 (Coverage-rank algebra theorem)**.** *Beyond $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$, the codon median dynamics are completely controlled by the coverage-rank algebra on $\Omega = \{s_1, f_1, s_2, f_2\}$. The same support-union function determines the median closure, the closed-set lattice, the submodular rank, the rank enumerator, the blocker independence polynomial, the reliability polynomial, and the trigger ideal.*

Proof. The closure formula is Definition 9462.1566. The closed-set lattice is Definition 9462.1569, and the rank structure is Definition 9462.1570. The enumerator and blocker polynomial are Definition 9462.1572 and Definition 9462.1574. The reliability polynomial follows from Definition 9462.1575, and the trigger ideal is Definition 9462.1563. □

Definition 9462.1577 (Trigger energy)**.** *Let* $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$ *and* $E = Q_6 \setminus M^\star$*. For an external codon* $p \in E$*, define*

$$e(p) = |\sigma(p)|.$$

For $B \subseteq E$*, define its trigger energy by*

$$\mathcal{E}(B) = \sum_{p \in B} |\sigma(p)|.$$

This is the total first-two-position Hamming distance from the anchor CUY*, counted over the selected external codons.*

Theorem 9462.1578 (Energy lower bound)**.** *If* $B \subseteq E$ *is a full trigger, then*

$$\mathcal{E}(B) \geq 4.$$

Proof. Full triggering means $J(B) = \Omega$, where $\Omega = \{s_1, f_1, s_2, f_2\}$. Hence each of the four trigger coordinates appears in at least one support $\sigma(p)$. Counting appearances of coordinates across the selected supports gives $\mathcal{E}(B) \geq |\Omega| = 4$. □

Theorem 9462.1579 (Partition criterion)**.** *For a full trigger* B*, equality*

$$\mathcal{E}(B) = 4$$

holds if and only if the family of supports

$$\{\sigma(p) : p \in B\}$$

is a set partition of Ω*.*

Proof. If $\mathcal{E}(B) = 4$, then the four coordinates of Ω are covered with exactly four total coordinate appearances. Since full triggering requires all four coordinates to appear, each coordinate appears exactly once; the supports are therefore pairwise disjoint and their union is Ω. Conversely, if the supports partition Ω, each coordinate is counted exactly once, so $\mathcal{E}(B) = 4$. □

Theorem 9462.1580 (Energy-minimal trigger counts)**.** *At quotient level, the full triggers of minimal energy are the set partitions of the four-coordinate set* Ω*. Thus there are* 15 *of them. By trigger size they are*

trigger size	*partition type*	*quotient count*	*codon count*
1	4	1	2
2	$1+3$ *or* $2+2$	7	28
3	$1+1+2$	6	48
4	$1+1+1+1$	1	16
total		15	94.

Proof. By Definition 9462.1579, energy-minimal full triggers correspond exactly to set partitions of a four-element set. The four partition types have counts $1, 7, 6, 1$. At codon level, a trigger of size m has 2^m independent f_3-lift choices. □

Theorem 9462.1581 (Minimal triggers by energy)**.** *The codon-level minimal full triggers have energy distribution*

$$94y^4 + 144y^5 + 56y^6.$$

Equivalently,

energy	*quotient count*	*codon count*
4	15	94
5	24	144
6	10	56.

Thus 94 *of the* 294 *codon-level minimal full triggers are energy-minimal.*

Proof. Combine the support-size type enumeration of Definition 9462.1559 by total support size. The energy-four rows are precisely the partition rows; the energy-five rows come from overlapping types $(2, 3)$ and $(1, 2, 2)$; the energy-six rows come from $(3, 3)$ and $(2, 2, 2)$. Multiplying each quotient trigger of size m by 2^m gives the codon counts. □

Theorem 9462.1582 (Bivariate minimal-trigger polynomial)**.** *Let*

$$T_q(z, y) = \sum_T z^{|T|} y^{\mathcal{E}(T)}$$

sum over quotient-level minimal full triggers. Then

$$T_q(z, y) = zy^4 + z^2(7y^4 + 12y^5 + 6y^6) + z^3(6y^4 + 12y^5 + 4y^6) + z^4y^4.$$

At codon level,

$$T_c(z, y) = 2zy^4 + z^2(28y^4 + 48y^5 + 24y^6) + z^3(48y^4 + 96y^5 + 32y^6) + 16z^4y^4.$$

Setting $y = 1$ *recovers*

$$T_c(z, 1) = 2z + 100z^2 + 176z^3 + 16z^4,$$

and setting $z = 1$ *gives*

$$T_c(1, y) = 94y^4 + 144y^5 + 56y^6.$$

Proof. The terms are obtained by grouping the minimal-trigger support types from Definition 9462.1559 by trigger size and total support size. Passing from quotient level to codon level multiplies every size-m term by 2^m. □

Corollary 9462.1583 (Energy and cardinality)**.** *Energy-minimal full triggers exist at every cardinality* $1, 2, 3, 4$*. The cardinality-one case is the antipodal trigger* AGY*, while the cardinality-four case consists of one unit-support codon in each trigger coordinate.*

Proof. These are the four partition types in Definition 9462.1580. The one-block partition is Ω itself, realized by AGY. The four-block partition is the decomposition of Ω into singleton coordinates. □

Theorem 9462.1584 (Trigger-energy theorem)**.** *Beyond* $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$*, every full trigger has energy at least* 4*, and equality is exactly the set-partition case. There are* 15 *quotient-level and* 94 *codon-level energy-minimal full triggers, while the full minimal-trigger energy distribution at codon level is*

$$94y^4 + 144y^5 + 56y^6.$$

Proof. The lower bound is Definition 9462.1578, and the equality case is Definition 9462.1579. The enumerative statements are Definition 9462.1580 and Definition 9462.1581. □

Concretized in §3806: Trigger-energy partitions are realized as finite support, energy-ledger, partition, codon-lift, transport, replay, provenance, and NameCert rows.

Definition 9462.1585 (Energy-biased trigger weights)**.** *Let $E = Q_6 \setminus M^\star$ and let $e(p) = |\sigma(p)|$ be the trigger energy of $p \in E$. For parameters $t > 0$ and $0 < y \leq 1$, assign each external codon the weight*

$$w(p) = ty^{e(p)}.$$

For $B \subseteq E$, set

$$W(B) = t^{|B|} y^{\mathcal{E}(B)}.$$

The parameter t is the activity of external activation, while y penalizes distance from the anchor CUY*.*

Definition 9462.1586 (Energy partition factors)**.** *For $0 \leq d \leq 4$, define*

$$A_d(t, y) = \prod_{k=1}^{d} (1 + ty^k)^{2\binom{d}{k}}.$$

Thus

$$A_4(t, y) = (1 + ty)^8 (1 + ty^2)^{12} (1 + ty^3)^8 (1 + ty^4)^2$$

is the partition function of all external subsets.

Theorem 9462.1587 (Energy-biased blocker partition function)**.** *The partition function of non-trigger external sets is*

$$Z_{\text{block}}(t, y) = 4A_3(t, y) - 6A_2(t, y) + 4A_1(t, y) - 1.$$

Proof. Non-triggering means that at least one coordinate of $\Omega = \{s_1, f_1, s_2, f_2\}$ is absent. If a fixed set of $4 - d$ coordinates is absent, the allowed supports lie inside a fixed d-coordinate set, whose weighted partition function is $A_d(t, y)$. Inclusion-exclusion over the four omitted-coordinate events gives the displayed expression; the final -1 accounts for the empty four-fold intersection. □

Theorem 9462.1588 (Energy-biased reliability)**.** *The full-trigger reliability in the energy-biased model is*

$$R(t, y) = 1 - \frac{4A_3(t, y) - 6A_2(t, y) + 4A_1(t, y) - 1}{A_4(t, y)}.$$

Proof. The numerator in the fraction is the non-trigger partition function of Definition 9462.1587, and the denominator is the all-external partition function from Definition 9462.1586. Their ratio is the non-trigger probability under the product measure induced by the weights $w(p)$. □

Corollary 9462.1589 (Uniform reliability as a specialization)**.** *At $y = 1$,*

$$A_d(t, 1) = (1 + t)^{2(2^d - 1)}.$$

With $t = p/(1 - p)$, the energy-biased reliability specializes to

$$R(p) = 1 - 4(1 - p)^{16} + 6(1 - p)^{24} - 4(1 - p)^{28} + (1 - p)^{30}.$$

Proof. Substitute $y = 1$ in Definition 9462.1588. Multiplying the resulting blocker ratio by the common Bernoulli factor $(1-p)^{30}$ gives the polynomial of Definition 9462.1560. □

Corollary 9462.1590 (Low-energy expansion)**.** *As $y \to 0$, the full-trigger partition function satisfies*

$$Z_{\text{trig}}(t, y) = y^4(2t + 28t^2 + 48t^3 + 16t^4) + O(y^5).$$

Proof. By Definition 9462.1578, the lowest full-trigger energy is 4. By Definition 9462.1580, the energy-four codon-level triggers have counts $2, 28, 48, 16$ in cardinalities $1, 2, 3, 4$, respectively. □

Theorem 9462.1591 (Energy-biased threshold table)**.** *For target reliability α, let $t_\alpha(y)$ be the activity solving $R(t_\alpha(y), y) = \alpha$. The expected external-codon count at that activity is*

$$\mathbb{E}_{t,y}[|B|] = \sum_{k=1}^{4} 2\binom{4}{k} \frac{ty^k}{1 + ty^k}.$$

For $\alpha = 0.50$, the thresholds are

y	$t_{0.50}(y)$	$\mathbb{E}[\lvert B\rvert]$
1.00	0.0962	2.63
0.75	0.2008	3.01
0.50	0.5108	3.53
0.25	1.9830	4.23
0.10	8.5128	4.69.

For $\alpha = 0.90$, they are

y	$t_{0.90}(y)$	$\mathbb{E}[\lvert B\rvert]$
1.00	0.2415	5.84
0.75	0.4903	6.39
0.50	1.2207	7.04
0.25	4.7581	7.69
0.10	21.7497	7.80.

For $\alpha = 0.95$, they are

y	$t_{0.95}(y)$	$\mathbb{E}[\lvert B\rvert]$
1.00	0.3022	6.96
0.75	0.6114	7.55
0.50	1.5224	8.22
0.25	6.0003	8.80
0.10	28.2281	8.77.

Proof. The thresholds are the unique positive solutions of Definition 9462.1588. The expectation formula follows from the independent inclusion probability of an energy-k codon, namely $ty^k/(1 + ty^k)$, and the fact that there are $2\binom{4}{k}$ such codons. □

Corollary 9462.1592 (Energy-biased trigger regimes)**.** *At low activity, the cardinality-one term $2ty^4$ favors the two antipodal codon triggers* AGU *and* AGC*. At higher activity under energy penalty, the terms*

$$28t^2y^4, \qquad 48t^3y^4, \qquad 16t^4y^4$$

express the increasing contribution of partition-minimal multi-codon triggers.

Proof. These are the four terms in the low-energy expansion of Definition 9462.1590. The power of t records the trigger cardinality, while the common y^4 records minimal trigger energy. □

Theorem 9462.1593 (Energy-biased trigger reliability theorem)**.** *Beyond $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$, the Boolean trigger lattice admits the explicit two-parameter reliability function*

$$R(t,y) = 1 - \frac{4A_3(t,y) - 6A_2(t,y) + 4A_1(t,y) - 1}{A_4(t,y)}.$$

The specialization $y = 1$ recovers the uniform Bernoulli reliability, while the limit $y \to 0$ is governed by the 94 partition-minimal full triggers.

Proof. The formula is Definition 9462.1588. The uniform specialization is Definition 9462.1589, and the low-energy leading term is Definition 9462.1590. □

Concretized in §3583: Energy-biased trigger reliability is realized as finite weight, partition, blocker, and reliability NameCert rows.

Definition 9462.1594 (Conditional trigger ensemble)**.** *Let $E = Q_6 \setminus M^\star$ and weight external subsets by*

$$W(B) = t^{|B|} y^{\mathcal{E}(B)}.$$

The full-trigger partition function is

$$Z_{\mathrm{trig}}(t,y) = Z_{\mathrm{all}}(t,y) - Z_{\mathrm{block}}(t,y).$$

The conditional trigger ensemble is the probability distribution on full-trigger subsets defined by

$$\Pr(B \mid \mathrm{trig}) = \frac{t^{|B|} y^{\mathcal{E}(B)}}{Z_{\mathrm{trig}}(t,y)}.$$

Theorem 9462.1595 (Conditional trigger derivatives)**.** *In the conditional trigger ensemble,*

$$\mathbb{E}[|B| \mid \mathrm{trig}] = t \frac{\partial}{\partial t} \log Z_{\mathrm{trig}}(t,y),$$

and

$$\mathbb{E}[\mathcal{E}(B) \mid \mathrm{trig}] = y \frac{\partial}{\partial y} \log Z_{\mathrm{trig}}(t,y).$$

Proof. Differentiating Z_{trig} with $t\partial_t$ multiplies each monomial $t^{|B|} y^{\mathcal{E}(B)}$ by $|B|$. Dividing by Z_{trig} gives the conditional expectation. The same argument with $y\partial_y$ gives the conditional expected energy. □

Theorem 9462.1596 (Conditional means at half reliability)**.** *At the activity $t_{0.50}(y)$ satisfying $R(t,y) = 0.50$, the conditional means are*

y	$t_{0.50}(y)$	$\mathbb{E}[\lvert B\rvert \mid \mathrm{trig}]$	$\mathbb{E}[\mathcal{E}(B) \mid \mathrm{trig}]$
1.00	0.0962	3.596	8.184
0.75	0.2008	4.013	8.294
0.50	0.5108	4.580	8.308
0.25	1.9830	5.318	8.008
0.10	8.5128	5.751	7.296.

Proof. The activity values solve Definition 9462.1588. The conditional means are then evaluated by Definition 9462.1595. □

Theorem 9462.1597 (Conditional means at high reliability)**.** *At the activity $t_{0.90}(y)$ satisfying $R(t, y) = 0.90$, the conditional means are*

y	$t_{0.90}(y)$	$\mathbb{E}[\lvert B\rvert \mid \text{trig}]$	$\mathbb{E}[\mathcal{E}(B) \mid \text{trig}]$
1.00	0.2415	6.144	13.237
0.75	0.4903	6.699	13.271
0.50	1.2207	7.354	13.060
0.25	4.7581	7.989	12.201
0.10	21.7497	8.070	10.710.

Proof. This is the same derivative evaluation as Definition 9462.1596, now at the reliability level 0.90. □

Theorem 9462.1598 (Low-energy conditional distribution)**.** *As $y \to 0$, the conditional trigger ensemble is supported on partition-minimal triggers. If*

$$P(t) = 2t + 28t^2 + 48t^3 + 16t^4,$$

then the limiting cardinality distribution is

$$\Pr_{\min}(|B| = m) = \frac{a_m t^m}{P(t)},$$

where

$$a_1 = 2, \qquad a_2 = 28, \qquad a_3 = 48, \qquad a_4 = 16.$$

The limiting conditional mean cardinality is

$$\mathbb{E}_{\min}[|B|] = \frac{2t + 56t^2 + 144t^3 + 64t^4}{2t + 28t^2 + 48t^3 + 16t^4}.$$

Proof. By Definition 9462.1590, the lowest full-trigger energy is 4, with cardinality counts $2, 28, 48, 16$. Dividing the four leading terms by their sum gives the limiting conditional distribution. □

Theorem 9462.1599 (Low-energy crossover table)**.** *In the low-energy limiting ensemble, the cardinality probabilities and mean size are*

t	Pr(1)	Pr(2)	Pr(3)	Pr(4)	$\mathbb{E}_{\min}[\lvert B\rvert]$
0.10	0.3776	0.5287	0.0906	0.0030	1.719
0.25	0.1633	0.5714	0.2449	0.0204	2.122
0.50	0.0667	0.4667	0.4000	0.0667	2.467
1.00	0.0213	0.2979	0.5106	0.1702	2.830
2.00	0.0053	0.1481	0.5079	0.3386	3.180
5.00	0.0006	0.0419	0.3591	0.5984	3.555
10.00	0.0001	0.0133	0.2277	0.7589	3.745.

Proof. Substitute each value of t into Definition 9462.1598. □

Corollary 9462.1600 (Activity crossover points)**.** *The adjacent leading terms in the low-energy ensemble cross at*

$$t = \frac{1}{14}, \qquad t = \frac{7}{12}, \qquad t = 3.$$

Thus the dominant low-energy trigger type passes from singleton antipodal triggers, to two-codon partition triggers, to three-codon partition triggers, and finally to four unit-direction triggers.

Proof. The three equalities are

$$2t = 28t^2, \qquad 28t^2 = 48t^3, \qquad 48t^3 = 16t^4.$$

Solving them gives the displayed activities. □

Theorem 9462.1601 (Conditional trigger ensemble theorem)**.** *Beyond* $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$*, the full-trigger event has an explicit conditional ensemble. Its conditional mean cardinality and energy are logarithmic derivatives of* $Z_{\mathrm{trig}}(t, y)$*, and its low-energy limit is governed by the partition-minimal trigger polynomial*

$$2t + 28t^2 + 48t^3 + 16t^4.$$

Proof. The derivative formulas are Definition 9462.1595. The low-energy limiting distribution is Definition 9462.1598, and the activity crossovers are Definition 9462.1600. □

Concretized in §3870: The conditional trigger ensemble is realized as finite weighted trigger, blocker, partition, expectation, transport, replay, provenance, and NameCert rows.

Concretized in §7816: The finite trigger-cube packet realizes the conditional trigger ensemble as finite cube, trigger, blocker, energy, rank, and NameCert rows.

Definition 9462.1602 (Alexander-dual coordinate monomials)**.** *Let* $R_0 = k[x_p : p \in E]$ *be the squarefree polynomial ring on the external codons. For each trigger coordinate* $i \in \Omega$*, define*

$$U_i = \prod_{\sigma(p) \ni i} x_p.$$

Since a fixed coordinate lies in 2^3 *quotient supports and each support has two* f_3*-lifts, every* U_i *has degree* 16*.*

Theorem 9462.1603 (Alexander-dual blocker ideal)**.** *Let* $\mathcal{B}$ *be the blocker complex. Its Alexander-dual ideal is*

$$I_{\mathcal{B}}^{\vee} = \langle U_{s_1}, U_{f_1}, U_{s_2}, U_{f_2} \rangle.$$

Proof. The facets of $\mathcal{B}$ are the four maximal blockers $B_{\neg i} = \{p \in E : i \notin \sigma(p)\}$. Alexander duality sends each facet to its complement in E:

$$E \setminus B_{\neg i} = \{p \in E : i \in \sigma(p)\}.$$

The squarefree monomial on this complement is precisely U_i. □

Theorem 9462.1604 (LCM degrees)**.** *For* $S \subseteq \Omega$ *with* $|S| = k$*,*

$$\deg \operatorname{lcm}(U_i : i \in S) = 32 - 2^{5-k}.$$

Thus the lcm degrees are

$\lvert S\rvert$	*number of subsets*	*lcm degree*
1	4	16
2	6	24
3	4	28
4	1	30.

Proof. The lcm contains exactly those external codons whose support intersects S. Among the 15 nonempty quotient supports, the supports disjoint from S are the nonempty subsets of $\Omega \setminus S$, hence number $2^{4-k} - 1$. Therefore the quotient supports meeting S number $15 - (2^{4-k} - 1) = 16 - 2^{4-k}$, and each has two f_3-lifts. □

Theorem 9462.1605 (Minimal Taylor resolution)**.** *For*

$$J = I_{\mathcal{B}}^{\vee},$$

the Taylor resolution is minimal, with graded shifts

$$0 \to R_0(-30) \to R_0(-28)^4 \to R_0(-24)^6 \to R_0(-16)^4 \to J \to 0.$$

Equivalently, the quotient R_0/J has the resolution

$$0 \to R_0(-30) \to R_0(-28)^4 \to R_0(-24)^6 \to R_0(-16)^4 \to R_0 \to R_0/J \to 0.$$

Proof. The four generators have lcms whose degrees depend only on the size of the chosen coordinate subset and strictly increase with that size. Hence no Taylor differential can cancel equal multidegrees. The ranks of the Taylor modules are $\binom{4}{1}, \binom{4}{2}, \binom{4}{3}$ and $\binom{4}{4}$, and the shifts are those of Definition 9462.1604. □

Corollary 9462.1606 (Dual compression of the trigger hypergraph)**.** *The Stanley-Reisner ideal $I_{\mathcal{B}}$ has 294 minimal squarefree generators, but its Alexander dual has only four. The Betti rank pattern of the dual resolution is*

$$1,\ 4,\ 6,\ 4,\ 1.$$

Proof. The 294 generators of $I_{\mathcal{B}}$ are the minimal full triggers from Definition 9462.1563. The dual ideal has the four generators of Definition 9462.1603; its Taylor ranks are the binomial coefficients in four variables. □

Theorem 9462.1607 (Reliability from the lcm lattice)**.** *For $q = 1 - p$, the non-trigger reliability polynomial is*

$$P_{\text{non}}(p) = \sum_{\emptyset \neq S \subseteq \Omega} (-1)^{|S|+1} q^{\deg \operatorname{lcm}(U_i : i \in S)} = 4q^{16} - 6q^{24} + 4q^{28} - q^{30}.$$

Proof. The event U_i is absent is the event that coordinate i is missed. Inclusion-exclusion over the four missed-coordinate events uses exactly the lcm degrees of Definition 9462.1604. The coefficients are $4, -6, 4, -1$ according to subset size. □

Theorem 9462.1608 (Alexander-dual trigger algebra theorem)**.** *Beyond $M^\star = \mathrm{NNR} \cup \mathrm{CUY}$, the trigger side has 294 codon-level minimal full triggers, while the blocker-dual side is the four-generator squarefree monomial ideal*

$$I_{\mathcal{B}}^{\vee} = \langle U_{s_1}, U_{f_1}, U_{s_2}, U_{f_2} \rangle.$$

Its lcm degrees are $16, 24, 28, 30$*, its minimal Taylor ranks are* $1, 4, 6, 4, 1$*, and its lcm-lattice inclusion-exclusion is exactly*

$$4q^{16} - 6q^{24} + 4q^{28} - q^{30}.$$

Proof. The four-generator description is Definition 9462.1603. The shifts and Betti pattern are Definition 9462.1605. The probability polynomial is Definition 9462.1607. □

Concretized in §3555: finite Alexander-dual trigger/blocker NameCert packet

Definition 9462.1609 (Coverage-trigger system)**.** *For integers* $n \geq 1$ *and* $\ell \geq 1$*, let*

$$E_{n,\ell} = \{(S, a) : \varnothing \neq S \subseteq [n],\ a \in [\ell]\}.$$

The support of (S, a) *is* $\sigma(S, a) = S$*. Thus*

$$|E_{n,\ell}| = \ell(2^n - 1).$$

For $B \subseteq E_{n,\ell}$*, set*

$$J(B) = \bigcup_{e \in B} \sigma(e).$$

The subset B *is a full trigger when* $J(B) = [n]$*.*

Theorem 9462.1610 (Universal coverage closure)**.** *Define*

$$\mathrm{cl}(B) = \{e \in E_{n,\ell} : \sigma(e) \subseteq J(B)\}.$$

Then

$$\mathrm{cl}(B) = E_{J(B)}, \qquad E_J = \{e : \sigma(e) \subseteq J\}.$$

The closed-set lattice is isomorphic to $2^{[n]}$*, and if* $|J(B)| = r$*, then*

$$|\,\mathrm{cl}(B)| = \ell(2^r - 1).$$

Proof. The identity is the definition of cl with $J(B)$ substituted. Every $J \subseteq [n]$ gives a closed set E_J, and the operations satisfy

$$E_I \cap E_J = E_{I \cap J}, \qquad \mathrm{cl}(E_I \cup E_J) = E_{I \cup J}.$$

The size formula counts the nonempty supports contained in a fixed r-coordinate set and multiplies by ℓ lifts. □

Theorem 9462.1611 (Universal blocker topology)**.** *Let*

$$\mathcal{B}_{n,\ell} = \{B \subseteq E_{n,\ell} : J(B) \neq [n]\}.$$

Then

$$\mathcal{B}_{n,\ell} \simeq S^{n-2}.$$

The maximal blockers are

$$B_{\neg i} = \{e : i \notin \sigma(e)\}, \qquad i \in [n],$$

and have size $\ell(2^{n-1} - 1)$*. If* k *coordinates are omitted simultaneously, the corresponding intersection has size*

$$\ell(2^{n-k} - 1).$$

Proof. The complex is the union of the n simplices $B_{\neg i}$. Any proper intersection is a simplex on the elements whose supports avoid the omitted coordinates, hence contractible when at least one coordinate remains. The intersection of all n blockers is empty because supports are nonempty. The nerve is therefore $\partial\Delta^{n-1} \simeq S^{n-2}$. □

Theorem 9462.1612 (Universal blocker counts and threshold)**.** *The number of m-element non-trigger subsets is*

$$F_m(n,\ell) = \sum_{k=1}^{n} (-1)^{k+1} \binom{n}{k} \binom{\ell(2^{n-k}-1)}{m}.$$

The largest blocker has size $\ell(2^{n-1}-1)$, so every subset of size at least

$$\ell(2^{n-1}-1)+1$$

is a full trigger.

Proof. Apply inclusion-exclusion to the n events that a coordinate is missed. If a specified set of k coordinates is missed, the available elements are precisely those whose supports are nonempty subsets of the remaining $n-k$ coordinates, with ℓ lifts. The threshold is one more than the largest maximal blocker size. □

Theorem 9462.1613 (Universal Bernoulli reliability)**.** *If each element of $E_{n,\ell}$ is independently activated with probability p and $q = 1-p$, then*

$$R_{n,\ell}(p) = 1 - \sum_{k=1}^{n} (-1)^{k+1} \binom{n}{k} q^{\ell(2^n - 2^{n-k})}.$$

Proof. If a specified set of k coordinates is missed, every element whose support intersects that set must be inactive. The number of such elements is

$$\ell(2^n-1) - \ell(2^{n-k}-1) = \ell(2^n - 2^{n-k}).$$

Inclusion-exclusion over missed coordinates gives the non-trigger probability; the reliability is its complement. □

Theorem 9462.1614 (Universal Markov rank transition)**.** *Draw elements without replacement. If m elements have been drawn and the current covered rank is r, then*

$$\Pr(\Delta r = 0 \mid m, r) = \frac{\ell(2^r-1)-m}{\ell(2^n-1)-m},$$

and for $1 \le j \le n-r$,

$$\Pr(\Delta r = j \mid m, r) = \frac{\ell 2^r \binom{n-r}{j}}{\ell(2^n-1)-m}.$$

Moreover,

$$\mathbb{E}[\Delta r \mid m, r] = \frac{\ell 2^{n-1}(n-r)}{\ell(2^n-1)-m}.$$

Proof. Rank-preserving elements have nonempty support contained in the current r-coordinate set; after m draws, $\ell(2^r-1)-m$ remain. To add exactly j coordinates, choose those j coordinates among the $n-r$ uncovered coordinates and choose any subset of the old r coordinates, giving $\ell 2^r\binom{n-r}{j}$ elements. The drift formula uses

$$\sum_{j=1}^{n-r} j\binom{n-r}{j} = (n-r)2^{n-r-1}.$$

□

Theorem 9462.1615 (Universal Alexander dual)**.** *For each $i \in [n]$, set*

$$U_i = \prod_{\sigma(e)\ni i} x_e.$$

Then

$$I^{\vee}_{\mathcal{B}_{n,\ell}} = \langle U_1, \dots, U_n\rangle.$$

The degree of U_i is $\ell 2^{n-1}$, and the lcm degree of any k generators is

$$D_k = \ell(2^n - 2^{n-k}).$$

Proof. The facets of $\mathcal{B}_{n,\ell}$ are the blockers $B_{\neg i}$. Their complements are the elements whose supports contain i, which give the monomials U_i. The lcm of k such generators contains exactly the elements whose supports meet the chosen k coordinates, whose number is $\ell(2^n-2^{n-k})$. □

Theorem 9462.1616 (Universal energy-minimal triggers)**.** *Let the energy of an element be $|\sigma(e)|$ and the energy of a trigger be the sum of element energies. Every full trigger has energy at least n, with equality exactly when its supports form a set partition of $[n]$. Therefore the quotient-level energy-minimal triggers are counted by the Bell number B_n, and by trigger size m by the Stirling number $S(n,m)$. With ℓ lifts, the energy-minimal trigger polynomial is*

$$\sum_{m=1}^{n} \ell^m S(n,m) z^m y^n.$$

Proof. Every coordinate of $[n]$ must be covered at least once, so total energy is at least n. Equality means that every coordinate is counted exactly once, which is precisely a set partition. Each block has ℓ lift choices, giving the factor ℓ^m for an m-block partition. □

Theorem 9462.1617 (Codon case as $(4,2)$)**.** *The post-$M^\star$ codon trigger system is the $(n,\ell) = (4,2)$ coverage-trigger system. Substituting $n=4$ and $\ell=2$ gives*

$$|E| = 30, \qquad \mathcal{B}_{4,2} \simeq S^2, \qquad \ell(2^3-1)+1 = 15,$$

$$R_{4,2}(p) = 1 - 4q^{16} + 6q^{24} - 4q^{28} + q^{30},$$

$$D_1, D_2, D_3, D_4 = 16, 24, 28, 30,$$

and

$$2zy^4 + 28z^2y^4 + 48z^3y^4 + 16z^4y^4$$

for the energy-minimal codon-level trigger polynomial.

Proof. The four coordinates are s_1, f_1, s_2, f_2 and the two lifts are the two third-position Y codons in each support class. Each formula is the specialization of the preceding universal theorems at $(n, \ell) = (4, 2)$. □

Theorem 9462.1618 (Universal coverage-trigger algebra theorem)**.** *For every $n \geq 1$ and $\ell \geq 1$, the system $E_{n,\ell}$ has Boolean closed-set lattice $2^{[n]}$, blocker complex homotopy type S^{n-2}, forcing threshold $\ell(2^{n-1} - 1) + 1$, Bernoulli reliability Definition 9462.1613, Markov rank transition Definition 9462.1614, Alexander-dual ideal $\langle U_1, \ldots, U_n \rangle$, and energy-minimal partition polynomial*

$$\sum_{m=1}^{n} \ell^m S(n, m) z^m y^n.$$

The codon terminal system after $M^\star$ is exactly the $(4, 2)$ instance.

Proof. This is the collection of Definition 9462.1610, Definition 9462.1611, Definition 9462.1612, Definition 9462.1613, Definition 9462.1614, Definition 9462.1615, and Definition 9462.1616, with the codon specialization supplied by Definition 9462.1617. □

Concretized in §3478: finite support-closure trigger algebra realized as a NameCert packet

Theorem 9462.1619 (Thickened tetrahedral blocker boundary)**.** *For the post-$M^\star$ blocker complex*

$$\mathcal{B} = \{B \subseteq E : \bigcup_{p \in B} \sigma(p) \subsetneq \Omega\},$$

one has

$$\mathcal{B} = B_{\neg s_1} \cup B_{\neg f_1} \cup B_{\neg s_2} \cup B_{\neg f_2},$$

where $B_{\neg i} = \{p \in E : i \notin \sigma(p)\}$. The intersection profile is

intersection type	*multiplicity*	*vertices*	*simplex dimension*
facet	4	14	13
pair	6	6	5
triple	4	2	1
quadruple	1	0	−1.

Thus the nerve is $\partial\Delta^3$.

Proof. Missing one trigger coordinate leaves the nonempty supports inside a three-coordinate set, hence $2(2^3-1) = 14$ codons. Missing two coordinates leaves $2(2^2-1) = 6$ codons, and missing three coordinates leaves $2(2^1 - 1) = 2$ codons. Missing all four trigger coordinates leaves no nonempty support. These are exactly the intersection numbers of the four maximal blockers, so their nerve is the tetrahedral boundary. □

Concretized in §3932: The Hilbert-series blocker complex is realized as a finite NameCert packet over blocker-cover, face-polynomial, and Hilbert-row data.

Corollary 9462.1620 (Dimension and homotopy type)**.** *The blocker complex satisfies*

$$\mathcal{B} \simeq S^2, \qquad \dim \mathcal{B} = 13, \qquad \widetilde{H}_2(\mathcal{B}; k) \cong k.$$

Proof. All nonempty members of the cover in Definition 9462.1619 and all their nonempty intersections are simplices. The nerve theorem gives $\mathcal{B} \simeq \partial\Delta^3 \simeq S^2$. Since every maximal blocker has 14 vertices, the facets of $\mathcal{B}$ are 13-simplices. □

Theorem 9462.1621 (Blocker face polynomial)**.** *The face polynomial of $\mathcal{B}$ is*

$$I_{\mathcal{B}}(t) = \sum_{B \in \mathcal{B}} t^{|B|} = 4(1+t)^{14} - 6(1+t)^6 + 4(1+t)^2 - 1.$$

Its positive-dimensional face counts are

$$(28, 278, 1336, 3914, 7972, 12006, 13728, 12012, 8008, 4004, 1456, 364, 56, 4).$$

The Euler characteristic is 2*.*

Proof. The four facets contribute $4(1+t)^{14}$. Their six pairwise intersections contribute $6(1+t)^6$ and are subtracted. Their four triple intersections contribute $4(1+t)^2$ and are added. The quadruple intersection is empty, whose face polynomial is 1, and is subtracted. Expanding gives the stated face counts, and their alternating sum is 2. □

Theorem 9462.1622 (Hilbert series of the blocker ring)**.** *Let $R_0 = k[x_p : p \in E]$ and let $k[\mathcal{B}] = R_0/I_{\mathcal{B}}$. Then*

$$H_{k[\mathcal{B}]}(z) = \frac{4}{(1-z)^{14}} - \frac{6}{(1-z)^6} + \frac{4}{(1-z)^2} - 1.$$

Proof. For a simplex on m vertices,

$$\sum_F \left(\frac{z}{1-z}\right)^{|F|} = \left(1 + \frac{z}{1-z}\right)^m = \frac{1}{(1-z)^m}.$$

Applying the same inclusion-exclusion pattern as in Definition 9462.1621 to the four 14-vertex facets, the six 6-vertex intersections, the four 2-vertex intersections, and the empty total intersection gives the displayed Hilbert series. □

Theorem 9462.1623 (h-polynomial)**.** *Since* $\dim k[\mathcal{B}] = 14$*, write*

$$H_{k[\mathcal{B}]}(z) = \frac{h_{\mathcal{B}}(z)}{(1-z)^{14}}.$$

Then

$$h_{\mathcal{B}}(z) = 4 - 6(1-z)^8 + 4(1-z)^{12} - (1-z)^{14}.$$

Equivalently, the h-vector is

$$(1, 14, 5, -180, 559, -830, 525, 312, -1029, 1122, -737, 316, -87, 14, -1).$$

Proof. Multiplying the Hilbert series in Definition 9462.1622 by $(1-z)^{14}$ gives the stated numerator. The coefficient vector is the binomial expansion of that numerator. □

Theorem 9462.1624 (Non-Cohen–Macaulay blocker ring)**.** *The Stanley-Reisner ring $k[\mathcal{B}]$ is not Cohen–Macaulay.*

Proof. The complex has dimension 13, while Definition 9462.1620 gives nonzero reduced homology in degree 2. A Cohen–Macaulay 13-dimensional simplicial complex over k has no such lower-degree reduced homology in its global Reisner condition. Equivalently, the h-vector in Definition 9462.1623 contains negative entries, which is incompatible with Cohen–Macaulay nonnegativity for a standard Stanley-Reisner ring. □

Theorem 9462.1625 (Hochster witness)**.** *For the Stanley-Reisner ring $k[\mathcal{B}]$, Hochster's formula detects the full-vertex Betti number*

$$\beta_{27,30}(k[\mathcal{B}]) = 1.$$

Proof. Hochster's formula gives

$$\beta_{i,j}(k[\mathcal{B}]) = \sum_{|W|=j} \dim_k \widetilde{H}_{j-i-1}(\mathcal{B}_W; k).$$

Take $W = E$, so $j = 30$ and $\mathcal{B}_W = \mathcal{B}$. By Definition 9462.1620, $\widetilde{H}_2(\mathcal{B}; k) \cong k$. The equation $j - i - 1 = 2$ with $j = 30$ gives $i = 27$, hence the displayed Betti number. □

Theorem 9462.1626 (Depth and regularity)**.** *The blocker Stanley-Reisner ring satisfies*

$$\operatorname{pd}_{R_0} k[\mathcal{B}] = 27, \qquad \operatorname{depth} k[\mathcal{B}] = 3, \qquad \operatorname{reg} k[\mathcal{B}] = 3.$$

Proof. The Hochster witness in Definition 9462.1625 gives $\operatorname{pd}_{R_0} k[\mathcal{B}] \geq 27$. On the Alexander-dual side, Definition 9462.1605 has shifts $16, 24, 28, 30$, so

$$\operatorname{reg}(I_{\mathcal{B}}^{\vee}) = \max\{16 - 1, 24 - 2, 28 - 3, 30 - 4\} = 27.$$

Terai duality gives

$$\operatorname{pd}_{R_0} k[\mathcal{B}] = \operatorname{reg}(I_{\mathcal{B}}^{\vee}),$$

hence the projective dimension is 27. Since R_0 has 30 variables, Auslander–Buchsbaum gives

$$\operatorname{depth} k[\mathcal{B}] = 30 - 27 = 3.$$

Terai duality also gives

$$\operatorname{reg} k[\mathcal{B}] = \operatorname{pd}(I_{\mathcal{B}}^{\vee}).$$

The four-generator dual ideal has minimal Taylor resolution of length 3 as an ideal, so $\operatorname{reg} k[\mathcal{B}] = 3$. This is also realized by the Hochster Betti number, where $30 - 27 = 3$. □

Corollary 9462.1627 (Cohen–Macaulay defect)**.** *The Cohen–Macaulay defect of $k[\mathcal{B}]$ is*

$$\dim k[\mathcal{B}] - \operatorname{depth} k[\mathcal{B}] = 14 - 3 = 11.$$

Proof. The dimension is 14 by Definition 9462.1623, and the depth is 3 by Definition 9462.1626. □

Theorem 9462.1628 (Homological invariants for coverage blockers)**.** *For the coverage blocker complex $\mathcal{B}_{n,\ell}$, let*

$$N = \ell(2^n - 1).$$

Then

$$\dim k[\mathcal{B}_{n,\ell}] = \ell(2^{n-1} - 1),$$

and

$$\operatorname{depth} k[\mathcal{B}_{n,\ell}] = n-1, \qquad \operatorname{reg} k[\mathcal{B}_{n,\ell}] = n-1,$$
$$\operatorname{pd} k[\mathcal{B}_{n,\ell}] = N-(n-1).$$

The full-vertex Hochster witness is

$$\beta_{N-(n-1),\,N}(k[\mathcal{B}_{n,\ell}]) = 1.$$

Proof. The maximal blocker has $\ell(2^{n-1}-1)$ vertices, giving the Stanley-Reisner dimension. By Definition 9462.1611, $\mathcal{B}_{n,\ell} \simeq S^{n-2}$; applying Hochster's formula to the full vertex set gives $j = N$ and $j-i-1 = n-2$, hence $i = N-(n-1)$. The Alexander-dual ideal has n generators by Definition 9462.1615, and its Taylor resolution has ideal projective dimension $n-1$. Terai duality and Auslander–Buchsbaum give the displayed projective dimension, depth, and regularity. □

Definition 9462.1629 (Saturated blocker faces)**.** *For $J \subsetneq \Omega$, define the saturated face*

$$F_J = \{p \in E : \sigma(p) \subseteq J\}.$$

It has size

$$|F_J| = 2(2^{|J|}-1).$$

Theorem 9462.1630 (Link of a saturated face)**.** *Let $J \subsetneq \Omega$, set $r = |J|$, and put $U = \Omega \setminus J$ with $u = |U| = 4-r$. Then*

$$\operatorname{Lk}_{\mathcal{B}}(F_J) \cong \mathcal{B}_{u,\,2\cdot 2^r}.$$

Consequently

$$\operatorname{Lk}_{\mathcal{B}}(F_J) \simeq S^{u-2} = S^{2-r}.$$

Proof. The face F_J already covers exactly the coordinates in J. A codon outside F_J contributes to the link through the nonempty projection of its support to U. For each nonempty $A \subseteq U$, the original support can be $A \cup B$ with arbitrary $B \subseteq J$, giving 2^r choices, and each support has two third-position lifts. Hence each nonempty support over U has $2 \cdot 2^r$ lifts in the link. The condition for remaining in $\mathcal{B}$ is precisely that these projected supports do not cover all of U, so the link is the coverage blocker complex $\mathcal{B}_{u,\,2\cdot 2^r}$. Its homotopy type is S^{u-2} by Definition 9462.1611. □

Corollary 9462.1631 (Codon local sphere strata)**.** *The saturated faces of rank $r = |J|$ have the following local links:*

r	*number of J*	$\lvert F_J\rvert$	*link model*	*link homotopy*
0	1	0	$\mathcal{B}_{4,2}$	S^2
1	4	2	$\mathcal{B}_{3,4}$	S^1
2	6	6	$\mathcal{B}_{2,8}$	S^0
3	4	14	$\mathcal{B}_{1,16}$	S^{-1}.

Proof. Substitute $r = 0,1,2,3$ in Definition 9462.1630. The number of saturated faces of rank r is $\binom{4}{r}$, and Definition 9462.1629 gives $|F_J| = 2(2^r-1)$. □

Corollary 9462.1632 (Coordinate examples)**.** *For $J = \{s_1\}$, the saturated face is*

$$F_J = \mathrm{GUY} = \{\mathrm{GUU}, \mathrm{GUC}\},$$

and

$$\operatorname{Lk}_{\mathcal{B}}(F_J) \simeq S^1.$$

For $J = \{s_1, f_1\}$, the saturated face is

$$F_J = \{\mathrm{UUY}, \mathrm{AUY}, \mathrm{GUY}\},$$

with two Y lifts in each displayed family, and

$$\mathrm{Lk}_{\mathcal{B}}(F_J) \simeq S^0.$$

Proof. The anchor is CUY. Flipping only s_1 changes the first base from C to G, giving GUY. Allowing both first-base bits to vary while the second base stays U gives UUY, CUY, AUY, GUY, but CUY lies in $M^\star$ rather than E. The link homotopy types are the $r = 1$ and $r = 2$ rows of Definition 9462.1631. □

Theorem 9462.1633 (Non-saturated links are cones)**.** *Let $F \in \mathcal{B}$ and set*

$$J(F) = \bigcup_{p \in F} \sigma(p).$$

If $F \neq F_{J(F)}$, then $\mathrm{Lk}_{\mathcal{B}}(F)$ is a cone and is therefore contractible.

Proof. Choose $q \in F_{J(F)} \setminus F$. For every $G \in \mathrm{Lk}_{\mathcal{B}}(F)$, the face $F \cup G$ is still a blocker. Adding q cannot enlarge the covered coordinate set, because $\sigma(q) \subseteq J(F)$. Hence $F \cup G \cup \{q\} \in \mathcal{B}$ for every link face G, so q is a cone vertex of the link. □

Corollary 9462.1634 (Local obstruction support)**.** *Every nontrivial local reduced homology group of $\mathcal{B}$ occurs in the link of a saturated face. The saturated stratum F_J carries the local sphere*

$$F_J \longmapsto S^{2-|J|}.$$

Proof. Saturated links are the spheres of Definition 9462.1630. Non-saturated links are contractible by Definition 9462.1633. □

Theorem 9462.1635 (Failure of Buchsbaum property)**.** *The blocker complex $\mathcal{B}$ is not Buchsbaum.*

Proof. A pure Buchsbaum complex has Cohen–Macaulay links at every nonempty face. Take $F_{\{s_1\}} = \mathrm{GUY}$. Its link is $\mathcal{B}_{3,4}$ by Definition 9462.1630; this link has dimension

$$4(2^2 - 1) - 1 = 11$$

but has the homotopy type S^1. Thus it has lower-degree homology relative to its dimension and is not Cohen–Macaulay. □

Theorem 9462.1636 (Universal link stratification)**.** *For the coverage blocker complex $\mathcal{B}_{n,\ell}$ and $J \subsetneq [n]$, set*

$$F_J = \{e : \sigma(e) \subseteq J\}.$$

If $r = |J|$ and $u = n - r$, then

$$|F_J| = \ell(2^r - 1), \qquad \mathrm{Lk}(F_J) \cong \mathcal{B}_{u,\,\ell 2^r} \simeq S^{n-r-2}.$$

Every non-saturated face has contractible link.

Proof. The proof of Definition 9462.1630 does not use the codon-specific values $n = 4$ and $\ell = 2$. For a projected nonempty support $A \subseteq [n] \setminus J$, the old-coordinate part can be any subset of J, giving 2^r choices, and each is multiplied by the original ℓ lifts. The cone argument for non-saturated faces is identical to Definition 9462.1633. □

Theorem 9462.1637 (Hilbert–Alexander structure theorem)**.** *The post-$M^\star$ blocker system is a thickened tetrahedral boundary with*

$$\mathcal{B} \simeq S^2, \qquad \dim \mathcal{B} = 13, \qquad \operatorname{depth} k[\mathcal{B}] = \operatorname{reg} k[\mathcal{B}] = 3.$$

Its projective dimension over the 30*-variable ring is* 27*, and its Cohen–Macaulay defect is* 11*. Its face polynomial is*

$$4(1+t)^{14} - 6(1+t)^6 + 4(1+t)^2 - 1,$$

its Hilbert series is

$$\frac{4}{(1-z)^{14}} - \frac{6}{(1-z)^6} + \frac{4}{(1-z)^2} - 1,$$

and its h-polynomial is

$$4 - 6(1-z)^8 + 4(1-z)^{12} - (1-z)^{14}.$$

At the same time, the Alexander dual ideal has only four generators, with lcm degrees $16, 24, 28, 30$*, and the non-trigger reliability polynomial is*

$$4q^{16} - 6q^{24} + 4q^{28} - q^{30}.$$

The local links are stratified by saturated faces:

$$\operatorname{Lk}_{\mathcal{B}}(F_J) \simeq S^{2-|J|}, \qquad J \subsetneq \Omega,$$

while non-saturated faces have contractible links. In particular, $\mathcal{B}$ is not Buchsbaum.

Proof. The thickened boundary, Hilbert series, and h-polynomial are the preceding theorems. The depth, regularity, projective dimension, and Cohen–Macaulay defect are Definition 9462.1626 and Definition 9462.1627. The four-generator Alexander-dual description and the lcm degrees are Definition 9462.1603 and Definition 9462.1604. The reliability identity is Definition 9462.1607. The local link stratification is Definition 9462.1630 and Definition 9462.1633; the Buchsbaum obstruction is Definition 9462.1635. □

Definition 9462.1638 (Induced blocker nerve)**.** *For $W \subseteq E$, let $\mathcal{B}_W$ be the induced subcomplex of $\mathcal{B}$ on W. Define a simplicial complex N_W on the vertex set Ω by declaring $T \subseteq \Omega$ to be a face when there exists $p \in W$ such that*

$$\sigma(p) \cap T = \varnothing.$$

Equivalently, T is a face exactly when some support in W is contained in $\Omega \setminus T$.

Theorem 9462.1639 (Hochster–nerve reduction)**.** *For every $W \subseteq E$,*

$$\mathcal{B}_W \simeq N_W.$$

Proof. The induced complex is covered by the four simplices

$$W \cap B_{\neg s_1}, \quad W \cap B_{\neg f_1}, \quad W \cap B_{\neg s_2}, \quad W \cap B_{\neg f_2}.$$

For $T \subseteq \Omega$, the corresponding intersection is nonempty exactly when some $p \in W$ omits every coordinate in T, that is, $\sigma(p) \cap T = \varnothing$. All nonempty intersections are simplices. The nerve theorem identifies $\mathcal{B}_W$ with this four-vertex nerve. □

Corollary 9462.1640 (Hochster homology range)**.** *All reduced homology groups appearing in Hochster's formula for $k[\mathcal{B}]$ are computed on four-vertex nerves. Hence they occur only in degrees*

$$-1,\ 0,\ 1,\ 2.$$

Consequently the Betti table of $k[\mathcal{B}]$ lies on the four diagonals

$$j - i = 0,\ 1,\ 2,\ 3,$$

and

$$\operatorname{reg} k[\mathcal{B}] = 3.$$

Proof. Hochster's formula is

$$\beta_{i,j}(k[\mathcal{B}]) = \sum_{|W|=j} \dim_k \widetilde{H}_{j-i-1}(\mathcal{B}_W; k).$$

By Definition 9462.1639, $\mathcal{B}_W$ has the homology of a complex on at most four vertices. Such a complex has no reduced homology above degree 2. The full complex has nonzero $\widetilde{H}_2$ by Definition 9462.1620, so the regularity bound is sharp. □

Theorem 9462.1641 (Top Betti strand)**.** *For $4 \le j \le 30$, the highest Betti strand is*

$$\beta_{j-3,j}(k[\mathcal{B}]) = [x^j](2x + x^2)^4(1 + x)^{22}.$$

Proof. The term $\widetilde{H}_2(N_W)$ is nonzero precisely when $N_W = \partial\Delta^3$. Since the full four-coordinate face is never present in N_W, this is equivalent to the presence of every proper face. It is enough and necessary to have every three-coordinate face; the face $\Omega \setminus \{i\}$ requires a codon in W with support contained in $\{i\}$, hence one of the two singleton-support lifts for coordinate i.

Thus W must choose at least one of the two singleton lifts for each of the four coordinates. Each coordinate contributes $(1 + x)^2 - 1 = 2x + x^2$. The remaining $30 - 8 = 22$ external codons are unrestricted and contribute $(1 + x)^{22}$. In Hochster's formula, $\widetilde{H}_2$ appears when $j - i - 1 = 2$, namely $i = j - 3$. □

Definition 9462.1642 (Hochster diagonal series)**.** *For $q = -1, 0, 1, 2$, define*

$$B_q(x) = \sum_j \beta_{j-q-1,j}(k[\mathcal{B}])x^j.$$

Theorem 9462.1643 (Complete Hochster diagonal series)**.** *The four Hochster diagonal generating functions are*

$$B_{-1}(x) = (1 + x)^2,$$

$$B_0(x) = x^2(x + 1)^2(x + 2)^2 P_0(x),$$

where

$$\begin{aligned} P_0(x) =& 4x^{12} + 48x^{11} + 268x^{10} + 920x^9 + 2167x^8 \\ &+ 3704x^7 + 4736x^6 + 4592x^5 + 3373x^4 \\ &+ 1844x^3 + 720x^2 + 184x + 25, \end{aligned}$$

$$B_1(x) = x^3(x + 1)^{10}(x + 2)^3 P_1(x),$$

where

$$\begin{aligned} P_1(x) =& 6x^{10} + 60x^9 + 278x^8 + 784x^7 + 1491x^6 \\ &+ 2002x^5 + 1928x^4 + 1320x^3 + 617x^2 \\ &+ 178x + 22, \end{aligned}$$

and

$$B_2(x) = x^4(x+1)^{22}(x+2)^4.$$

Proof. Enumerate support-type subsets

$$A \subseteq 2^{\Omega} \setminus \{\varnothing\}.$$

Each chosen support type has two codon lifts, so its nonempty lift selection contributes $(1+x)^2-1 = 2x+x^2$. For each A, form the four-vertex nerve N_A as in Definition 9462.1638. Hochster's formula therefore gives

$$B_q(x) = \sum_A \dim_k \widetilde{H}_q(N_A; k)(2x+x^2)^{|A|}.$$

There are only 2^{15} support-type subsets. Computing the reduced homology of their four-vertex nerves gives the displayed factorizations. □

Corollary 9462.1644 (Diagonal masses)**.** *Evaluating the four diagonal series at $x = 1$ gives*

q	$j - i = q + 1$	$B_q(1)$
-1	0	4
0	1	813060
1	2	240150528
2	3	339738624.

Proof. Substitute $x = 1$ in Definition 9462.1643. □

Corollary 9462.1645 (Low-degree diagonal entries)**.** *The first terms of the two middle diagonals are*

j	$\beta_{j-1,j}$
2	100
3	1036
4	5413
5	18558
6	46109
7	87320
8	129681
9	153426
10	145609

and

j	$\beta_{j-2,j}$
3	176
4	3448
5	32004
6	188174
7	789384
8	2519871
9	6368866
10	13082137.

Proof. These are the coefficients of $B_0(x)$ and $B_1(x)$ in Definition 9462.1643. □

Definition 9462.1646 (Support-level Betti polynomials)**.** *Let*

$$\mathcal{S} = 2^{\Omega} \setminus \{\varnothing\}.$$

For $A \subseteq \mathcal{S}$, define the support nerve

$$N_A = \bigcup_{S \in A} 2^{\Omega \setminus S}.$$

For $q = -1, 0, 1, 2$, set

$$Q_q(z) = \sum_{A \subseteq \mathcal{S}} \dim_k \widetilde{H}_q(N_A; k) z^{|A|}.$$

Theorem 9462.1647 (Support-level Betti polynomials)**.** *The support-level Hochster polynomials are*

$$Q_{-1}(z) = 1 + z,$$

$$Q_0(z) = z^2(1+z)\left(4z^6 + 28z^5 + 87z^4 + 152z^3 + 157z^2 + 92z + 25\right),$$

$$Q_1(z) = z^3(1+z)^5\left(6z^5 + 38z^4 + 99z^3 + 132z^2 + 89z + 22\right),$$

and

$$Q_2(z) = z^4(1+z)^{11}.$$

Proof. Enumerate the 2^{15} subsets of the support-type set $\mathcal{S}$. For each A, the nerve is the four-vertex complex N_A. Computing its reduced homology and summing by $|A|$ gives the four displayed polynomials. The highest polynomial has the direct form $Q_2(z) = z^4(1+z)^{11}$ because $\widetilde{H}_2$ occurs exactly when the four singleton supports are present, while the other 11 support types are unrestricted. □

Theorem 9462.1648 (Support-lift Betti transform)**.** *If each support type has ℓ lifts, then the lifted Hochster diagonal series is*

$$B_q^{(\ell)}(x) = Q_q\left((1+x)^{\ell} - 1\right).$$

In the codon case $\ell = 2$, so

$$B_q(x) = Q_q(2x + x^2).$$

Proof. For a fixed support type, either no lift is chosen, or a nonempty subset of its ℓ lifts is chosen. The nonempty choice generating function is $(1+x)^{\ell} - 1$. If the support-type set is A, its lift contribution is therefore $\left((1+x)^{\ell} - 1\right)^{|A|}$, while the homology factor is $\dim \widetilde{H}_q(N_A)$. Summing over A gives the formula. □

Corollary 9462.1649 (Codon support-lift compression)**.** *The complete* 30*-variable Betti table of $k[\mathcal{B}]$ is determined by the four support-level polynomials*

$$Q_{-1},\ Q_0,\ Q_1,\ Q_2$$

and the substitution

$$z \mapsto (1+x)^2 - 1 = 2x + x^2.$$

Equivalently,

$$30\text{-}\textit{variable Betti data} \longrightarrow 15\text{-}\textit{support-type nerves} \longrightarrow 4\ \textit{support polynomials.}$$

Proof. The four codon-level diagonal series are Definition 9462.1643. By Definition 9462.1648, each is obtained from the corresponding support-level polynomial by the codon substitution $z = 2x + x^2$. □

Corollary 9462.1650 (Top Betti strand values)**.** *The nonzero values of the top strand are*

j	$\beta_{j-3,j}$
4	16
5	384
6	4424
7	32568
8	172041
9	694254
10	2224607
11	5808396
12	12582427
13	22907654
14	35377221
15	46646368
16	52738794
17	51252348
18	42843366
19	30778024
20	18951702
21	9957596
22	4434562
23	1658184
24	513821
25	129558
26	25899
27	3948
28	431
29	30
30	1.

In particular,

$$\beta_{27,30}(k[\mathcal{B}]) = 1.$$

Proof. These are the coefficients of Definition 9462.1641. The final entry corresponds to choosing all 30 external codons, so the induced complex is $\mathcal{B}$ itself. □

Corollary 9462.1651 (Generator row)**.** *The first Betti row records the minimal full triggers:*

$$\beta_{1,1} = 2, \qquad \beta_{1,2} = 100, \qquad \beta_{1,3} = 176, \qquad \beta_{1,4} = 16.$$

Proof. The Stanley-Reisner ideal $I_{\mathcal{B}}$ is generated by minimal full triggers. By Definition 9462.1563, their codon-level degree distribution is $2, 100, 176, 16$ in degrees $1, 2, 3, 4$. □

Theorem 9462.1652 (Betti diagonal compression)**.** *The nonzero Betti entries of $k[\mathcal{B}]$ lie on four diagonals. Their homological interpretation is*

$j-i$	*nerve homology*	*nonzero entries*
0	$\widetilde{H}_{-1}$	3
1	$\widetilde{H}_0$	17
2	$\widetilde{H}_1$	24
3	$\widetilde{H}_2$	27.

Proof. The diagonal $j-i=d$ corresponds in Hochster's formula to reduced homology degree $d-1$. By Definition 9462.1640, only $d=0,1,2,3$ can occur. The displayed counts are the exhaustive four-vertex nerve enumeration induced by the 30 external codons; the top diagonal is the strand of Definition 9462.1641. □

Theorem 9462.1653 (Universal top Betti strand)**.** *For the coverage blocker complex $\mathcal{B}_{n,\ell}$, the highest Betti strand is*

$$\beta_{j-(n-1),j}(k[\mathcal{B}_{n,\ell}]) = [x^j]\left((1+x)^\ell - 1\right)^n (1+x)^{\ell(2^n-1-n)}.$$

Proof. The induced nerve is the boundary $\partial\Delta^{n-1}$ exactly when each singleton coordinate support has at least one selected lift. Each of the n singleton supports has ℓ lifts, contributing $(1+x)^\ell - 1$. All other elements number $\ell(2^n-1-n)$ and may be chosen freely. The boundary sphere has homology degree $n-2$, so Hochster gives $j-i-1=n-2$, or $i=j-(n-1)$. □

Theorem 9462.1654 (Hochster–nerve Betti theorem)**.** *Every induced subcomplex $\mathcal{B}_W$ of the post-$M^\star$ blocker complex has the homology of a four-coordinate nerve N_W. Therefore the Betti table of $k[\mathcal{B}]$ is governed by the nerve homology degrees $\widetilde{H}_{-1}, \widetilde{H}_0, \widetilde{H}_1, \widetilde{H}_2$, has regularity 3, has projective dimension 27, and has depth 3. The four Hochster diagonal generating functions are those of Definition 9462.1643, and they are obtained from the support-level polynomials of Definition 9462.1647 by the substitution $z = 2x + x^2$. In particular, its top strand is*

$$\beta_{j-3,j} = [x^j](2x+x^2)^4(1+x)^{22}.$$

Proof. The nerve reduction is Definition 9462.1639. The homology range and regularity are Definition 9462.1640. The top strand is Definition 9462.1641, and the four diagonal series are Definition 9462.1643. The support-lift compression is Definition 9462.1648. The projective dimension and depth are Definition 9462.1626. □

Concretized in §3744: Hochster nerve Betti reduction is realized as finite support, nerve-face, homology-range, Betti-strand, and ledger NameCert rows.

Theorem 9462.1655 (Support-nerve census)**.** *The 2^{15} support families $A \subseteq \mathcal{S}$ have the following reduced Betti signatures*

$$(\widetilde{\beta}_{-1}, \widetilde{\beta}_0, \widetilde{\beta}_1, \widetilde{\beta}_2)$$

for their support nerves N_A:

signature	*support-family count*
$(1,0,0,0)$	2
$(0,0,0,0)$	18680
$(0,1,0,0)$	908
$(0,2,0,0)$	56
$(0,3,0,0)$	2
$(0,0,1,0)$	9760
$(0,0,2,0)$	1216
$(0,0,3,0)$	32
$(0,1,1,0)$	64
$(0,0,0,1)$	2048.

Proof. For each of the 2^{15} subsets $A \subseteq 2^{\Omega} \setminus \{\varnothing\}$, form the four-vertex nerve

$$N_A = \bigcup_{S \in A} 2^{\Omega \setminus S}.$$

Computing reduced homology of these four-vertex complexes gives the displayed census. The total count is

$$2 + 18680 + 908 + 56 + 2 + 9760 + 1216 + 32 + 64 + 2048 = 32768.$$

□

Corollary 9462.1656 (Support-level homology distribution)**.** *Among the support nerves,* 18680 *are acyclic,* $2048 = 2^{11}$ *have top reduced homology* $\widetilde{H}_2$*, and all nonzero support-level homology appears in degrees* $-1, 0, 1, 2$*.*

Proof. This is the census of Definition 9462.1655. The degree range also follows from the fact that every N_A has at most four vertices. □

Theorem 9462.1657 (Top support nerve criterion)**.** *The support nerve N_A has nonzero $\widetilde{H}_2$ if and only if A contains the four singleton supports*

$$\{s_1\}, \quad \{f_1\}, \quad \{s_2\}, \quad \{f_2\}.$$

Consequently exactly 2^{11} *support families have* $\widetilde{H}_2(N_A) \neq 0$*, and*

$$Q_2(z) = z^4(1+z)^{11}.$$

Proof. For a four-vertex nerve to have $\widetilde{H}_2$, it must be the tetrahedron boundary. The three-face $\Omega \setminus \{i\}$ appears precisely when A contains a support contained in $\{i\}$, namely the singleton support $\{i\}$. Thus all four singleton supports are necessary and sufficient. The other $15 - 4 = 11$ support types may be chosen freely. □

Theorem 9462.1658 (Support-nerve census theorem)**.** *The post-$M^\star$ Betti table is determined by the following three finite layers:*

$$N_A \quad (A \subseteq \mathcal{S},\ |\mathcal{S}| = 15),$$
$$Q_q(z) = \sum_{A \subseteq \mathcal{S}} \dim_k \widetilde{H}_q(N_A; k) z^{|A|},$$

and the codon lift substitution

$$z \mapsto (1+x)^2 - 1 = 2x + x^2.$$

Thus

$$B_q(x) = Q_q(2x + x^2).$$

Proof. The nerve reduction is Definition 9462.1639. The support-level polynomials are Definition 9462.1647, and the lift transform is Definition 9462.1648. The census in Definition 9462.1655 records the finite homology types from which the four polynomials are formed. □

Concretized in §4035: The support-nerve census and codon-lifted Betti table are realized as finite incidence, nerve-realization, simplicial-complex, finite-chain, homology, lifted-ledger, transport, replay, provenance, and NameCert rows.

Theorem 9462.1659 (Support-to-nerve realization)**.** *The assignment*

$$A \subseteq \mathcal{S} \longmapsto N_A = \bigcup_{S \in A} 2^{\Omega \setminus S}$$

has image exactly the set of subcomplexes of the tetrahedron boundary $\partial\Delta^3$, with both the void complex and the complex consisting only of the empty face included.

Proof. For every nonempty support $S \subseteq \Omega$, the complement $\Omega \setminus S$ is a proper face of Δ^3. Hence N_A is the downward closure of a family of proper faces, and therefore is a subcomplex of $\partial\Delta^3$.

Conversely, let $K \subseteq \partial\Delta^3$ be a subcomplex. For each maximal face F of K, set $S_F = \Omega \setminus F$. These supports are nonempty. If $A = \{S_F : F \in \mathrm{Facets}(K)\}$, then

$$N_A = \bigcup_{F \in \mathrm{Facets}(K)} 2^F = K.$$

Thus every subcomplex of $\partial\Delta^3$ is realized. □

Concretized in §4079: The support-family-to-boundary-subcomplex realization route is recorded as a finite NameCert packet between support rows, nerve rows, census rows, and lifted-Betti consumers.

Theorem 9462.1660 (Support-family fiber)**.** *Let $K \subseteq \partial\Delta^3$ be a subcomplex, and let $|K|$ denote its number of faces, including the empty face. The generating function for support families A with $N_A = K$ is*

$$G_K(z) = z^{|\mathrm{Facets}(K)|}(1+z)^{|K| - |\mathrm{Facets}(K)|}.$$

Proof. Write

$$C_A = \{\Omega \setminus S : S \in A\}.$$

Then N_A is the downward closure of C_A. The equality $N_A = K$ holds exactly when $C_A \subseteq K$ and C_A contains every maximal face of K. The maximal faces are forced, and the remaining $|K| - |\mathrm{Facets}(K)|$ faces may be chosen independently. □

Corollary 9462.1661 (Subcomplex-weighted support polynomials)**.** *For $q = -1, 0, 1, 2$,*

$$Q_q(z) = \sum_{K \subseteq \partial\Delta^3} \dim_k \widetilde{H}_q(K; k) z^{|\mathrm{Facets}(K)|}(1+z)^{|K| - |\mathrm{Facets}(K)|}.$$

Proof. Group the defining sum for $Q_q(z)$ by the realized subcomplex $K = N_A$ and apply Definition 9462.1660. □

Theorem 9462.1662 (Tetrahedron-boundary subcomplex census)**.** *The boundary $\partial\Delta^3$ has* 167 *subcomplexes under the convention of Definition 9462.1659. Their reduced Betti signatures are:*

signature	*subcomplex count*
$(1,0,0,0)$	2
$(0,0,0,0)$	64
$(0,1,0,0)$	37
$(0,2,0,0)$	10
$(0,3,0,0)$	1
$(0,0,1,0)$	37
$(0,0,2,0)$	10
$(0,0,3,0)$	1
$(0,1,1,0)$	4
$(0,0,0,1)$	1.

Moreover,

$$\sum_{K\subseteq\partial\Delta^3} 2^{|K|-|\operatorname{Facets}(K)|} = 32768.$$

Proof. Enumerate the downward-closed families of proper faces of a four-vertex simplex and compute reduced homology for each subcomplex. The displayed rows sum to 167. The final identity is the specialization $G_K(1)$ summed over all realized subcomplexes; by Definition 9462.1660, it counts all 2^{15} support families. □

Theorem 9462.1663 (Support-to-nerve Betti formula)**.** *The complete Hochster diagonal series of $k[\mathcal{B}]$ satisfy*

$$B_q(x) = \sum_{K\subseteq\partial\Delta^3} \dim_k \widetilde{H}_q(K;k)(2x+x^2)^{|\operatorname{Facets}(K)|}(1+2x+x^2)^{|K|-|\operatorname{Facets}(K)|}.$$

Equivalently,

$$B_q(x) = \sum_{K\subseteq\partial\Delta^3} \dim_k \widetilde{H}_q(K;k)x^{|\operatorname{Facets}(K)|}(x+2)^{|\operatorname{Facets}(K)|}(1+x)^{2(|K|-|\operatorname{Facets}(K)|)}.$$

Proof. Combine Definition 9462.1661 with the codon lift substitution of Definition 9462.1648. The two displayed forms are identical because $2x+x^2 = x(x+2)$ and $1+2x+x^2 = (1+x)^2$. □

Corollary 9462.1664 (Top diagonal from the boundary complex)**.** *The top Hochster diagonal is contributed by the single subcomplex $K = \partial\Delta^3$. Since this complex has four facets and fifteen proper faces,*

$$B_2(x) = (2x+x^2)^4(1+2x+x^2)^{11} = x^4(x+2)^4(1+x)^{22}.$$

In particular,

$$\beta_{27,30} = 1.$$

Proof. Among subcomplexes of $\partial\Delta^3$, nonzero $\widetilde{H}_2$ occurs only for $\partial\Delta^3$ itself. The formula is the $q = 2$ specialization of Definition 9462.1663. □

Theorem 9462.1665 (Minimal trigger sphere)**.** *Let*

$$A = \{S_1, \dots, S_m\} \subseteq 2^\Omega \setminus \{\varnothing\}$$

be a quotient-level minimal full trigger. Put

$$F_i = \Omega \setminus S_i.$$

Then the support nerve

$$N_A = \bigcup_{i=1}^{m} 2^{F_i}$$

is homotopy equivalent to S^{m-2}. Equivalently,

$$\widetilde{H}_{m-2}(N_A; k) \cong k.$$

Concretized in §4137: finite support-nerve NameCert packet for minimal trigger sphere cores

Proof. The full-trigger condition gives

$$\bigcup_{i=1}^{m} S_i = \Omega.$$

Taking complements,

$$\bigcap_{i=1}^{m} F_i = \varnothing.$$

Minimality says that every proper subfamily fails to cover Ω. Thus, for every proper $I \subsetneq \{1, \dots, m\}$,

$$\bigcap_{i \in I} F_i \neq \varnothing.$$

The cover of N_A by the simplices 2^{F_i} therefore has nerve $\partial\Delta^{m-1}$. Every nonempty intersection of these simplices is again a simplex, hence contractible. The nerve theorem gives

$$N_A \simeq \partial\Delta^{m-1} \simeq S^{m-2}.$$

□

Theorem 9462.1666 (Sphere core converse)**.** *Let $A = \{S_1, \dots, S_m\}$ and $F_i = \Omega \setminus S_i$. If the cover of N_A by the m simplices 2^{F_i} has nerve $\partial\Delta^{m-1}$, then A is a quotient-level minimal full trigger.*

Proof. The nerve condition says that every proper intersection $\bigcap_{i \in I} F_i$ is nonempty, while the full intersection $\bigcap_{i=1}^{m} F_i$ is empty. Taking complements gives

$$\bigcup_{i=1}^{m} S_i = \Omega,$$

and, for every proper I,

$$\bigcup_{i \in I} S_i \neq \Omega.$$

This is precisely the minimal full-trigger condition. □

Corollary 9462.1667 (Minimal triggers are minimal homology cores)**.** *At quotient level, a size-m minimal full trigger is the same support data as a minimal support-nerve core of type S^{m-2}:*

trigger size	*reduced homology*	*sphere*
1	$\widetilde{H}_{-1}$	S^{-1}
2	$\widetilde{H}_0$	S^0
3	$\widetilde{H}_1$	S^1
4	$\widetilde{H}_2$	S^2.

Proof. Apply Definition 9462.1665 and Definition 9462.1666. □

Theorem 9462.1668 (Minimal trigger homology core counts)**.** *For $\Omega = \{s_1, f_1, s_2, f_2\}$, the quotient-level minimal homology cores have counts*

trigger size	*quotient count*	*sphere*	*codon count*
1	1	S^{-1}	2
2	25	S^0	100
3	22	S^1	176
4	1	S^2	16.

Thus the quotient-level polynomial is

$$z + 25z^2 + 22z^3 + z^4,$$

and the codon-level polynomial is

$$2z + 100z^2 + 176z^3 + 16z^4.$$

Proof. The quotient-level counts are the minimal full-trigger counts of Definition 9462.1559. The sphere type is supplied by Definition 9462.1667. At codon level, each support in a size-m quotient trigger has two f_3-lifts, so the quotient count is multiplied by 2^m. □

Corollary 9462.1669 (Lowest Hochster witnesses)**.** *The minimal full triggers are the lowest-degree Hochster witnesses on the four diagonal series:*

series	*homology*	*minimal trigger degree*	*lowest coefficient*
B_{-1}	$\widetilde{H}_{-1}$	1	2
B_0	$\widetilde{H}_0$	2	100
B_1	$\widetilde{H}_1$	3	176
B_2	$\widetilde{H}_2$	4	16.

Proof. By Hochster's formula, the diagonal B_q records induced support nerves with nonzero $\widetilde{H}_q$. By Definition 9462.1667, a size-m minimal trigger contributes in degree $q = m - 2$. Its codon-level lift multiplicity is the lowest codon degree on that diagonal. The coefficients are exactly the codon counts in Definition 9462.1668. □

Corollary 9462.1670 (Energy-minimal subclass)**.** *The energy-minimal triggers are the partition subclass of the minimal homology cores. At quotient level there are* 15 *such cores, while all minimal homology cores number* 49*; at codon level the corresponding counts are* 94 *and* 294*.*

Proof. By Definition 9462.1579, energy minimality imposes that the supports form a set partition of Ω. This is stronger than the minimal full-trigger condition used in Definition 9462.1665; it selects the partition cores among all minimal support-nerve sphere cores. The counts are those of Definition 9462.1580 and Definition 9462.1668. □

Definition 9462.1671 (Private coordinate)**.** *Let $A = \{S_1, \dots, S_m\}$ be a quotient-level support family on an n-element trigger coordinate set Ω. A coordinate $a \in \Omega$ is private to S_i if*

$$a \in S_i \quad \text{and} \quad a \notin S_j \text{ for } j \neq i.$$

Theorem 9462.1672 (Private-coordinate criterion)**.** *A quotient-level support family*

$$A = \{S_1, \dots, S_m\}$$

is a minimal full trigger if and only if

$$\bigcup_{i=1}^{m} S_i = \Omega$$

and every S_i has at least one private coordinate.

Proof. If A is a minimal full trigger, deleting S_i destroys the cover of Ω. Hence some coordinate is covered by S_i and by no other member of the family; this is a private coordinate for S_i.

Conversely, if every S_i has a private coordinate, deleting S_i misses that coordinate. Since the full family covers Ω, the family is a minimal full trigger. □

Theorem 9462.1673 (Private-coordinate enumeration)**.** *Let $C(n, m)$ be the number of quotient-level minimal full triggers of size m on an n-coordinate trigger set. Then*

$$C(n, m) = \frac{1}{m!} \sum_{j=0}^{m} (-1)^j \binom{m}{j} (2^m - 1 - j)^n.$$

Proof. First count ordered tuples $(S_1, \dots, S_m)$. Each coordinate $a \in \Omega$ determines a nonempty incidence pattern

$$\phi(a) = \{i : a \in S_i\} \subseteq [m].$$

There are $2^m - 1$ nonempty patterns. By Definition 9462.1672, minimality is equivalent to requiring each singleton pattern $\{i\}$ to appear at least once. Inclusion-exclusion over the missing singleton patterns gives the ordered count

$$\sum_{j=0}^{m} (-1)^j \binom{m}{j} (2^m - 1 - j)^n.$$

Every support S_i has a private coordinate, so the S_i are pairwise distinct. Hence each unordered family is counted $m!$ times. □

Corollary 9462.1674 (Codon minimal-trigger counts)**.** *For the codon terminal system $n = 4$ and $\ell = 2$,*

m	$C(4, m)$	$2^m C(4, m)$
1	1	2
2	25	100
3	22	176
4	1	16.

Thus the codon-level minimal full-trigger polynomial is

$$2z + 100z^2 + 176z^3 + 16z^4.$$

Proof. Evaluate Definition 9462.1673 at $n = 4$:

$$C(4,1) = 1,$$

$$C(4,2) = \frac{3^4 - 2 \cdot 2^4 + 1}{2} = 25,$$

$$C(4,3) = \frac{7^4 - 3 \cdot 6^4 + 3 \cdot 5^4 - 4^4}{6} = 22,$$

and $C(4,4) = 1$. The codon layer has two f_3-lifts for each support, so a size-m quotient trigger has 2^m codon lifts. □

Theorem 9462.1675 (Energy-refined private-coordinate formula)**.** *Let $C_{n,m}(y)$ be the quotient-level energy generating polynomial for size-m minimal full triggers on n trigger coordinates, where*

$$E(A) = \sum_{S \in A} |S|.$$

Then

$$C_{n,m}(y) = \frac{1}{m!} \sum_{j=0}^{m} (-1)^j \binom{m}{j} \left((1+y)^m - 1 - jy\right)^n.$$

Proof. An incidence pattern $T \subseteq [m]$ contributes $y^{|T|}$ to the energy. The weight enumerator of all nonempty patterns is

$$\sum_{\varnothing \neq T \subseteq [m]} y^{|T|} = (1+y)^m - 1.$$

Forbidding j singleton patterns removes jy from this enumerator. Inclusion-exclusion over missing singleton patterns gives the ordered energy enumerator. Division by $m!$ removes the ordering of the support family. □

Corollary 9462.1676 (Codon energy refinement)**.** *For $n = 4$ and $\ell = 2$, the codon-level bivariate polynomial is*

$$\begin{aligned} T_c(z,y) = {} & 2zy^4 + z^2(28y^4 + 48y^5 + 24y^6) \\ & + z^3(48y^4 + 96y^5 + 32y^6) + 16z^4y^4. \end{aligned}$$

Consequently

$$T_c(z,1) = 2z + 100z^2 + 176z^3 + 16z^4,$$

and

$$T_c(1,y) = 94y^4 + 144y^5 + 56y^6.$$

Proof. Evaluate Definition 9462.1675 at $n = 4$, multiply the size-m quotient terms by 2^m, and collect by trigger size and energy. □

Corollary 9462.1677 (Energy-minimal partition subclass)**.** *For n trigger coordinates and ℓ lifts per support, the energy-minimal trigger polynomial is*

$$y^n \sum_{m=1}^{n} \ell^m S(n,m) z^m,$$

where $S(n,m)$ is the Stirling number of the second kind.

Proof. The minimum possible energy of a full trigger is n. Equality holds exactly when the supports form a set partition of Ω, by Definition 9462.1579. There are $S(n, m)$ set partitions with m blocks, and the lift layer contributes ℓ^m choices. □

Theorem 9462.1678 (Private-coordinate trigger enumeration theorem)**.** *In the post-$M^\star$ terminal trigger algebra, minimal full triggers are enumerated by private-coordinate inclusion-exclusion. For n trigger coordinates and ℓ lifts per support, the size-m lifted count is*

$$\ell^m \frac{1}{m!} \sum_{j=0}^{m} (-1)^j \binom{m}{j} (2^m - 1 - j)^n,$$

and the energy-refined quotient formula is

$$\frac{1}{m!} \sum_{j=0}^{m} (-1)^j \binom{m}{j} \left((1+y)^m - 1 - jy\right)^n .$$

Proof. The first formula is Definition 9462.1673 with the lift factor ℓ^m. The second formula is Definition 9462.1675. □

Concretized in §5812: Private-coordinate minimal-cover witnesses are realized as finite NameCert rows.

Concretized in §6786: Energy-refined private-coordinate enumeration is realized as finite witness, incidence, energy, and polynomial ledger rows.

Definition 9462.1679 (Overlap defect)**.** *For a quotient-level support family*

$$A = \{S_1, \ldots, S_m\}$$

on $\Omega = \{1, 2, 3, 4\}$, define its energy and overlap defect by

$$E(A) = \sum_{i=1}^{m} |S_i|, \qquad \delta(A) = E(A) - 4.$$

Theorem 9462.1680 (Defect range)**.** *Every quotient-level minimal full trigger on four coordinates has*

$$\delta(A) \in \{0, 1, 2\}.$$

Proof. By Definition 9462.1672, every support has a private coordinate. Hence a size-m minimal trigger has at least m coordinates of multiplicity one. The remaining $4 - m$ coordinates can contribute multiplicity at most m each, so

$$E(A) \leq m + m(4 - m).$$

For $m = 1, 2, 3, 4$, this gives $E(A) \leq 4, 6, 6, 4$, respectively. Since full triggering forces $E(A) \geq 4$, the defect is one of $0, 1, 2$. □

Theorem 9462.1681 (Nine orbit classification)**.** *Under the S_4 action on the four trigger coordinates, the quotient-level minimal full triggers split into the following nine normal forms:*

normal form	m	E	δ	*quotient count*	*codon count*
$\{1234\}$	1	4	0	1	2
$\{1, 234\}$	2	4	0	4	16
$\{12, 34\}$	2	4	0	3	12
$\{12, 234\}$	2	5	1	12	48
$\{123, 124\}$	2	6	2	6	24
$\{1, 2, 34\}$	3	4	0	6	48
$\{1, 24, 34\}$	3	5	1	12	96
$\{14, 24, 34\}$	3	6	2	4	32
$\{1, 2, 3, 4\}$	4	4	0	1	16.

The quotient counts sum to 49*, and the codon counts sum to* 294*.*

Proof. Classify support families by the private-coordinate criterion of Definition 9462.1672. For $m = 1$ the only type is $\{1234\}$. For $m = 2$, the possible support-size patterns with private coordinates and full union are $(1, 3)$, $(2, 2)$, $(2, 3)$, and $(3, 3)$, giving the four displayed two-support rows. For $m = 3$, the possible patterns are $(1, 1, 2)$, $(1, 2, 2)$, and $(2, 2, 2)$, giving the three displayed three-support rows. For $m = 4$, the four private coordinates force the four singleton supports.

The quotient counts are the sizes of the S_4 orbits of these normal forms. The codon count in a row is the quotient count multiplied by 2^m. □

Corollary 9462.1682 (Defect distribution)**.** *The quotient-level and codon-level defect distributions are*

δ	*quotient count*	*codon count*
0	15	94
1	24	144
2	10	56.

Proof. Group the rows of Definition 9462.1681 by their defect value. □

Corollary 9462.1683 (Orbit expansion of the trigger polynomial)**.** *The quotient-level bivariate minimal-trigger polynomial decomposes by orbit type as*

$$T_q(z, y) = zy^4 + 4z^2y^4 + 3z^2y^4 + 12z^2y^5 + 6z^2y^6$$
$$+6z^3y^4 + 12z^3y^5 + 4z^3y^6 + z^4y^4.$$

After applying the two-lift codon factor 2^m, this becomes

$$T_c(z, y) = 2zy^4 + z^2(28y^4 + 48y^5 + 24y^6)$$
$$+z^3(48y^4 + 96y^5 + 32y^6) + 16z^4y^4.$$

Proof. Attach the monomial $z^m y^E$ to each row of Definition 9462.1681, weighted by quotient orbit size. Multiplication by 2^m gives the codon-level polynomial. □

Corollary 9462.1684 (Partition and overlap mechanisms)**.** *The defect-*0 *rows are exactly the partition triggers. The defect-*1 *rows are the single-overlap normal forms*

$$\{12, 234\}, \qquad \{1, 24, 34\}.$$

The defect-2 rows are the double-overlap and triple-overlap normal forms

$$\{123, 124\}, \qquad \{14, 24, 34\}.$$

Proof. Defect is the total excess coordinate multiplicity beyond the four coordinates of Ω. Defect 0 is therefore equivalent to pairwise disjoint support blocks, namely a partition. The two defect-1 normal forms have one repeated coordinate. The two defect-2 normal forms respectively realize two repeated coordinates and one coordinate shared by three supports. □

Theorem 9462.1685 (Nine-orbit minimal trigger theorem)**.** *The post-$M^\star$ quotient-level minimal full triggers consist of* 49 *support covers arranged in nine S_4-orbit types. Their two-lift codon expansions contain* 294 *minimal full triggers. The defect classes are*

$$\delta = 0 : 94, \qquad \delta = 1 : 144, \qquad \delta = 2 : 56$$

at codon level.

Proof. This is the combined content of Definition 9462.1681 and Definition 9462.1682. □

Concretized in §4192: The nine orbit minimal-trigger classification is realized as finite normal-form, defect, quotient-count, codon-count, transport, replay, provenance, and local NameCert rows.

Definition 9462.1686 (Minimal trigger lift fiber)**.** *Let $A = \{S_1, \ldots, S_m\}$ be a quotient-level minimal full trigger. Each support S_i has two f_3-lifts. The lift fiber over A is the set of choices*

$$\epsilon = (\epsilon_1, \ldots, \epsilon_m) \in \{0, 1\}^m,$$

with lifted trigger

$$A^\epsilon = \{S_1^{(\epsilon_1)}, \ldots, S_m^{(\epsilon_m)}\}.$$

Theorem 9462.1687 (Lift-bundle decomposition)**.** *Let $\mathcal{T}_q$ be the quotient-level minimal full triggers and let $\mathcal{T}_c$ be the codon-level minimal full triggers. Then*

$$\mathcal{T}_c = \bigsqcup_{A \in \mathcal{T}_q} Q_{|A|}.$$

In the codon case this gives

$$\mathcal{T}_c = Q_1 \sqcup 25Q_2 \sqcup 22Q_3 \sqcup Q_4.$$

Proof. Projection along the f_3 coordinate sends a codon-level minimal trigger to a quotient-level minimal support cover. Conversely, every support in a size-m quotient trigger has two independent f_3-lift choices, and these choices do not change the support union or minimality. Hence the fiber over the quotient trigger is Q_m, and distinct quotient triggers have disjoint lift sets. □

Concretized in §4129: The minimal trigger lift-fiber decomposition is realized as finite quotient-support, lift-choice, orbit-fiber, and flip-ledger NameCert data.

Concretized in §8695: The finite trigger flip graph is realized as quotient-support, lift-fiber, edge-budget, transport, replay, provenance, and NameCert data.

Corollary 9462.1688 (Lift-fiber distribution)**.** *The fiber dimensions and codon counts are*

m	*quotient count*	*fiber*	*codon count*
1	1	Q_1	2
2	25	Q_2	100
3	22	Q_3	176
4	1	Q_4	16.

Thus $|\mathcal{T}_c| = 294$.

Proof. This is the size distribution of quotient-level minimal triggers from Definition 9462.1674, with the fiber Q_m attached to each size-m trigger. □

Corollary 9462.1689 (Orbit fibers)**.** *The nine quotient orbit types carry the following lift fibers:*

normal form	m	*quotient count*	*fiber*	*codon count*
$\{1234\}$	1	1	Q_1	2
$\{1, 234\}$	2	4	Q_2	16
$\{12, 34\}$	2	3	Q_2	12
$\{12, 234\}$	2	12	Q_2	48
$\{123, 124\}$	2	6	Q_2	24
$\{1, 2, 34\}$	3	6	Q_3	48
$\{1, 24, 34\}$	3	12	Q_3	96
$\{14, 24, 34\}$	3	4	Q_3	32
$\{1, 2, 3, 4\}$	4	1	Q_4	16.

Proof. Combine Definition 9462.1681 with Definition 9462.1687. □

Definition 9462.1690 (Lift-flip graph)**.** *Inside one fiber over* $A = \{S_1, \ldots, S_m\}$*, two lifted triggers are adjacent if their lift choices differ in exactly one coordinate.*

Theorem 9462.1691 (Lift-flip edge count)**.** *The total number of lift-flip edges inside all fibers is* 397*.*

Proof. The fiber over a size-m quotient trigger is Q_m, whose edge count is $m2^{m-1}$. Therefore the total number of lift-flip edges is

$$1 \cdot 1 + 25 \cdot 4 + 22 \cdot 12 + 1 \cdot 32 = 397.$$

□

Definition 9462.1692 (Quotient support-flip graph)**.** *For fixed size* m*, two quotient-level minimal triggers are adjacent if they have the same size and differ by replacing exactly one support:*

$$|A \triangle B| = 2.$$

Theorem 9462.1693 (Quotient support-flip graph)**.** *The fixed-size quotient support-flip graphs have the following statistics:*

m	*vertices*	*edges*	*components*	*diameter*
1	1	0	1	0
2	25	102	1	3
3	22	48	1	4
4	1	0	1	0.

Proof. Enumerate the quotient-level minimal full triggers at each size. In a fixed-size layer, join two vertices when their symmetric difference has size two. Computing the connected components and graph diameters gives the displayed table. □

Theorem 9462.1694 (Orbit-edge structure)**.** *In the $m = 2$ quotient support-flip graph, the orbit-edge counts are*

orbit pair	*edge count*
$\{1, 234\}$–$\{12, 234\}$	12
$\{1, 234\}$–$\{123, 124\}$	12
$\{12, 34\}$–$\{12, 234\}$	12
$\{12, 234\}$–$\{12, 234\}$	18
$\{12, 234\}$–$\{123, 124\}$	36
$\{123, 124\}$–$\{123, 124\}$	12.

In the $m = 3$ layer the counts are

orbit pair	*edge count*
$\{1, 2, 34\}$–$\{1, 24, 34\}$	24
$\{1, 24, 34\}$–$\{1, 24, 34\}$	12
$\{1, 24, 34\}$–$\{14, 24, 34\}$	12.

Proof. Refine the support-flip graph of Definition 9462.1693 by the orbit labels of Definition 9462.1681 and count edges by unordered orbit pair. □

Corollary 9462.1695 (Defect-one transition layer)**.** *In the nontrivial quotient flip layers, defect-1 orbit types form the transition layer between partition triggers and high-overlap triggers.*

Proof. In the $m = 3$ layer, the partition orbit $\{1, 2, 34\}$ only connects to the defect-1 orbit $\{1, 24, 34\}$, and the defect-2 orbit $\{14, 24, 34\}$ also only connects to that defect-1 orbit. In the $m = 2$ layer, every partition-to-overlap path passes through or touches the displayed defect-1 orbit $\{12, 234\}$, while the high-overlap orbit also has internal edges. □

Theorem 9462.1696 (Minimal-trigger bundle theorem)**.** *The post-$M^\star$ codon-level minimal trigger space is an f_3-lift hypercube bundle over the quotient minimal-cover base:*

$$\mathcal{T}_c = Q_1 \sqcup 25Q_2 \sqcup 22Q_3 \sqcup Q_4.$$

Its base has 49 vertices arranged in nine S_4-orbit types, the lift fibers contribute 397 internal lift-flip edges, and the nontrivial fixed-size quotient layers are connected.

Proof. The bundle decomposition is Definition 9462.1687. The orbit stratification is Definition 9462.1681. The lift-flip count and quotient connectivity are Definition 9462.1691 and Definition 9462.1693. □

Definition 9462.1697 (Private and shared coordinates)**.** *Let $A = \{S_1, \ldots, S_m\}$ be a quotient-level support family on Ω. The private coordinate set of S_i is*

$$P_i = S_i \setminus \bigcup_{j \neq i} S_j.$$

The shared coordinate set is

$$H = \Omega \setminus \bigcup_{i=1}^{m} P_i.$$

For $a \in H$, write

$$R_a = \{i : a \in S_i\}.$$

Theorem 9462.1698 (Private-shared decomposition)**.** *A quotient-level minimal full trigger of size m is equivalently the following data:*

$$H \subseteq \Omega,$$

a partition of the complement into nonempty private blocks

$$\Omega \setminus H = P_1 \sqcup \cdots \sqcup P_m,$$

and, for each $a \in H$, a row set

$$R_a \subseteq \{P_1, \ldots, P_m\}, \qquad |R_a| \geq 2.$$

The support corresponding to a private block P is recovered by

$$S_P = P \cup \{a \in H : P \in R_a\}.$$

This decomposition is unique.

Proof. Given a minimal full trigger, every coordinate has a well-defined multiplicity among the supports. If the multiplicity is one, the coordinate belongs to the unique private block attached to its support. If the multiplicity is at least two, the coordinate lies in H and has the unique set of private blocks whose supports contain it. Minimality gives every private block nonempty by Definition 9462.1672.

Conversely, the displayed data define supports S_P whose union is Ω. Since every P_i is nonempty, each S_i has a private coordinate, so the family is a minimal full trigger. The construction also proves uniqueness. □

Theorem 9462.1699 (Decoration enumeration)**.** *The number of quotient-level size-m minimal full triggers on n trigger coordinates is*

$$C(n, m) = \sum_{h=0}^{n-m} \binom{n}{h} S(n-h, m)(2^m - m - 1)^h,$$

where $S(n-h, m)$ is the Stirling number of the second kind.

Proof. Choose the h shared coordinates in $\binom{n}{h}$ ways. Partition the remaining $n-h$ private coordinates into m nonempty private blocks in $S(n-h, m)$ ways. For each shared coordinate, choose a row set of size at least two. The number of such row sets is

$$\sum_{r=2}^{m} \binom{m}{r} = 2^m - m - 1.$$

Summing over all possible h gives the formula. □

Corollary 9462.1700 (Codon counts from decorated partitions)**.** *For $n = 4$, the decoration formula gives*

$$C(4, 1) = 1, \qquad C(4, 2) = 25, \qquad C(4, 3) = 22, \qquad C(4, 4) = 1.$$

With two f_3-lifts per support, the codon-level counts are

$$2, \quad 100, \quad 176, \quad 16.$$

Proof. For $m = 2$, the shared coordinate has only one possible row set, so

$$C(4,2) = S(4,2) + 4S(3,2) + 6S(2,2) = 7 + 12 + 6.$$

For $m = 3$, one shared coordinate has four possible row sets, giving

$$C(4,3) = S(4,3) + 4S(3,3) \cdot 4 = 6 + 16.$$

The cases $m = 1$ and $m = 4$ have no shared coordinates. Multiplying the size-m quotient count by 2^m gives the codon counts. □

Theorem 9462.1701 (Defect from shared coordinates)**.** *For a minimal full trigger with private-shared decomposition, the overlap defect is*

$$\delta(A) = \sum_{a \in H} (|R_a| - 1).$$

Proof. Private coordinates contribute one occurrence and hence no excess over the four-coordinate cover. A shared coordinate a appears in $|R_a|$ supports, while one occurrence would suffice for coverage. Its excess contribution is therefore $|R_a| - 1$. Summing over shared coordinates gives the formula. □

Theorem 9462.1702 (Defect-refined decoration polynomial)**.** *Put*

$$A_m(y) = \sum_{r=2}^{m} \binom{m}{r} y^{r-1}.$$

Then the quotient-level defect polynomial for size-m minimal triggers on n coordinates is

$$D_{n,m}(y) = \sum_{h=0}^{n-m} \binom{n}{h} S(n-h, m) A_m(y)^h.$$

Proof. For a shared coordinate, choosing a row set of size r contributes defect $r - 1$ and can be done in $\binom{m}{r}$ ways. Thus the defect enumerator for one shared coordinate is $A_m(y)$. The remaining choices are exactly those counted in Definition 9462.1699. □

Corollary 9462.1703 (Codon defect polynomials)**.** *For $n = 4$,*

$$D_{4,2}(y) = 7 + 12y + 6y^2,$$

and

$$D_{4,3}(y) = 6 + 12y + 4y^2.$$

Together with the $m = 1$ and $m = 4$ singleton terms, this gives quotient defect counts

$$\delta = 0 : 15, \qquad \delta = 1 : 24, \qquad \delta = 2 : 10.$$

After the two-lift codon factor, the counts are

$$94, \quad 144, \quad 56.$$

Proof. For $m = 2$, $A_2(y) = y$, so

$$D_{4,2}(y) = 7 + 12y + 6y^2.$$

For $m = 3$, $A_3(y) = 3y + y^2$, so

$$D_{4,3}(y) = 6 + 4(3y + y^2).$$

The codon counts are obtained by multiplying the size-m quotient terms by 2^m. □

Corollary 9462.1704 (Orbit decoration table)**.** *The nine orbit normal forms have the following private and shared decoration data:*

normal form	*private blocks*	*shared data*
$\{1234\}$	$\{1234\}$	$\varnothing$
$\{1, 234\}$	$\{1\}, \{234\}$	$\varnothing$
$\{12, 34\}$	$\{12\}, \{34\}$	$\varnothing$
$\{12, 234\}$	$\{1\}, \{34\}$	$2 : \{1, 2\}$
$\{123, 124\}$	$\{3\}, \{4\}$	$1 : \{1, 2\},\ 2 : \{1, 2\}$
$\{1, 2, 34\}$	$\{1\}, \{2\}, \{34\}$	$\varnothing$
$\{1, 24, 34\}$	$\{1\}, \{2\}, \{3\}$	$4 : \{2, 3\}$
$\{14, 24, 34\}$	$\{1\}, \{2\}, \{3\}$	$4 : \{1, 2, 3\}$
$\{1, 2, 3, 4\}$	$\{1\}, \{2\}, \{3\}, \{4\}$	$\varnothing$.

Proof. For each normal form, read off coordinates of multiplicity one as private blocks and coordinates of multiplicity at least two as shared decorations with their row sets. □

Theorem 9462.1705 (Private-shared decoration theorem)**.** *Post-$M^\star$ quotient-level minimal full triggers are decorated set partitions: a nonempty private partition of the non-shared coordinates, plus shared coordinates decorated by row sets of size at least two. For n coordinates and ℓ lifts per support, the lifted size-m count is*

$$\ell^m \sum_{h=0}^{n-m} \binom{n}{h} S(n-h, m)(2^m - m - 1)^h.$$

The defect-refined quotient polynomial is

$$\sum_{h=0}^{n-m} \binom{n}{h} S(n-h, m) \left(\sum_{r=2}^{m} \binom{m}{r} y^{r-1} \right)^h.$$

Proof. The decomposition is Definition 9462.1698; the enumeration and defect formulas are Definition 9462.1699 and Definition 9462.1702. The lift factor is ℓ^m because each support in a size-m quotient trigger has ℓ independent lift choices. □

Concretized in §5542: Private/shared coordinate decomposition is realized as finite support, private-block, shared-coordinate, row-set, hsame, Cont, Pkg, and NameCert data.

Concretized in §5896: Private/shared decoration models are realized as finite private-block, shared-row, lift-count, defect-ledger, transport, replay, provenance, and NameCert rows.

Concretized in §5881: The private/shared decoration packet realizes the window-six boundary tile decomposition and decoration enumeration as finite NameCert rows.

Concretized in §7630: The defect-refined decoration polynomial is realized as finite private/shared row-set arity, exponent, coefficient, transport, replay, provenance, and NameCert rows.

Definition 9462.1706 (Codon-level lift orbit)**.** *Let $A = \{S_1, \ldots, S_m\}$ be a quotient-level minimal full trigger. The codon-level lift fiber over A is $\{0,1\}^m$. The natural symmetry group is*

$$G = S_4 \times C_2^{(f_3)},$$

where S_4 permutes the four trigger coordinates and $C_2^{(f_3)}$ acts on a lift vector by global complement

$$\epsilon \longmapsto 1 - \epsilon.$$

For a fixed support family A, let $\mathrm{Aut}(A)$ be the coordinate stabilizer of A, acting on the m support rows. The lift-orbit set over A is

$$\{0,1\}^m / (\mathrm{Aut}(A) \times C_2^{(f_3)}).$$

Theorem 9462.1707 (Codon-level lift-orbit classification)**.** *Under the action of $S_4 \times C_2^{(f_3)}$, the 294 codon-level minimal full triggers split into 20 orbit types.*

Proof. The quotient-level support families split into the nine orbit types of Definition 9462.1681. For each representative A, the remaining problem is the binary coloring quotient

$$\{0,1\}^{|A|} / (\mathrm{Aut}(A) \times C_2^{(f_3)}).$$

Computing these nine finite quotients gives the orbit counts

support normal form	quotient count	lift orbits
$\{1234\}$	1	1
$\{1, 234\}$	4	2
$\{12, 34\}$	3	2
$\{12, 234\}$	12	2
$\{123, 124\}$	6	2
$\{1, 2, 34\}$	6	3
$\{1, 24, 34\}$	12	3
$\{14, 24, 34\}$	4	2
$\{1, 2, 3, 4\}$	1	3.

The sum of the lift-orbit counts is

$$1 + 2 + 2 + 2 + 2 + 3 + 3 + 2 + 3 = 20.$$

□

Theorem 9462.1708 (Lift-orbit table)**.** *The codon-level orbit types are exactly the rows in the*

following table:

support normal form	*lift pattern*	*codon orbit size*
$\{1234\}$	0/1	2
$\{1, 234\}$	*same*	8
$\{1, 234\}$	*opposite*	8
$\{12, 34\}$	*same*	6
$\{12, 34\}$	*opposite*	6
$\{12, 234\}$	*same*	24
$\{12, 234\}$	*opposite*	24
$\{123, 124\}$	*same*	12
$\{123, 124\}$	*opposite*	12
$\{1, 2, 34\}$	*all same*	12
$\{1, 2, 34\}$	*pair same, block opposite*	12
$\{1, 2, 34\}$	*singleton split*	24
$\{1, 24, 34\}$	*all same*	24
$\{1, 24, 34\}$	*shared-pair same, singleton opposite*	24
$\{1, 24, 34\}$	*shared-pair split*	48
$\{14, 24, 34\}$	*all same*	8
$\{14, 24, 34\}$	*mixed*	24
$\{1, 2, 3, 4\}$	*all same*	2
$\{1, 2, 3, 4\}$	*one-vs-three*	8
$\{1, 2, 3, 4\}$	*two-vs-two*	6.

The orbit sizes add to 294.

Proof. For each support normal form, the row stabilizer $\mathrm{Aut}(A)$ acts on binary lift vectors, while $C_2^{(f_3)}$ identifies a vector with its complement. The $m = 1$ fiber has one orbit. For $m = 2$, the complement quotient leaves the same and opposite lift patterns. For the type $\{1, 2, 34\}$, the two singleton rows may be exchanged, giving the three patterns displayed in the table. For the type $\{1, 24, 34\}$, the two shared-pair rows may be exchanged, giving the analogous three patterns. For the type $\{14, 24, 34\}$, the three rows are symmetric, so the nonconstant patterns form one orbit. For $\{1, 2, 3, 4\}$, the four rows are symmetric, and complement identifies weights w and $4 - w$, leaving the three classes 0/4, 1/3, and 2/2. Multiplying each lift-orbit size by the number of quotient triggers in its support orbit gives the displayed codon orbit sizes. □

Theorem 9462.1709 (Burnside lift-orbit formula)**.** *For a quotient-level minimal trigger A, let $\Gamma = \mathrm{Aut}(A)$. If $c(\gamma)$ is the number of cycles of the row permutation γ, then the number of lift orbits over A is*

$$N_{\mathrm{lift}}(A) = \frac{1}{2|\Gamma|} \sum_{\gamma \in \Gamma} \left(2^{c(\gamma)} + \mathbf{1}_{\mathrm{even}}(\gamma) 2^{c(\gamma)} \right),$$

where $\mathbf{1}_{\mathrm{even}}(\gamma) = 1$ exactly when every cycle of γ has even length.

Proof. Burnside's lemma applies to the action of $\Gamma \times C_2^{(f_3)}$ on $\{0, 1\}^m$. A row permutation γ fixes $2^{c(\gamma)}$ binary strings. The complemented element $\tau\gamma$ fixes the solutions of $\epsilon = 1 - \gamma\epsilon$. Along a cycle, such assignments exist exactly for even cycle length, and then contribute two assignments per cycle. Hence the complemented fixed-point term is $2^{c(\gamma)}$ when all cycles are even and zero otherwise. □

Definition 9462.1710 (Lift imbalance)**.** *For a lift vector $\epsilon \in \{0,1\}^m$, define*

$$b(\epsilon) = \min\{w(\epsilon), m - w(\epsilon)\},$$

where $w(\epsilon)$ is its Hamming weight.

Theorem 9462.1711 (Codon-level minimal trigger orbit theorem)**.** *The post-$M^\star$ codon-level minimal trigger space is the f_3-lift hypercube bundle*

$$\mathcal{T}_c = Q_1 \sqcup 25Q_2 \sqcup 22Q_3 \sqcup Q_4,$$

and its natural $S_4 \times C_2^{(f_3)}$ quotient has 20 orbit types. Each orbit type is determined by a support normal form together with a lift coloring orbit modulo support automorphisms and global f_3 complement.

Proof. The bundle decomposition is Definition 9462.1687. The support orbit types are supplied by Definition 9462.1681. The lift-coloring quotient and the count of 20 orbit types are Definition 9462.1707 and Definition 9462.1708. □

Concretized in §4059: Codon lift-orbit classifiers realize the finite support, binary lift, support-automorphism, complement-action, Burnside ledger, classifier, transport, replay, provenance, and NameCert rows behind the twenty orbit types.

Definition 9462.1712 (Orbit inventory variables)**.** *For a codon-level minimal full trigger (A, ϵ), write $m = |A|$ for its size, write*

$$\delta(A) = \sum_{S \in A} |S| - 4$$

for its overlap defect, and write

$$b(\epsilon) = \min\{w(\epsilon), m - w(\epsilon)\}$$

for its f_3-lift imbalance. The variable u records m, the variable v records δ, and the variable w records b.

Definition 9462.1713 (Orbit and codon inventory polynomials)**.** *The orbit inventory polynomial counts symmetry-normal forms:*

$$\mathcal{O}(u,v,w) = \sum_{\mathcal{Q}} u^{m(\mathcal{Q})} v^{\delta(\mathcal{Q})} w^{b(\mathcal{Q})},$$

where $\mathcal{Q}$ ranges over codon-level orbit types. The codon inventory polynomial counts actual lifted triggers:

$$\mathcal{C}(u,v,w) = \sum_{\mathcal{Q}} |\mathcal{Q}| u^{m(\mathcal{Q})} v^{\delta(\mathcal{Q})} w^{b(\mathcal{Q})}.$$

Theorem 9462.1714 (Orbit inventory polynomial)**.** *For the post-$M^\star$ codon-level minimal full triggers,*

$$\begin{aligned}\mathcal{O}(u,v,w) = u &+ u^2\big((2+2w) + v(1+w) + v^2(1+w)\big) \\ &+ u^3\big((1+2w) + v(1+2w) + v^2(1+w)\big) + u^4(1+w+w^2).\end{aligned}$$

Thus $\mathcal{O}(1,1,1) = 20$.

Proof. Group the 20 rows of Definition 9462.1708 by the triple (m, δ, b). Each orbit row contributes one monomial $u^m v^\delta w^b$. Summing the grouped rows gives the displayed polynomial, and substituting $u = v = w = 1$ counts the orbit types. □

Theorem 9462.1715 (Codon inventory polynomial)**.** *The corresponding codon-count polynomial is*

$$\begin{aligned}\mathcal{C}(u, v, w) = {} & 2u + u^2(1 + w)(14 + 24v + 12v^2) \\ & + u^3\big((12 + 36w) + v(24 + 72w) + v^2(8 + 24w)\big) \\ & + u^4(2 + 8w + 6w^2).\end{aligned}$$

Thus $\mathcal{C}(1, 1, 1) = 294$.

Proof. Use the same grouping as Definition 9462.1714, but weight each orbit row by its codon orbit size. The orbit sizes in Definition 9462.1708 sum to 294. □

Corollary 9462.1716 (Inventory marginals)**.** *The codon-count marginals are*

$$\mathcal{C}(u, 1, 1) = 2u + 100u^2 + 176u^3 + 16u^4,$$

$$\mathcal{C}(1, v, 1) = 94 + 144v + 56v^2,$$

and

$$\mathcal{C}(1, 1, w) = 98 + 190w + 6w^2.$$

Proof. These are the three one-variable specializations of Definition 9462.1715. □

Corollary 9462.1717 (Inventory joint tables)**.** *The size-defect codon counts are*

m	$\delta = 0$	$\delta = 1$	$\delta = 2$	*total*
1	2	0	0	2
2	28	48	24	100
3	48	96	32	176
4	16	0	0	16.

The defect-imbalance counts are

δ	$b = 0$	$b = 1$	$b = 2$	*total*
0	30	58	6	94
1	48	96	0	144
2	20	36	0	56.

The size-imbalance counts are

m	$b = 0$	$b = 1$	$b = 2$	*total*
1	2	0	0	2
2	50	50	0	100
3	44	132	0	176
4	2	8	6	16.

Proof. Set one of the variables in Definition 9462.1715 equal to 1 and read off the remaining bivariate coefficients. □

Corollary 9462.1718 (Inventory means and largest orbit)**.** *Under the uniform distribution on the* 294 *codon-level minimal full triggers,*

$$\mathbb{E}[m] = \frac{397}{147}, \qquad \mathbb{E}[\delta] = \frac{128}{147},$$
$$\mathbb{E}[E] = \frac{716}{147}, \qquad \mathbb{E}[b] = \frac{101}{147}.$$

The largest codon-level orbit has size 48*; it is the* $\{1, 24, 34\}$ *support orbit with shared-pair split lift pattern, hence has* $(m, \delta, b) = (3, 1, 1)$*.*

Proof. The expectations are obtained from the first logarithmic moments of $\mathcal{C}$ at $u = v = w = 1$, equivalently from the numerator sums

$$\sum m = 794, \qquad \sum \delta = 256, \qquad \sum E = 1432, \qquad \sum b = 202$$

over the 294 triggers. The largest orbit is read from Definition 9462.1708. □

Theorem 9462.1719 (Orbit inventory polynomial theorem)**.** *The post-*$M^\star$ *codon-level minimal trigger space is encoded by the two inventory polynomials* $\mathcal{O}(u, v, w)$ *and* $\mathcal{C}(u, v, w)$*. The first records the* 20 *natural orbit types, and the second records the* 294 *lifted codon triggers with their joint statistics* (m, δ, b)*.*

Proof. The orbit classification is Definition 9462.1707. Grouping those orbit rows by size, overlap defect, and lift imbalance gives Definition 9462.1714; weighting by orbit size gives Definition 9462.1715. □

Concretized in §4220: finite orbit-inventory polynomial certificate

Definition 9462.1720 (Defect-lowering move)**.** *Let* $A = \{S_1, \ldots, S_m\}$ *be a quotient-level minimal full trigger with private-shared decomposition as in Definition 9462.1698. If* $a \in H$ *is a shared coordinate and* $i \in R_a$*, a defect-lowering move deletes the single incidence* $a \in S_i$*, equivalently replacing*

$$R_a \quad \text{by} \quad R_a \setminus \{i\},$$

under the condition that $R_a \setminus \{i\}$ *remains nonempty.*

Theorem 9462.1721 (Defect lowering preserves minimality)**.** *If a quotient-level minimal full trigger admits a defect-lowering move, then the result is again a quotient-level minimal full trigger, and the defect decreases by one.*

Proof. Only one shared-coordinate incidence is removed. Since the coordinate remains in at least one other support, the union of the supports remains Ω. Since the removed coordinate was shared, no private block P_i changes. Hence every support still has a private coordinate, so Definition 9462.1672 gives minimality. The formula

$$\delta(A) = \sum_{a \in H} (|R_a| - 1)$$

from Definition 9462.1701 shows that removing one shared incidence decreases δ by one. □

Concretized in §4236: The defect-flow partition skeleton is realized as finite cubical-incidence and boundary-flow NameCert data.

Theorem 9462.1722 (Defect flow to the partition skeleton)**.** *Every quotient-level minimal full trigger flows by repeated defect-lowering moves to a partition trigger. The number of moves in any maximal decreasing path is exactly the initial defect.*

Proof. Each defect-lowering move reduces δ by one and never makes δ negative. Hence the process terminates after exactly the initial value of δ. At termination, no shared incidence remains removable, so every coordinate occurs in exactly one support. The supports therefore form a partition of Ω. □

Corollary 9462.1723 (Partition sinks)**.** *The sink set of the defect flow is the partition trigger skeleton. It has* 15 *quotient-level vertices and* 94 *codon-level vertices.*

Proof. The quotient sink count is the Bell number $B_4 = 15$. With two f_3-lifts per support, the codon sink count is

$$2S(4,1) + 2^2S(4,2) + 2^3S(4,3) + 2^4S(4,4) = 94.$$

□

Theorem 9462.1724 (Defect-flow edge counts)**.** *The quotient-level defect-flow graph has* 49 *vertices and* 84 *directed edges. The codon-level defect-flow graph has* 294 *vertices and* 480 *directed edges. The edge counts by layer are*

layer	*quotient edges*	*codon edges*
$\delta = 1 \to 0$	48	288
$\delta = 2 \to 1$	36	192.

Proof. The defect-1 quotient orbits are $\{12, 234\}$ and $\{1, 24, 34\}$. Each has one shared coordinate covered by two supports, hence outdegree two. Their quotient contributions are $12 \cdot 2$ and $12 \cdot 2$, giving 48 quotient edges; after lift multiplication they contribute $48 \cdot 2$ and $96 \cdot 2$, giving 288 codon edges.

The defect-2 quotient orbits are $\{123, 124\}$ and $\{14, 24, 34\}$. The first has two shared coordinates of row-size two, hence outdegree four; the second has one shared coordinate of row-size three, hence outdegree three. Their quotient contributions are $6 \cdot 4$ and $4 \cdot 3$, giving 36 quotient edges; after lift multiplication they contribute $24 \cdot 4$ and $32 \cdot 3$, giving 192 codon edges. □

Theorem 9462.1725 (Partition-core incidence)**.** *For a minimal full trigger A with shared-coordinate row sets R_a, the number of partition cores below A is*

$$N_{\text{core}}(A) = \prod_{a \in H} |R_a|.$$

The total quotient-level trigger–partition incidence is 99*, and the total codon-level incidence is* 574*.*

Proof. For each shared coordinate a, a terminal partition core is obtained by choosing exactly one row of R_a to retain a. These choices are independent, giving the product formula.

By quotient orbit type, the incidences are

normal form	quotient count	N_{core}	contribution
$\{1234\}$	1	1	1
$\{1, 234\}$	4	1	4
$\{12, 34\}$	3	1	3
$\{12, 234\}$	12	2	24
$\{123, 124\}$	6	4	24
$\{1, 2, 34\}$	6	1	6
$\{1, 24, 34\}$	12	2	24
$\{14, 24, 34\}$	4	3	12
$\{1, 2, 3, 4\}$	1	1	1.

The quotient contributions sum to 99. Multiplying each row by its codon lift count gives codon contributions

$$2, 16, 12, 96, 96, 48, 192, 96, 16,$$

which sum to 574. □

Theorem 9462.1726 (Defect-flow theorem)**.** *The post-$M^\star$ minimal full trigger system carries a natural acyclic defect-lowering flow. Its height function is the overlap defect*

$$\delta \in \{0, 1, 2\},$$

its sinks are exactly the partition triggers, and the f_3-lift coordinates are passive along the flow.

Proof. Acyclicity follows because every directed edge lowers δ by one. The sink identification is Definition 9462.1722. The lift vector does not enter the definition of a defect-lowering move, so each quotient-level edge lifts horizontally across the corresponding f_3-fiber. □

Definition 9462.1727 (Partition core)**.** *Let A be a minimal full trigger. A partition core of A is a partition trigger P obtained from A by a maximal sequence of defect-lowering moves.*

Theorem 9462.1728 (Core count of a trigger)**.** *If A has shared-coordinate row sets R_a, then the number of partition cores below A is*

$$N_{\text{core}}(A) = \prod_{a \in H} |R_a|.$$

Proof. To obtain a terminal partition, each shared coordinate a must be assigned to exactly one of the supports in R_a. The choices for distinct shared coordinates are independent. □

Theorem 9462.1729 (Basin size of a partition core)**.** *Let $P = \{P_1, \ldots, P_m\}$ be a quotient-level partition trigger with block sizes $s_i = |P_i|$. The number of minimal triggers for which P is a partition core is*

$$B(P) = \prod_{i=1}^{m} \left((2^{m-1})^{s_i} - (2^{m-1} - 1)^{s_i} \right).$$

Proof. For a coordinate $a \in P_i$, a trigger above P must keep a in row i and may additionally place it in any subset of the other $m - 1$ rows. Thus a has 2^{m-1} decoration choices. To preserve the private-coordinate condition for row i, at least one coordinate in P_i must choose no additional row. Hence the number of legal decorations for block P_i is

$$(2^{m-1})^{s_i} - (2^{m-1} - 1)^{s_i}.$$

Multiplying over blocks gives the formula. □

Corollary 9462.1730 (Partition basin table)**.** *For four trigger coordinates, the quotient partition basins are*

partition type	*quotient partitions*	$B(P)$	*incidence*
4	1	1	1
$3+1$	4	7	28
$2+2$	3	9	27
$2+1+1$	6	7	42
$1+1+1+1$	1	1	$1.$

The quotient incidence total is 99*. At codon level the corresponding incidence counts are*

$$2, \quad 112, \quad 108, \quad 336, \quad 16,$$

which sum to 574*.*

Proof. Evaluate Definition 9462.1729 on the five partition types of a four-element set. At codon level, a partition with m blocks has 2^m lift choices. □

Corollary 9462.1731 (Balanced basin maximum)**.** *Among quotient partition types, the largest basin per partition core is the balanced type* $2+2$*, with basin size* 9*.*

Proof. The basin sizes in Definition 9462.1730 are $1, 7, 9, 7, 1$, so the maximum occurs at type $2+2$. □

Theorem 9462.1732 (Descending path count)**.** *For a minimal full trigger* A*, the number of maximal descending paths from* A *to the partition skeleton is*

$$N_{\text{path}}(A) = \delta(A)! \prod_{a \in H} |R_a|.$$

Proof. Fix a partition core below A. The multiset of duplicate incidences to be removed has cardinality $\delta(A)$, and any ordering of these removals gives a valid decreasing path to that fixed core. Hence each core receives $\delta(A)!$ paths. Multiplying by Definition 9462.1728 gives the formula. □

Theorem 9462.1733 (Total descending paths)**.** *The quotient-level defect flow has* 135 *maximal descending paths to the partition skeleton. The codon-level defect flow has* 766 *maximal descending paths.*

Proof. By quotient orbit type, the path contributions are

normal form	quotient count	paths per trigger	contribution
$\{1234\}$	1	1	1
$\{1, 234\}$	4	1	4
$\{12, 34\}$	3	1	3
$\{12, 234\}$	12	2	24
$\{123, 124\}$	6	8	48
$\{1, 2, 34\}$	6	1	6
$\{1, 24, 34\}$	12	2	24
$\{14, 24, 34\}$	4	6	24
$\{1, 2, 3, 4\}$	1	1	$1.$

These contributions sum to 135. Multiplying the same paths-per-trigger values by codon counts gives codon contributions

$$2, 16, 12, 96, 192, 48, 192, 192, 16,$$

which sum to 766. □

Theorem 9462.1734 (Partition basin theorem)**.** *The partition skeleton is an attracting incidence geometry for the post-$M^\star$ minimal trigger system. The trigger–partition correspondence has* 99 *quotient-level incidences and* 574 *codon-level incidences, and the defect flow has* 135 *quotient-level and* 766 *codon-level maximal descending paths to this skeleton.*

Proof. The incidence totals are Definition 9462.1725 and Definition 9462.1730. The descending path totals are Definition 9462.1733. Since a trigger can have more than one partition core, the basin relation is a correspondence rather than a function. □

Concretized in §4363: The finite partition-basin product formula and four-coordinate incidence rows are realized as block-size, decoration, defect, product, specialization, and incidence NameCert data.

Concretized in §??: Partition-basin finite counting is realized as concrete NameCert data.

Definition 9462.1735 (Partition basin defect polynomial)**.** *Let $P = \{P_1, \dots, P_m\}$ be a quotient-level partition core with block sizes $s_i = |P_i|$. Its basin defect polynomial is*

$$\mathcal{B}_P(q) = \sum_{A:\, P \text{ is a core of } A} q^{\delta(A)}.$$

Theorem 9462.1736 (Partition basin polynomial)**.** *For a partition core with block sizes $(s_1, \dots, s_m)$,*

$$\mathcal{B}_P(q) = \prod_{i=1}^{m} \left[(1+q)^{(m-1)s_i} - \left((1+q)^{m-1} - 1 \right)^{s_i} \right].$$

Proof. For a coordinate in block P_i, the core row i is fixed, while any subset of the other $m-1$ rows may be added. Choosing r additional rows contributes q^r, so one coordinate contributes $(1+q)^{m-1}$. A block of size s_i therefore has all decorations enumerated by $(1+q)^{(m-1)s_i}$. The private-coordinate condition excludes the case in which every coordinate of P_i receives at least one additional row; that excluded polynomial is $((1+q)^{m-1} - 1)^{s_i}$. Multiplying the legal block enumerators gives the displayed product. □

Corollary 9462.1737 (Four-coordinate basin polynomials)**.** *For four trigger coordinates, the partition-type basin polynomials are*

partition type	*quotient partitions*	$\mathcal{B}_P(q)$	$\mathcal{B}_P(1)$
4	1	1	1
$3+1$	4	$1+3q+3q^2$	7
$2+2$	3	$1+4q+4q^2$	9
$2+1+1$	6	$1+4q+2q^2$	7
$1+1+1+1$	1	1	1.

Proof. Substitute the five block-size types of a four-element set into Definition 9462.1736. □

Theorem 9462.1738 (Basin incidence polynomials)**.** *The quotient-level trigger–partition incidence polynomial is*

$$\mathcal{I}_q(q) = 15 + 48q + 36q^2.$$

The codon-level incidence polynomial is

$$\mathcal{I}_c(q) = 94 + 288q + 192q^2.$$

Thus $\mathcal{I}_q(1) = 99$ and $\mathcal{I}_c(1) = 574$.

Proof. Sum the rows of Definition 9462.1737, weighting by the number of quotient partitions of each type. For codon-level incidence, multiply a partition type with m blocks by 2^m lift cores. This gives

$$2 \cdot 1 + 16(1 + 3q + 3q^2) + 12(1 + 4q + 4q^2)$$
$$+48(1 + 4q + 2q^2) + 16 \cdot 1 = 94 + 288q + 192q^2.$$

□

Theorem 9462.1739 (Descending path polynomials)**.** *Weighting each defect-δ incidence by $\delta!$ gives*

$$\mathcal{P}_q(q) = 15 + 48q + 72q^2$$

and

$$\mathcal{P}_c(q) = 94 + 288q + 384q^2.$$

Thus $\mathcal{P}_q(1) = 135$ and $\mathcal{P}_c(1) = 766$.

Proof. For a fixed partition core below a trigger of defect δ, the duplicate incidences may be removed in $\delta!$ orders by Definition 9462.1732. Apply this factor to the coefficients of Definition 9462.1738. □

Corollary 9462.1740 (Basin-size averages)**.** *The codon-level partition skeleton has 94 cores and total incidence 574, so its average basin size is*

$$\frac{574}{94}.$$

The largest basin per core is the balanced type $2 + 2$, with size 9.

Proof. The average is total codon-level incidence divided by the number of codon-level partition cores. The maximum follows from Definition 9462.1737. □

Theorem 9462.1741 (Partition basin polynomial theorem)**.** *The defect-flow basins over the partition skeleton are completely enumerated by the product formula for $\mathcal{B}_P(q)$. In the codon case $(n, \ell) = (4, 2)$, the total codon-level basin incidence and descending path polynomials are*

$$\mathcal{I}_c(q) = 94 + 288q + 192q^2, \qquad \mathcal{P}_c(q) = 94 + 288q + 384q^2.$$

Proof. The product formula is Definition 9462.1736. The codon-level specialization is Definition 9462.1738 and Definition 9462.1739. □

Concretized in §4363: Partition basin polynomials are realized as finite block-size, decoration, defect, incidence, transport, replay, provenance, and NameCert rows.

Definition 9462.1742 (Partition-core incidence kernel)**.** *Let $\mathcal{P}_m$ be the set of m-block partition cores of $\Omega = \{1, 2, 3, 4\}$, and let $\mathcal{T}_m$ be the quotient-level minimal full triggers of size m. For $P \in \mathcal{P}_m$ and $A \in \mathcal{T}_m$, write $P \preceq A$ when the blocks of P can be matched to the supports of A so that every block is contained in its matched support. Equivalently, P is a partition core below A in the defect-lowering flow.*

The incidence matrix is

$$I_m(P, A) = \begin{cases} 1, & P \preceq A, \\ 0, & \text{otherwise}, \end{cases}$$

and the partition-core Gram kernel is

$$K_m = I_m I_m^{\mathsf{T}}.$$

Thus

$$K_m(P,Q) = |\{A \in \mathcal{T}_m : P \preceq A,\ Q \preceq A\}|.$$

Theorem 9462.1743 (Incidence decomposition by trigger size)**.** *The quotient-level partition-core incidence relation decomposes over $m = 1, 2, 3, 4$ with rows*

m	$\lvert\mathcal{P}_m\rvert$	$\lvert\mathcal{T}_m\rvert$	*incidences*
1	1	1	1
2	7	25	55
3	6	22	42
4	1	1	1.

The incidence total is 99.

Proof. A size-m trigger lowers only to an m-block partition core, so different values of m do not interact. The row counts are obtained by enumerating the partition cores and the quotient-level minimal triggers of Definition 9462.1530, then applying Definition 9462.1742. The total $1 + 55 + 42 + 1 = 99$ agrees with Definition 9462.1738. □

Theorem 9462.1744 (Two-block partition-core kernel)**.** *Order the two-block partition cores as*

$$1|234, \quad 2|134, \quad 3|124, \quad 4|123, \quad 12|34, \quad 13|24, \quad 14|23.$$

Then

$$K_2 = \begin{pmatrix} 7 & 1 & 1 & 1 & 3 & 3 & 3 \\ 1 & 7 & 1 & 1 & 3 & 3 & 3 \\ 1 & 1 & 7 & 1 & 3 & 3 & 3 \\ 1 & 1 & 1 & 7 & 3 & 3 & 3 \\ 3 & 3 & 3 & 3 & 9 & 2 & 2 \\ 3 & 3 & 3 & 3 & 2 & 9 & 2 \\ 3 & 3 & 3 & 3 & 2 & 2 & 9 \end{pmatrix}.$$

Equivalently,

$$K_2 = \begin{pmatrix} 6I_4 + J_4 & 3J_{4,3} \\ 3J_{3,4} & 7I_3 + 2J_3 \end{pmatrix}.$$

Proof. The first four rows are the $3+1$ partition cores and the last three rows are the $2+2$ partition cores. Direct evaluation of $K_2(P,Q) = |\{A : P \preceq A,\ Q \preceq A\}|$ gives the displayed matrix. The block expression groups equal entries by the two partition types. □

Theorem 9462.1745 (Spectrum of the two-block kernel)**.** *The spectrum of K_2 is*

$$22, \quad 7, 7, \quad 6, 6, 6, \quad 1.$$

The Perron eigenvector is constant on partition types, with relative weights

$$3 + 1 : 1, \qquad 2 + 2 : \frac{4}{3}.$$

Proof. In the block form of Definition 9462.1744, $6I_4 + J_4$ acts as 6 on the three-dimensional subspace orthogonal to $\mathbf{1}_4$, while $7I_3 + 2J_3$ acts as 7 on the two-dimensional subspace orthogonal to $\mathbf{1}_3$. The remaining two-dimensional quotient spanned by vectors constant on the $3+1$ and $2+2$ parts has eigenvalues 22 and 1. Solving the Perron equations on that quotient gives weight ratio $1 : 4/3$. □

Theorem 9462.1746 (Three-block partition-core kernel)**.** *Order the three-block partition cores as*

$$12|3|4, \quad 13|2|4, \quad 14|2|3, \quad 23|1|4, \quad 24|1|3, \quad 34|1|2.$$

Then

$$K_3 = \begin{pmatrix} 7 & 2 & 2 & 2 & 2 & 0 \\ 2 & 7 & 2 & 2 & 0 & 2 \\ 2 & 2 & 7 & 0 & 2 & 2 \\ 2 & 2 & 0 & 7 & 2 & 2 \\ 2 & 0 & 2 & 2 & 7 & 2 \\ 0 & 2 & 2 & 2 & 2 & 7 \end{pmatrix}.$$

Equivalently,

$$K_3 = 7I_6 + 2A(L(K_4)),$$

where the six partition cores are identified with the six edges of K_4.

Proof. Each three-block core has type $2 + 1 + 1$. Two such cores share the off-diagonal value 2 exactly when their two-element blocks share one coordinate, and share value 0 when those two-element blocks are disjoint. This is precisely the adjacency relation in the line graph $L(K_4)$, with diagonal basin size 7. □

Theorem 9462.1747 (Spectrum of the three-block kernel)**.** *The spectrum of K_3 is*

$$15, \quad 7, 7, 7, \quad 3, 3.$$

The Perron eigenvector is the constant vector.

Proof. The line graph $L(K_4)$ has adjacency spectrum

$$4, \quad 0, 0, 0, \quad -2, -2.$$

Since $K_3 = 7I_6 + 2A(L(K_4))$, the eigenvalues are $7 + 2 \cdot 4 = 15$, $7 + 2 \cdot 0 = 7$ with multiplicity 3, and $7 + 2(-2) = 3$ with multiplicity 2. The graph $L(K_4)$ is regular, so the Perron eigenvector is constant. □

Theorem 9462.1748 (Partition-core incidence kernel theorem)**.** *The partition skeleton of the post-$M^\star$ minimal trigger system carries a size-graded Gram kernel. Its nontrivial quotient-level spectra are*

$$\mathrm{Spec}(K_2) = \{22, 7, 7, 6, 6, 6, 1\},$$

and

$$\mathrm{Spec}(K_3) = \{15, 7, 7, 7, 3, 3\}.$$

At codon level the incidence counts are

$$2, \quad 220, \quad 336, \quad 16,$$

which sum to 574.

Proof. The size decomposition is Definition 9462.1743. The two nontrivial spectra are Definition 9462.1745 and Definition 9462.1747. A size-m quotient incidence has 2^m codon lifts, giving $2 \cdot 1$, $4 \cdot 55$, $8 \cdot 42$, and $16 \cdot 1$. □

Concretized in §4214: Finite partition-core incidence rows are realized as a concrete NameCert carrier.

Definition 9462.1749 (S_4 representation labels)**.** *Let S_4 act on the trigger coordinate set $\Omega = \{s_1, f_1, s_2, f_2\}$. Its irreducible real representations are denoted by*

symbol	*dimension*
$\mathbf{1}$	1
sgn	1
V	3
$V \otimes \mathrm{sgn}$	3
W	2.

Here V is the standard representation and W is the two-dimensional representation associated to the partition $2 + 2$.

Theorem 9462.1750 (Partition-core permutation modules)**.** *The S_4 permutation representations on m-block partition cores are*

m	$\mathbb{R}[\mathcal{P}_m]$
1	$\mathbf{1}$
2	$2\mathbf{1} \oplus V \oplus W$
3	$\mathbf{1} \oplus V \oplus W$
4	$\mathbf{1}$.

In particular, neither sgn *nor $V \otimes \mathrm{sgn}$ appears on the partition-core side.*

Proof. Compute the permutation character by counting fixed set partitions in each conjugacy class of S_4 and decompose against the character table of Definition 9462.1749. For $m = 2$, the partition cores split into the two orbits $3 + 1$ and $2 + 2$, giving two copies of the trivial representation. For $m = 3$, all cores have type $2 + 1 + 1$, giving only one copy of the trivial representation. □

Theorem 9462.1751 (Minimal-trigger permutation modules)**.** *The S_4 permutation representations on quotient-level size-m minimal full triggers are*

m	$\mathbb{R}[\mathcal{T}_m]$
1	$\mathbf{1}$
2	$4\mathbf{1} \oplus 4V \oplus (V \otimes \mathrm{sgn}) \oplus 3W$
3	$3\mathbf{1} \oplus 4V \oplus (V \otimes \mathrm{sgn}) \oplus 2W$
4	$\mathbf{1}$.

Proof. For each conjugacy class of S_4, count the size-m minimal full support families fixed by a representative coordinate permutation. The resulting permutation characters decompose against the same S_4 character table. The dimensions are $1, 25, 22, 1$, agreeing with Definition 9462.1530. □

Theorem 9462.1752 (Incidence kernel representation)**.** *The incidence map*

$$I_m : \mathbb{R}[\mathcal{T}_m] \longrightarrow \mathbb{R}[\mathcal{P}_m]$$

is S_4-equivariant. Its kernel representations are

m	$\ker I_m$
1	0
2	$\mathbf{21} \oplus 3V \oplus (V \otimes \mathrm{sgn}) \oplus 2W$
3	$\mathbf{21} \oplus 3V \oplus (V \otimes \mathrm{sgn}) \oplus W$
4	0.

Thus $V \otimes \mathrm{sgn}$ is entirely invisible to partition-core incidence.

Proof. Equivariance follows because relabeling coordinates commutes with the condition $P \preceq A$. The image is the full partition-core module in each nonzero size layer by Definition 9462.1743; hence the kernel multiplicities are obtained by subtracting Definition 9462.1750 from Definition 9462.1751. Since $V \otimes \mathrm{sgn}$ does not occur on the partition side, every such trigger-side component lies in the kernel. □

Theorem 9462.1753 (Representation meaning of the Gram spectra)**.** *The spectra of the partition-core Gram kernels are the S_4 isotypic decomposition of the partition-core modules:*

m	*eigenvalue*	*representation*
2	22, 1	*trivial two-plane*
2	7	W
2	6	V
3	15	$\mathbf{1}$
3	7	V
3	3	W.

Proof. The kernels $K_m = I_m I_m^{\mathsf{T}}$ commute with the S_4 action on $\mathbb{R}[\mathcal{P}_m]$. By Schur's lemma, they act by scalars on each irreducible isotypic summand, except that repeated trivial summands may mix. For $m = 2$, the two partition orbits $3+1$ and $2+2$ give a two-dimensional trivial sector whose eigenvalues are 22 and 1 by Definition 9462.1745; the W and V sectors carry eigenvalues 7 and 6. For $m = 3$, there is only one trivial summand, and Definition 9462.1747 gives the eigenvalues 15, 7, and 3 on $\mathbf{1}$, V, and W. □

Corollary 9462.1754 (Balanced bias and uniformity)**.** *The $m = 2$ Perron vector favors $2 + 2$ partition cores over $3 + 1$ partition cores with relative weight $4/3 : 1$. The $m = 3$ Perron vector is uniform.*

Proof. In the $m = 2$ layer, the two copies of $\mathbf{1}$ mix across the two partition-core orbits; the Perron vector in Definition 9462.1745 has relative weights $3+1 : 1$ and $2+2 : 4/3$. In the $m = 3$ layer, the partition-core representation has a single trivial summand, so the Perron vector is the constant vector by Definition 9462.1747. □

Theorem 9462.1755 (Representation-theoretic incidence theorem)**.** *For the full quotient-level partition-core incidence map*

$$I : \mathbb{R}[\mathcal{T}] \to \mathbb{R}[\mathcal{P}],$$

the source, target, and kernel decompose as

$$\mathbb{R}[\mathcal{P}] = 5\mathbf{1} \oplus 2V \oplus 2W,$$

$$\mathbb{R}[\mathcal{T}] = 9\mathbf{1} \oplus 8V \oplus 2(V \otimes \mathrm{sgn}) \oplus 5W,$$

and

$$\ker I = 4\mathbf{1} \oplus 6V \oplus 2(V \otimes \mathrm{sgn}) \oplus 3W.$$

The partition-basin spectra of Definition 9462.1748 are therefore representation-theoretic spectra.

Proof. Sum the four size layers in Definition 9462.1750, Definition 9462.1751, and Definition 9462.1752. The dimensions are 15, 49, and 34, with $49 - 15 = 34$. The spectral identification follows from Definition 9462.1753. □

Concretized in §4017: The finite partition-core incidence packet records the boundary-tile incidence kernel as NameCert data.

Definition 9462.1756 (BEDC local suffix support rank)**.** *On the stop face*

$$\mathsf{StopTrpFace} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\},$$

use UAA *as the local basepoint and read only the family coordinates of the second and third positions. Thus the suffix coordinate map is*

codon	*family suffix*	*support*	ρ_{BEDC}
UAA	00	$\varnothing$	0
UAG	01	$\{f_3\}$	1
UGA	10	$\{f_2\}$	1
UGG	11	$\{f_2, f_3\}$	2.

The local BEDC rank is the support size

$$\rho_{\mathrm{BEDC}}(c) = |\{i \in \{f_2, f_3\} : c_i \textit{ differs from the } \mathrm{UAA} \textit{ suffix coordinate}\}|.$$

Theorem 9462.1757 (Stop L-shape as rank deficiency)**.** *Under the two-axis readback and the standard-code biological bridge, the stop class in the* $\mathrm{U} + \mathrm{RR}$ *face is the proper-support part of the local two-coordinate square:*

$$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\} = \mathsf{StopTrpFace} \cap \{c : \rho_{\mathrm{BEDC}}(c) < 2\}.$$

Equivalently, the local BEDC legality condition is

$$\mathrm{supp}_{\mathrm{BEDC}}(c) \subsetneq \{f_2, f_3\}.$$

Proof. The suffix table in Definition 9462.1756 identifies UAA, UAG, and UGA with supports $\varnothing$, $\{f_3\}$, and $\{f_2\}$, respectively. These are exactly the proper subsets of $\{f_2, f_3\}$. The remaining corner UGG has full support $\{f_2, f_3\}$. The standard-code bridge labels the proper-support vertices as Stop and the full-support corner as Trp by Definition 9462.1154. □

Theorem 9462.1758 (Completion of the stop L-shape in the median closure)**.** *Let*

$$S_{\mathrm{BEDC}} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}.$$

Then

$$S_{\mathrm{BEDC}} \subset \mathcal{R}, \qquad \mathrm{UGG} \notin \mathcal{R},$$

but

$$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\} \subset \mathrm{Med}(\mathcal{R}).$$

In particular,

$$\mathrm{Med}(\mathcal{R}) \cap \mathsf{StopTrpFace} = \mathsf{StopTrpFace}.$$

Proof. The inclusion $S_{\mathrm{BEDC}} \subset \mathcal{R}$ and the exclusion $\mathrm{UGG} \notin \mathcal{R}$ are read from Definition 9462.1275. By Definition 9462.1320,

$$\mathrm{Med}(\mathcal{R}) = \mathrm{WNR} \cup \mathrm{CUN}.$$

Since $\mathsf{StopTrpFace} = \mathrm{URR}$ and $\mathrm{URR} \subset \mathrm{WNR}$, the whole four-point face lies in $\mathrm{Med}(\mathcal{R})$. □

Corollary 9462.1759 (Full-support corners have separated bridge roles)**.** *The full-support corner of the BEDC stop face is a retained sense corner:*

$$\mathrm{UGG} \in \mathrm{Med}(\mathcal{R}) \setminus \mathcal{R}.$$

The full-support corner of the post-$M^\star$ terminal trigger algebra is a global median trigger:

$$\mathrm{Med}(M^\star \cup \{\mathrm{AGU}\}) = Q_6, \qquad \mathrm{Med}(M^\star \cup \{\mathrm{AGC}\}) = Q_6.$$

Proof. The first statement follows from Definition 9462.1758. For the second, the two codons AGU and AGC have anchor support $\{s_1, f_1, s_2, f_2\}$ relative to CUY. Thus Definition 9462.1522 gives full-cube median closure. □

Theorem 9462.1760 (Rank-deficiency prototype)**.** *The local BEDC no-11 stop rule and the post-$M^\star$ blocker rule are the same proper-support law in two dimensions. Under the support identification $00 \leftrightarrow \varnothing$, $01 \leftrightarrow \{f_3\}$, $10 \leftrightarrow \{f_2\}$, and $11 \leftrightarrow \{f_2, f_3\}$,*

$$n = 2: \qquad X_2 = \{S : S \subsetneq \{f_2, f_3\}\},$$

and

$$n = 4: \qquad \mathcal{B} = \{B \subseteq Q_6 \setminus M^\star : J(B) \subsetneq \{s_1, f_1, s_2, f_2\}\}.$$

Thus the BEDC stop L-shape is the two-coordinate local prototype of the four-coordinate terminal trigger blocker algebra.

Proof. The $n = 2$ equality is Definition 9462.1757. The $n = 4$ equality is the definition of the blocker complex in Definition 9462.1547. Both say that proper supports are non-triggering or legal at their respective scale, while full support is the separated corner. □

Corollary 9462.1761 (Local and terminal blocker spheres)**.** *The local proper-support blocker for two coordinates has nerve $\partial\Delta^1 \cong S^0$, while the post-$M^\star$ blocker complex has homotopy type S^2:*

$$n = 2: \ S^0, \qquad n = 4: \ S^2.$$

Proof. For $n = 2$, the two maximal proper-support blockers omit f_2 and f_3, and their intersection is empty; the nerve is therefore two points. For $n = 4$, use Definition 9462.1552. □

Theorem 9462.1762 (BEDC rank-deficiency theorem)**.** *The BEDC stop-tile reading supplies a local rank-deficiency grammar:*

$$\textit{proper support in } \{f_2, f_3\} \Longleftrightarrow \mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}.$$

The post-$M^\star$ terminal trigger lattice supplies the global four-coordinate form:

$$B \textit{ is a non-trigger} \Longleftrightarrow J(B) \subsetneq \{s_1, f_1, s_2, f_2\}.$$

This is a conditional structural reconstruction inside the chosen two-axis readback and the external standard-code bridge. It is not a claim that Zeckendorf legality alone determines biological stop codons or that a full-support codon is biologically absent.

Proof. The local statement is Definition 9462.1757. The global statement is the trigger/blocker criterion of Definition 9462.1555. The final restriction is the cannot-claim boundary of Definition 9462.1206. □

Definition 9462.1763 (BEDC closure tower)**.** *The BEDC closure tower associated to the stop face is the chain*

$$\begin{gathered}\mathrm{U} = 00, \quad \mathrm{C} = 01, \quad \mathrm{A} = 10, \quad \mathrm{G} = 11,\\ \textit{proper support in } \{f_2, f_3\},\\ \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\} \subset \mathcal{R},\\ \mathsf{StopTrpFace} \subset \mathrm{Med}(\mathcal{R}),\\ M^\star = \mathrm{NNR} \cup \mathrm{CUY},\\ \textit{proper support in } \{s_1, f_1, s_2, f_2\}.\end{gathered}$$

The first proper-support layer is the based local system obtained from the $(2, 1)$ *coverage-blocker algebra by adjoining the basepoint* $00 \leftrightarrow \varnothing$*. The terminal layer is the* $(4, 2)$ *coverage-trigger algebra of Definition 9462.1617.*

Theorem 9462.1764 (BEDC-to-trigger prototype theorem)**.** *The BEDC stop-face grammar is the based* $(n, \ell) = (2, 1)$ *instance of the coverage-blocker law, while the post-*$M^\star$ *terminal trigger lattice is the* $(n, \ell) = (4, 2)$ *instance. In both cases the non-triggering or legal condition is proper support, and the full-support state is the separated corner.*

Proof. For the local BEDC face, the non-base supports are $\{f_2\}$, $\{f_3\}$, and $\{f_2, f_3\}$, with one lift. The proper-support part, together with the basepoint $\varnothing \leftrightarrow 00$, gives $\{00, 01, 10\}$, while the full support $\{f_2, f_3\}$ gives the 11 corner. This is Definition 9462.1757. For the terminal codon system, the four support coordinates are s_1, f_1, s_2, f_2 and the two lifts are the two f_3-family codons over the Y side; this is Definition 9462.1617. The full-trigger criterion is Definition 9462.1522. □

Corollary 9462.1765 (Topology of the BEDC closure tower)**.** *The blocker topology in the tower moves from*

$$\mathcal{B}_{2,1} \simeq S^0$$

at the local BEDC layer to

$$\mathcal{B}_{4,2} \simeq S^2$$

at the terminal post-$M^\star$ *layer.*

Proof. Apply the universal formula $\mathcal{B}_{n,\ell} \simeq S^{n-2}$ from Definition 9462.1611. The local stop-face layer has $n = 2$ and $\ell = 1$, while the terminal codon layer has $n = 4$ and $\ell = 2$ by Definition 9462.1764. □

Theorem 9462.1766 (BEDC closure tower theorem)**.** *The stop-tile BEDC reading, the reassignment support, the median closure, and the post-*$M^\star$ *trigger lattice form the closure tower*

$$\begin{gathered}\mathrm{BEDC}_{2,1} \longrightarrow \mathrm{Stop/Trp}\ X_2/11 \longrightarrow \mathcal{R} \longrightarrow \mathrm{Med}(\mathcal{R})\\ \longrightarrow M^\star \longrightarrow \mathrm{BEDC}_{4,2}.\end{gathered}$$

Here $\mathrm{BEDC}_{2,1}$ *denotes the based local proper-support grammar on the stop suffix coordinates, and* $\mathrm{BEDC}_{4,2}$ *denotes the post-*$M^\star$ *coverage-trigger algebra on* $\{s_1, f_1, s_2, f_2\}$ *with two* f_3 *lifts.*

Proof. The local stop-tile realization is Definition 9462.1154 and Definition 9462.1757. The inclusion of the stop seed in $\mathcal{R}$ and the recovery of the full $\mathsf{StopTrpFace}$ inside $\mathrm{Med}(\mathcal{R})$ are Definition 9462.1758. The post-$M^\star$ terminal trigger algebra is the $(4, 2)$ coverage-trigger instance by Definition 9462.1617. The common proper-support law is Definition 9462.1764. □

Concretized in §4090: The local stop/Trp suffix-support rank theorem is realized as a finite NameCert packet with source-window, boundary-tile, coverage, orbit, rank, ledger, transport, replay, provenance, and local naming rows.

Concretized in §7841: The rank-deficiency prototype is realized as a finite support-rank NameCert packet with support-universe, proper-support classifier, deficiency ledger, coverage-rank sibling, rank-nullity sibling, transport, replay, provenance, and local naming rows.

Definition 9462.1767 (Active median generator)**.** *Let $M = \mathrm{Med}(\mathcal{R})$. A subset $G \subseteq \mathcal{R}$ is an active median generator when*

$$\mathrm{Med}(G) = M.$$

It is minimal when no smaller subset of $\mathcal{R}$ has the same median closure.

Theorem 9462.1768 (Minimal active median generators)**.** *The minimum size of an active median generator is 7. There are exactly two generators of this size:*

$$\{\mathrm{AGG}, \mathrm{AUA}, \mathrm{CUA}, \mathrm{CUC}, \mathrm{CUU}, \mathrm{UAA}, \mathrm{UCA}\},$$
$$\{\mathrm{AGG}, \mathrm{AUA}, \mathrm{CUC}, \mathrm{CUG}, \mathrm{CUU}, \mathrm{UAA}, \mathrm{UCA}\}.$$

Proof. Enumerate all subsets $G \subseteq \mathcal{R}$ and compute $\mathrm{Med}(G)$ by iterating coordinatewise majority. No subset of size at most 6 generates M, and the two displayed subsets are exactly the size-7 subsets that generate M. □

Corollary 9462.1769 (Rigid median skeleton)**.** *The common part of the two minimum generators is*

$$\{\mathrm{AGG}, \mathrm{AUA}, \mathrm{CUC}, \mathrm{CUU}, \mathrm{UAA}, \mathrm{UCA}\}.$$

The only choice is between CUA *and* CUG*.*

Proof. Intersect the two generators in Definition 9462.1768. □

Definition 9462.1770 (Median-essential codon)**.** *A codon $c \in \mathcal{R}$ is median-essential when*

$$\mathrm{Med}(\mathcal{R} \setminus \{c\}) \neq \mathrm{Med}(\mathcal{R}).$$

Otherwise it is median-redundant.

Theorem 9462.1771 (Median-essential codons)**.** *The median-essential codons are exactly*

$$\mathrm{AGG}, \quad \mathrm{AUA}, \quad \mathrm{CUC}, \quad \mathrm{CUU}, \quad \mathrm{UCA}.$$

The remaining active codons are median-redundant.

Proof. For each codon $c \in \mathcal{R}$ compute $\mathrm{Med}(\mathcal{R} \setminus \{c\})$ and compare it with M. The closure sizes are

c	$\lvert \mathrm{Med}(\mathcal{R} \setminus \{c\}) \rvert$	preserves M
AAA	20	yes
AGA	20	yes
AGG	14	no
AUA	16	no
CUA	20	yes
CUC	19	no
CUG	20	yes
CUU	19	no
UAA	20	yes
UAG	20	yes
UCA	16	no
UGA	20	yes
UUA	20	yes.

□

Theorem 9462.1772 (Median deletion losses)**.** *The median-essential codons have the following closure losses:*

c	$M \setminus \mathrm{Med}(\mathcal{R} \setminus \{c\})$
AGG	AAG, ACG, AGG, AUG, UCG, UGG
AUA	ACA, ACG, AUA, AUG
UCA	ACA, ACG, UCA, UCG
CUC	CUC
CUU	CUU.

Proof. Subtract each deletion closure from M for the five median-essential codons of Definition 9462.1771. □

Corollary 9462.1773 (Weight and median generation differ)**.** *High reassignment weight is not the same as median-generating importance. In particular* UGA*,* UAA*,* UAG*,* AGA*, and* AAA *are median-redundant, even though several of them have high reassignment weight.*

Proof. This is the redundant part of the deletion table in Definition 9462.1771. □

Theorem 9462.1774 (Complementary active pairs)**.** *The reassigned support contains exactly two complementary pairs:*

$$\{\mathrm{CUC}, \mathrm{AGA}\}, \qquad \{\mathrm{CUU}, \mathrm{AGG}\}.$$

Each pair has Hamming distance 6 *in* Q_6*.*

Proof. Using $U = 00$, $C = 01$, $A = 10$, and $G = 11$, the bit words of CUC and AGA are complementary, and the same holds for CUU and AGG. No other pair in $\mathcal{R}$ has all six bits opposite. □

Corollary 9462.1775 (Convex hull is too coarse)**.** *The geodesic convex hull of* $\mathcal{R}$ *is all of* Q_6*, already witnessed by either complementary pair in Definition 9462.1774.*

Proof. In a hypercube, the interval between complementary vertices is the whole cube. □

Definition 9462.1776 (Q_2 completion closure)**.** *For $S \subseteq Q_6$, define $\mathrm{Comp}_{Q_2}(S)$ by iterating the rule that whenever a Q_2 face contains at least three current vertices, the whole face is adjoined.*

Theorem 9462.1777 (Single-deletion completion robustness)**.** *For every active codon $c \in \mathcal{R}$,*

$$\mathrm{Comp}_{Q_2}(\mathcal{R} \setminus \{c\}) = Q_6.$$

Proof. Delete each of the 13 active codons and run the finite Q_2-completion iteration. Every deletion case reaches all 64 vertices. □

Theorem 9462.1778 (Minimal percolating seeds)**.** *Among subsets of $\mathcal{R}$, the minimum size of a Q_2-completion seed that percolates to Q_6 is 7. There are 484 such size-7 seeds.*

Proof. Enumerate all subsets $G \subseteq \mathcal{R}$ and compute $\mathrm{Comp}_{Q_2}(G)$. No subset of size at most 6 percolates to Q_6, while 484 subsets of size 7 do. □

Theorem 9462.1779 (Generator-closure robustness)**.** *The reassigned support is rigid in median generation and robust in Q_2-completion:*

$$\textit{minimum active median generators: } 2 \textit{ subsets of size } 7,$$
$$\textit{minimum } Q_2\textit{-percolating seeds: } 484 \textit{ subsets of size } 7.$$

Thus the median closure identifies a small rigid generating skeleton, whereas Q_2-completion records a broad percolation capacity.

Proof. Combine Definition 9462.1768, Definition 9462.1777, and Definition 9462.1778. □

Concretized in §3837: Generator closure robustness is realized as finite active-generator, deletion-loss, Q2-completion, and trigger-closure NameCert data.

Definition 9462.1780 (Purine-suffix hotspot cube)**.** *Let*

$$W := \{\mathrm{U}, \mathrm{A}\}, \qquad R := \{\mathrm{A}, \mathrm{G}\}.$$

The purine-suffix hotspot cube is the axis-aligned Q_3 cube

$$\begin{aligned} C_{\mathrm{WRR}} &:= W \times R \times R \\ &= \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}, \mathrm{AAA}, \mathrm{AAG}, \mathrm{AGA}, \mathrm{AGG}\}. \end{aligned}$$

In the six-bit atlas its free coordinates are

$$b_1^s, \qquad b_2^f, \qquad b_3^f,$$

with $b_1^f = 0$, $b_2^s = 1$, and $b_3^s = 1$ fixed.

Theorem 9462.1781 (Purine-suffix hotspot count)**.** *In the standard-to-comparative reassignment spectrum of Definition 9462.1208, C_{WRR} contains 52 of the 65 reassignment rows:*

codon	*standard label*	*reassignment rows*
UAA	Stop	8
UAG	Stop	10
UGA	Stop	15
UGG	Trp	0
AAA	Lys	3
AAG	Lys	0
AGA	Arg	8
AGG	Arg	8
total		52.

Proof. Restrict the finite reassignment enumeration of Definition 9462.1210 to the eight codons of Definition 9462.1780. Summing the displayed codon counts gives

$$8 + 10 + 15 + 0 + 3 + 0 + 8 + 8 = 52.$$

□

Concretized in §3840: The purine-suffix hotspot cube is realized as a finite NameCert packet over cube vertex rows, reassignment-count ledgers, layer and transfer-square classifiers, sibling dependency rows, transport, replay, provenance, and local naming.

Corollary 9462.1782 (Comparative variation is concentrated in the hotspot cube)**.** *The cube C_{WRR} has eight codons, hence one eighth of the codon carrier, but it contains four fifths of the standard-to-comparative reassignment rows:*

$$\frac{8}{64} = \frac{1}{8}, \qquad \frac{52}{65} = \frac{4}{5}.$$

Proof. The carrier size is 64 by Definition 9462.1073. The reassignment count is Definition 9462.1781. □

Theorem 9462.1783 (The hotspot cube is the highest-scoring Q_3 cube)**.** *For an axis-aligned Q_3 cube $C \subset Q_6$, let*

$$S(C) := \sum_{c \in C} m(c),$$

where $m(c)$ is the number of comparative reassignment rows at codon c. Among the 160 *axis-aligned Q_3 cubes, the unique highest score is*

$$S(C_{\mathrm{WRR}}) = 52.$$

The next highest score is 41*.*

Proof. Enumerate the $\binom{6}{3}2^3 = 160$ axis-aligned Q_3 cubes and sum the codon-level reassignment counts on each cube. The cube C_{WRR} has the vertex set displayed in Definition 9462.1780 and score 52 by Definition 9462.1781. The same enumeration gives 41 as the second-largest score. □

Definition 9462.1784 (Layers of the hotspot cube)**.** *The first-base layers of C_{WRR} are*

$$U \times R \times R = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\},$$
$$A \times R \times R = \{\mathrm{AAA}, \mathrm{AAG}, \mathrm{AGA}, \mathrm{AGG}\}.$$

Under the standard classifier, the first layer is $\mathrm{Stop}_3 + \mathrm{Trp}_1$ *and the second layer is* $\mathrm{Lys}_2 + \mathrm{Arg}_2$*. Hence the whole cube has standard pattern* $3 + 2 + 2 + 1$*.*

Definition 9462.1785 (Transfer square)**.** *The transfer square is the Q_2 face*

$$Q_{\mathrm{transfer}} := \{\mathrm{UGA}, \mathrm{UGG}, \mathrm{AGA}, \mathrm{AGG}\} \subset C_{\mathrm{WRR}}.$$

It varies the first-base shape bit and the third-base family bit while keeping the second base fixed at G *and the third base in the purine layer. In the standard classifier its pattern is*

$$\mathrm{Stop}_1 + \mathrm{Trp}_1 + \mathrm{Arg}_2.$$

Theorem 9462.1786 (Vertebrate mitochondrial transfer square)**.** *In the vertebrate mitochondrial comparison table, the transfer square changes from*

	A	G
UG	Stop	Trp
AG	Arg	Arg

to

	A	G
UG	Trp	Trp
AG	Stop	Stop.

Proof. On Q_{transfer}, the standard classifier assigns UGA to Stop, UGG to Trp, and both AGA and AGG to Arg. In the vertebrate mitochondrial comparison row, UGA is assigned to Trp while AGA and AGG are assigned to Stop; UGG remains Trp. The two displayed tables are therefore the direct restriction of the two classifiers to the transfer square. □

Corollary 9462.1787 (AGA/AGG belongs to the hotspot transfer geometry)**.** *The AGA/AGG pair is the A-layer edge of the transfer square, coupled by the first-position shape direction to the UGA/UGG edge.*

Proof. The Hamming edges AGA $\leftrightarrow$ UGA and AGG $\leftrightarrow$ UGG differ only in b_1^s. Both edges lie inside Q_{transfer} by Definition 9462.1785. □

Definition 9462.1788 (Arg and Ser satellite edges)**.** *In the standard classifier,*

$$\begin{aligned}\text{Arg} &= \{\text{CGU}, \text{CGC}, \text{CGA}, \text{CGG}\} \sqcup \{\text{AGA}, \text{AGG}\},\\ \text{Ser} &= \{\text{UCU}, \text{UCC}, \text{UCA}, \text{UCG}\} \sqcup \{\text{AGU}, \text{AGC}\}.\end{aligned}$$

The two-point summands are the Arg and Ser satellite edges.

Theorem 9462.1789 (Arg satellite is active while Ser satellite is stable)**.** *Across the comparative reassignment spectrum, the Arg main box* $\{\text{CGU}, \text{CGC}, \text{CGA}, \text{CGG}\}$ *has no reassignment rows, while its satellite edge has*

$$m(\text{AGA}) = 8, \qquad m(\text{AGG}) = 8.$$

The Ser satellite edge has

$$m(\text{AGU}) = m(\text{AGC}) = 0.$$

Proof. Restrict the codon-level reassignment count m to the displayed standard Arg and Ser fibers. The four codons in the Arg main box have count zero. The Arg satellite counts are both eight, while the Ser satellite counts are both zero. □

Corollary 9462.1790 (AGR is the active purine satellite)**.** *The active satellite is not any detached two-codon sense edge. It is specifically the purine satellite*

$$\text{AGR} = \{\text{AGA}, \text{AGG}\} \subset C_{\text{WRR}},$$

whereas the pyrimidine-side Ser satellite $\text{AGY} = \{\text{AGU}, \text{AGC}\}$ *remains stable in the comparison.*

Proof. The activity and stability counts are Definition 9462.1789. The inclusion $\text{AGR} \subset C_{\text{WRR}}$ is immediate from Definition 9462.1780. □

Theorem 9462.1791 (AGA/AGG reassignment targets)**.** *The observed AGA/AGG reassignment rows have the following pair targets:*

table identifiers	AGA	AGG
2	Stop	Stop
$5, 9, 14, 21$	Ser	Ser
13	Gly	Gly
$24, 33$	Ser	Lys.

Proof. Compare the AGA and AGG assignments in each non-standard table with the standard Arg assignment. The tables with a change are exactly the rows displayed, grouped by the resulting pair of labels. □

Theorem 9462.1792 (Hotspot cube cannot-claim boundary)**.** *The hotspot-cube spectrum does not license any claim that purine suffixes cause genetic-code reassignment, that the displayed comparison family is biologically exhaustive, that the vertebrate mitochondrial row is a temporal ancestor of the other rows, or that the AGA/AGG edge has already been reduced to a biochemical mechanism.*

Proof. The hotspot cube is a finite bridge-side spectrum over curated translation classifiers. It records codon positions, labels, local cube geometry, and reassignment counts. It does not supply biochemical causality, evolutionary ordering, exhaustive biological coverage, or a mechanistic model of tRNA, release-factor, or ribosome behavior. □

Corollary 9462.1793 (Allowed hotspot-cube claim)**.** *Under the two-axis codon bridge, the main comparative deformation region is the purine-suffix cube C_{WRR}. It contains the Stop/Trp tile, the Lys/Arg purine layer, the transfer square, and the active Arg satellite edge, and it is the highest-scoring Q_3 cube under codon-level reassignment counts.*

Proof. Combine Definition 9462.1781, Definition 9462.1783, Definition 9462.1784, Definition 9462.1785, and Definition 9462.1789. □

Definition 9462.1794 (Hotspot state vector)**.** *For a genetic-code table t, the C_{WRR} state vector is*

$$\begin{aligned} S_t(C_{\mathrm{WRR}}) := (&E_t(\mathrm{UAA}), E_t(\mathrm{UAG}), E_t(\mathrm{UGA}), E_t(\mathrm{UGG}), \\ &E_t(\mathrm{AAA}), E_t(\mathrm{AAG}), E_t(\mathrm{AGA}), E_t(\mathrm{AGG})). \end{aligned}$$

This is a finite assignment vector over the hotspot cube, not a claim about biochemical transition time.

Theorem 9462.1795 (Hotspot state spectrum)**.** *Across the current curated genetic-code tables, the one-letter assignment vectors $S_t(C_{\mathrm{WRR}})$ realize 19 distinct states. The standard hotspot state*

$$(*, *, *, W, K, K, R, R)$$

appears in exactly the tables

$$1, \quad 11, \quad 12, \quad 23, \quad 26.$$

Proof. For each table, read the eight assignments in the order fixed by Definition 9462.1794 and identify equal one-letter assignment vectors. The finite enumeration gives 19 distinct vectors. The vector equal to the standard one occurs precisely in the five displayed table identifiers. □

Theorem 9462.1796 (Invariant anchors of the hotspot cube)**.** *The codons* UGG *and* AAG *are invariant across the comparison family:*

$$E_t(\mathrm{UGG}) = W, \qquad E_t(\mathrm{AAG}) = K$$

for every table t in the comparison.

Proof. The codon-level reassignment counts in Definition 9462.1781 are zero for UGG and AAG. Their standard labels are W and K, respectively. □

Corollary 9462.1797 (Active hotspot support)**.** *The active support of the hotspot cube is the six-point set*

$$C_{\mathrm{active}} = C_{\mathrm{WRR}} \setminus \{\mathrm{UGG}, \mathrm{AAG}\} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{AAA}, \mathrm{AGA}, \mathrm{AGG}\}.$$

Proof. Remove the two invariant anchors of Definition 9462.1796 from the eight vertices of Definition 9462.1780. □

Definition 9462.1798 (Reassignment-set preorder)**.** *For codons x and y, write*

$$x \preceq y$$

when every table that reassigns x also reassigns y:

$$\Delta(x) \subseteq \Delta(y).$$

This is an observed inclusion relation on finite comparison rows. It is not a causality relation.

Theorem 9462.1799 (Arg satellite reassignment is contained in UGA reassignment)**.** *The Arg satellite codons satisfy*

$$\Delta(\mathrm{AGA}) = \Delta(\mathrm{AGG}) \subseteq \Delta(\mathrm{UGA}).$$

Moreover,

$$|\Delta(\mathrm{AGA})| = |\Delta(\mathrm{AGG})| = |\Delta(\mathrm{AGA}) \cap \Delta(\mathrm{UGA})| = |\Delta(\mathrm{AGG}) \cap \Delta(\mathrm{UGA})| = 8.$$

Proof. The finite reassignment enumeration gives

$$\Delta(\mathrm{AGA}) = \{2, 5, 9, 13, 14, 21, 24, 33\},$$
$$\Delta(\mathrm{AGG}) = \{2, 5, 9, 13, 14, 21, 24, 33\}.$$

Each displayed table identifier also lies in $\Delta(\mathrm{UGA})$. The cardinality and co-occurrence equations follow. □

Theorem 9462.1800 (AAA reassignment is a deeper hotspot event)**.** *The lysine codon* AAA *satisfies*

$$\Delta(\mathrm{AAA}) \subseteq \Delta(\mathrm{UGA}) \cap \Delta(\mathrm{AGA}) \cap \Delta(\mathrm{AGG}),$$

and $|\Delta(\mathrm{AAA})| = 3$.

Proof. The finite comparison gives

$$\Delta(\mathrm{AAA}) = \{9, 14, 21\}.$$

Each of these table identifiers also reassigns UGA, AGA, and AGG. Thus the displayed inclusion holds, with cardinality three. □

Theorem 9462.1801 (Ile/Met active point is contained in UGA reassignment)**.** *The Ile/Met active point satisfies*

$$\Delta(\mathrm{AUA}) \subseteq \Delta(\mathrm{UGA}), \qquad |\Delta(\mathrm{AUA})| = 5.$$

Proof. The AUA-to-Met reassignment occurs in exactly the tables $2, 3, 5, 13, 21$, as recorded in Definition 9462.1222. Each of those tables also reassigns UGA. □

Corollary 9462.1802 (Core reassignment preorder)**.** *Inside the hotspot core, the observed reassignment inclusions include*

$$\mathrm{AUA} \preceq \mathrm{UGA}, \qquad \mathrm{AGA} \preceq \mathrm{UGA}, \qquad \mathrm{AGG} \preceq \mathrm{UGA},$$

and

$$\mathrm{AAA} \preceq \mathrm{AGA}, \qquad \mathrm{AAA} \preceq \mathrm{AGG}, \qquad \mathrm{AAA} \preceq \mathrm{UGA}.$$

Proof. This is the preorder notation of Definition 9462.1798 applied to Definition 9462.1799, Definition 9462.1800, and Definition 9462.1801. □

Definition 9462.1803 (Core hotspot support)**.** *The core hotspot support is*

$$\mathcal{H}_{\mathrm{core}} := C_{\mathrm{WRR}} \cup \{\mathrm{AUA}\}.$$

It has nine codons. Its state vector appends $E_t(\mathrm{AUA})$ *to* $S_t(C_{\mathrm{WRR}})$*.*

Theorem 9462.1804 (Core hotspot captures most reassignment rows)**.** *The support* C_{WRR} *captures* 52 *of the* 65 *reassignment rows. The support* $\mathcal{H}_{\mathrm{core}}$ *captures* 57 *of the* 65 *reassignment rows:*

$$\frac{52}{65} = \frac{4}{5}, \qquad \frac{57}{65} \approx 0.877.$$

The one-letter assignment vectors on $\mathcal{H}_{\mathrm{core}}$ *realize* 21 *distinct states across the comparison family.*

Proof. The first count is Definition 9462.1781. The codon AUA contributes five reassignment rows by Definition 9462.1801. Since AUA is not a vertex of C_{WRR}, the combined support captures $52 + 5 = 57$ rows. Enumerating the resulting nine-coordinate assignment vectors gives 21 distinct states. □

Corollary 9462.1805 (Finite state reading of the hotspot core)**.** *The comparative spectrum can be read as a finite state system on* $\mathcal{H}_{\mathrm{core}}$*: two coordinates of* C_{WRR} *are fixed anchors,* UGA *is the main reassignment hub, the Arg satellite edge is contained in UGA reassignment,* AAA *appears only inside the stronger hotspot event, and* AUA *couples the Ile/Met control tile to the same UGA hub.*

Proof. The fixed anchors are Definition 9462.1796. The inclusion relations are Definition 9462.1802. The nine-point support and capture count are Definition 9462.1804. □

Theorem 9462.1806 (Hotspot state-system cannot-claim boundary)**.** *The finite state reading does not license any claim that* UGA *causes the other reassignments, that table identifiers are temporal steps, that the observed preorder is an evolutionary tree, that all unobserved states are biologically impossible, or that the nine-point support determines translation dynamics without context.*

Proof. The construction uses finite assignment vectors and inclusion relations among observed reassignment sets. It has no temporal parameter, no mechanistic biochemical transition rule, no exhaustive biological state space, and no ribosome-context model. These would require separate external biological bridge rows. □

Corollary 9462.1807 (Allowed hotspot state-system claim)**.** *Under the two-axis codon bridge and the curated comparison family, standard-to-comparative genetic-code variation is strongly compressed by the nine-point support* $\mathcal{H}_{\text{core}}$*. The support captures* 57 *of* 65 *reassignment rows and organizes the main observed co-occurrences through the reassignment-set preorder.*

Proof. Combine Definition 9462.1804 and Definition 9462.1802. □

Concretized in §2368: WRR hotspot state vectors are realized as finite state, anchor, reassignment-preorder, table-provenance, transport, replay, and NameCert rows.

Definition 9462.1808 (Partial-aware core state)**.** *The partial-aware core state of a genetic-code table is the* $\mathcal{H}_{\text{core}}$ *state vector of Definition 9462.1803, except that ambiguous table rows are kept as separate labels. Thus a row such as* UGA = Stop *or* Trp *is recorded as* $*|W$ *rather than being collapsed to* W *or to* $*$*.*

Theorem 9462.1809 (Partial-aware core state spectrum)**.** *Across the comparison family, the partial-aware core states realize* 22 *distinct states. The standard core state*

$$(*, *, *, W, K, K, R, R, I)$$

appears in exactly the tables

$$1, \quad 11, \quad 12, \quad 23, \quad 26.$$

Proof. Read the nine core coordinates in the order

$$\text{UAA}, \text{UAG}, \text{UGA}, \text{UGG}, \text{AAA}, \text{AAG}, \text{AGA}, \text{AGG}, \text{AUA},$$

using the main one-letter row except when the difference table records an ambiguous row. Equal nine-tuples are then identified. The finite enumeration gives 22 distinct states, with the standard tuple appearing in the five displayed table identifiers. □

Definition 9462.1810 (Strict core state graph)**.** *Let* $G_1(\mathcal{H}_{\text{core}})$ *be the graph whose vertices are the distinct partial-aware core states. Two vertices are adjacent when their nine-coordinate assignment vectors differ in exactly one coordinate.*

Theorem 9462.1811 (Strict core state graph components)**.** *The graph* $G_1(\mathcal{H}_{\text{core}})$ *has* 9 *connected components. Their sizes are*

$$10, \quad 4, \quad 2, \quad 1, \quad 1, \quad 1, \quad 1, \quad 1, \quad 1.$$

The component containing the standard state has ten vertices represented by the table groups

$$\{1, 11, 12, 23, 26\}, \quad \{32\}, \quad \{25\}, \quad \{16, 22\}, \quad \{15\},$$
$$\{6\}, \quad \{27\}, \quad \{10\}, \quad \{4\}, \quad \{3\}.$$

The next two nontrivial components are represented by

$$\{5\}, \{21\}, \{9\}, \{14\}$$

and

$$\{24\}, \{33\}.$$

Proof. Enumerate the 22 partial-aware core states of Definition 9462.1809. For each pair of states, compute the Hamming distance of the nine assignment coordinates. Add an edge exactly when this distance is one. A finite connected-component computation gives the displayed component count, component sizes, and table-group representatives. □

Corollary 9462.1812 (Single-coordinate dynamics is insufficient)**.** *The observed core states are not connected by strict single-coordinate changes. A state-system reading therefore requires module-level moves in addition to codon-coordinate Hamming edges.*

Proof. If strict single-coordinate moves connected the observed core state space, the graph $G_1(\mathcal{H}_{\mathrm{core}})$ would be connected. By Definition 9462.1811, it has nine connected components. □

Definition 9462.1813 (Observed module generators)**.** *The observed module generators are schematic reassignment moves on the core support:*

generator	*support*
g_{UGA}	$\{\mathrm{UGA}\}$
$g_{\mathrm{UAA/UAG}}$	$\{\mathrm{UAA}, \mathrm{UAG}\}$
g_{AGR}	$\{\mathrm{AGA}, \mathrm{AGG}\}$
g_{AUA}	$\{\mathrm{AUA}\}$
g_{AAA}	$\{\mathrm{AAA}\}$.

The labels record supports, not mechanistic causes. Each generator has several observed target labels, such as g_{AGR} *sending* (R, R) *to* $(*, *)$, (S, S), (G, G), *or* (S, K).

Concretized in §2306: The partial-aware strict core-state graph is realized as finite state, edge, component, module-generator, transport, replay, provenance, and NameCert rows.

Theorem 9462.1814 (Module generators explain strict graph separation)**.** *Several observed core states differ from the standard state by a module combination rather than by a single coordinate. For example:*

table	*core module difference from standard*
2	$g_{\mathrm{UGA}} + g_{\mathrm{AUA}} + g_{\mathrm{AGR}}$
5	$g_{\mathrm{UGA}} + g_{\mathrm{AUA}} + g_{\mathrm{AGR}}$
9	$g_{\mathrm{UGA}} + g_{\mathrm{AGR}} + g_{\mathrm{AAA}}$
24	$g_{\mathrm{UGA}} + g_{\mathrm{AGR}}$
33	$g_{\mathrm{UAA/UAG}} + g_{\mathrm{UGA}} + g_{\mathrm{AGR}}$.

Proof. Project each displayed table to the nine core coordinates and compare with the standard core state. Table 2 changes UGA, AUA, and the AGA/AGG pair. Table 5 has the same support pattern with a different AGR target. Table 9 changes UGA, the AGR pair, and AAA. Table 24 changes UGA and the AGR pair. Table 33 changes a stop-arm coordinate, UGA, and the AGR pair. These are module-support differences, not single-coordinate edges from the standard state. □

Corollary 9462.1815 (Core dynamics uses hub, arm, satellite, leaf, and anchor roles)**.** *The core state graph separates roles:* UGA *is the hub coordinate,* UAA/UAG *forms a stop arm,* AGA/AGG *forms the active satellite pair,* AUA *is the Ile/Met leaf coupled to the hub,* AAA *is a deeper hotspot point, and* UGG *and* AAG *are fixed anchors.*

Proof. The hub and inclusion relations are Definition 9462.1802. The stop arm, satellite pair, leaf, and deeper point are the supports in Definition 9462.1813. The anchors are Definition 9462.1796. □

Definition 9462.1816 (Active core support partition)**.** *The active core support is obtained from* $\mathcal{H}_{\text{core}}$ *by removing the two invariant anchors* UGG *and* AAG*:*

$$\mathcal{A}_{\text{core}} = \{\text{UAA}, \text{UAG}, \text{UGA}, \text{AAA}, \text{AGA}, \text{AGG}, \text{AUA}\}.$$

A support partition of $\mathcal{A}_{\text{core}}$ *is a set partition of these seven coordinates. Given such a partition, two observed partial-aware core states are module-adjacent when their active coordinates differ inside exactly one block of the partition.*

Theorem 9462.1817 (Unique finest connected support partition)**.** *Among all* 877 *set partitions of* $\mathcal{A}_{\text{core}}$*, exactly* 52 *make the observed partial-aware core state graph connected. Among the connected partitions, the unique finest one is*

$$\{\text{UAA}, \text{UAG}\}, \quad \{\text{UGA}\}, \quad \{\text{AAA}\},$$
$$\{\text{AGA}, \text{AGG}\}, \quad \{\text{AUA}\}.$$

Proof. There are $B_7 = 877$ set partitions of the seven active coordinates. For each partition, compress each observed state to its blockwise coordinates and add an edge when two states differ in exactly one block. The finite enumeration gives 52 connected partitions. The maximum number of blocks among connected partitions is 5, and the only connected partition with 5 blocks is the displayed one. □

Corollary 9462.1818 (Stop arm and AGR satellite are forced blocks)**.** *The two non-singleton blocks in the unique finest connected partition are precisely the stop arm* $\{\text{UAA}, \text{UAG}\}$ *and the AGR satellite pair* $\{\text{AGA}, \text{AGG}\}$*.*

Proof. This is the non-singleton part of Definition 9462.1817. □

Theorem 9462.1819 (Finest module graph edge spectrum)**.** *For the unique finest connected support partition, the module graph on the* 22 *observed partial-aware core states is connected and has* 42 *edges. The edge labels are distributed as follows:*

module	*edge count*
$\{\text{UAA}, \text{UAG}\}$	25
$\{\text{UGA}\}$	7
$\{\text{AAA}\}$	1
$\{\text{AGA}, \text{AGG}\}$	7
$\{\text{AUA}\}$	2.

Proof. Use the partition of Definition 9462.1817. For every pair of observed states, count the blocks on which their active coordinates differ. Add an edge exactly when this count is one, and label the edge by that block. The resulting graph is connected and the finite edge count gives the displayed spectrum. □

Corollary 9462.1820 (Two centrality readings)**.** *The core comparison separates two centrality notions. The codon* UGA *is the principal reassignment hub by occurrence count, while the stop arm* $\{\text{UAA}, \text{UAG}\}$ *is the largest horizontal connector in the finest module graph.*

Proof. The codon-level hub property is Definition 9462.1802. The module edge maximum is the 25-edge stop-arm row of Definition 9462.1819. □

Theorem 9462.1821 (Standard-state module graph distances)**.** *In the finest module graph, the standard core state has degree* 9*. The shortest-path distance distribution from the standard state is*

distance	*state count*
0	1
1	9
2	4
3	5
4	1
5	1
6	1.

The diameter of the finest module graph is 9*.*

Proof. Run breadth-first search in the connected module graph of Definition 9462.1819, using the standard partial-aware state as the source. The degree and distance distribution are the displayed values. A breadth-first search from each vertex gives maximum shortest-path length 9. □

Theorem 9462.1822 (Unique finest generator system)**.** *Under the single condition that the observed partial-aware core states be connected by one-block module adjacency, the unique finest generator support system is*

$$\{\mathrm{UAA}, \mathrm{UAG}\}, \quad \{\mathrm{UGA}\}, \quad \{\mathrm{AAA}\}, \quad \{\mathrm{AGA}, \mathrm{AGG}\}, \quad \{\mathrm{AUA}\}.$$

Proof. By Definition 9462.1817, this is the unique connected support partition with the maximum number of blocks. Assigning one schematic generator to each block gives the stated support system, and uniqueness follows from uniqueness of the partition. □

Definition 9462.1823 (Module activation pattern)**.** *For the unique finest generator support system, write*

$$S = \{\mathrm{UAA}, \mathrm{UAG}\}, \qquad U = \{\mathrm{UGA}\}, \qquad N = \{\mathrm{AAA}\},$$
$$R = \{\mathrm{AGA}, \mathrm{AGG}\}, \qquad I = \{\mathrm{AUA}\}.$$

For a comparison table, a module is active when at least one coordinate inside that module differs from the standard assignment. The module activation pattern is the subset of $\{S, U, N, R, I\}$ *consisting of active modules.*

Theorem 9462.1824 (Observed module activation patterns)**.** *The comparison family realizes*

exactly 11 *module activation patterns:*

pattern	*table identifiers*
$\varnothing$	$1, 11, 12, 23, 26$
U	$4, 10, 25$
S	$6, 15, 16, 22, 29, 30, 32$
$U + I$	3
$U + R$	24
$S + U$	$27, 28, 31$
$U + R + I$	$2, 5, 13$
$U + N + R$	9
$S + U + R$	33
$U + N + R + I$	21
$S + U + N + R$	$14.$

Proof. For each table, compare the seven active coordinates with the standard assignment and mark a module active when any coordinate in that block differs. Identifying equal active-module subsets gives exactly the eleven displayed rows. □

Theorem 9462.1825 (Five-variable activation grammar)**.** *The observed module activation patterns are exactly the Boolean solutions on variables S, U, N, R, I satisfying*

$$R \Rightarrow U, \qquad I \Rightarrow U, \qquad N \Rightarrow R, \qquad S \wedge I = 0.$$

Proof. Necessity is a direct finite check on Definition 9462.1824: every row containing R contains U, every row containing I contains U, every row containing N contains R, and no row contains both S and I.

For sufficiency, enumerate the Boolean solutions. If $U = 0$, then $R = I = N = 0$, while S is free, giving $\varnothing$ and S. If $U = 1$ and $I = 0$, then S is free and (R, N) can be $(0, 0)$, $(1, 0)$, or $(1, 1)$, giving

$$U, \quad S + U, \quad U + R, \quad S + U + R, \quad U + N + R, \quad S + U + N + R.$$

If $U = 1$ and $I = 1$, then $S = 0$, and (R, N) again gives

$$U + I, \quad U + R + I, \quad U + N + R + I.$$

Thus the grammar has $2 + 6 + 3 = 11$ solutions, and the solution list is exactly the list in Definition 9462.1824. □

Corollary 9462.1826 (Hub, dependent branches, and transverse arm)**.** *The activation grammar separates four roles: U is a necessary hub for R, I, and N; N is dependent on the AGR satellite branch through $N \Rightarrow R$; the AUA leaf is dependent on U; and the stop arm S is a transverse axis that may occur with or without U but is disjoint from the AUA branch in the observed comparison family.*

Proof. Each role is one of the four clauses in Definition 9462.1825, together with the fact that both S and $S + U$ occur in Definition 9462.1824. □

Theorem 9462.1827 (Module value spectrum)**.** *Across the comparison family, the five modules have the following observed value spectra:*

module	*value count*	*values*
S	10	$(*,*),(*,Q),(*,L),(*,W),(Q,Q),(Q\|*,Q\|*),(Y,*),(Y,Y),(E,E),(E\|*,E\|*)$
U	5	$*,W,C,G,*\|W$
N	2	K,N
R	5	$(R,R),(*,*),(S,S),(G,G),(S,K)$
I	2	$I,M.$

Proof. Read each table on the active coordinates and group the coordinates by the unique finest support partition of Definition 9462.1817. The finite enumeration of distinct block values gives the displayed spectra. □

Theorem 9462.1828 (Four-branch module value grammar)**.** *The* 22 *observed module-value states are exactly the states generated by the following four branches.*

branch	*constraint*	*state cour*
A	$U=*,\ N=K,\ R=(R,R),\ I=I,\ S\in\{(*,*),(Q,Q),(*,Q),(*,L),(Y,Y),(E,E),(*,W)\}$	7
B	$S=(*,*),\ N=K,\ R=(R,R),\ I=I,\ U\in\{C,G\}$	2
C	$U=*\|W,\ N=K,\ R=(R,R),\ I=I,\ S\in\{(Q,Q),(Q\|*,Q\|*)\}$	2
D	$U=W$ *and one of the observed deep states*	11.

The deep branch consists of the eleven tuples

$$(*,*)/W/K/(R,R)/I,\quad (*,*)/W/K/(R,R)/M,\quad (E|*,E|*)/W/K/(R,R)/I,$$
$$(*,*)/W/K/(*,*)/M,\quad (*,*)/W/K/(S,S)/M,\quad (*,*)/W/K/(G,G)/M,$$
$$(*,*)/W/N/(S,S)/I,\quad (Y,*)/W/N/(S,S)/I,\quad (*,*)/W/N/(S,S)/M,$$
$$(*,*)/W/K/(S,K)/I,\quad (Y,*)/W/K/(S,K)/I.$$

Proof. The four displayed branches contain $7+2+2+11=22$ states. Direct finite enumeration of the module-value states obtained from the comparison family gives 22 states, and the generated set equals the observed set. □

Corollary 9462.1829 (Trp value as deep entrance)**.** *Among the nonstandard values of U, only $U=W$ opens the deep coupled branch. The values $U=C$ and $U=G$ occur only in the pure U branch, and $U=*|W$ occurs only in the partial-boundary branch.*

Proof. This is the branch separation in Definition 9462.1828. □

Theorem 9462.1830 (Deep value constraints)**.** *The observed module-value states satisfy the following value-level constraints:*

$$R\neq(R,R)\Rightarrow U=W,$$
$$I=M\Rightarrow U=W\ \text{ and }\ S=(*,*),$$
$$N=N\Rightarrow U=W\ \text{ and }\ R=(S,S),$$
$$R\in\{(*,*),(G,G)\}\Rightarrow I=M,\ S=(*,*),\ N=K,$$
$$R=(S,K)\Rightarrow I=I,\ N=K,\ U=W.$$

Proof. Check the four branches of Definition 9462.1828. In the first three branches, $R = (R, R)$ except for no case, $I = I$, and $N = K$. In the deep branch, the displayed eleven tuples verify each implication coordinatewise. □

Corollary 9462.1831 (AGR as value splitter)**.** *The AGR module is a value splitter inside the deep branch. The value $(*, *)$ is tied to the $I = M$ leaf, (S, S) is the only background in which $N = N$ occurs, (G, G) is tied to the $I = M$ leaf, and (S, K) is a split satellite value with $I = I$ and $N = K$.*

Proof. This is a restatement of the last three implications in Definition 9462.1830, restricted to the nonstandard values of R. □

Theorem 9462.1832 (Core state graph cannot-claim boundary)**.** *The strict core state graph and module generators do not license any claim that the observed tables form a temporal trajectory, that the generators are biochemical mutation mechanisms, that every generator can occur independently in nature, or that the finite comparison family exhausts all possible code states.*

Proof. The graph is built from observed assignment vectors and Hamming distances between them. The module generators summarize observed supports of difference from the standard state. Neither construction supplies time, mechanism, independence, or biological exhaustiveness. □

Corollary 9462.1833 (Allowed module-state claim)**.** *The partial-aware core comparison is best read as a finite module-state system: strict single-coordinate adjacency is disconnected, while the observed differences organize into hub, arm, satellite, leaf, deeper point, and anchor roles.*

Proof. The disconnection is Definition 9462.1812. The role decomposition is Definition 9462.1815. □

Definition 9462.1834 (Module-value monotone path)**.** *Let a module-value state be written as*

$$X = (S, U, N, R, I).$$

For a target state $T = (S_T, U_T, N_T, R_T, I_T)$, a path from the standard state to T is target-monotone when each step changes exactly one module from its standard value to its target value, and no step changes a module away from its target value.

Theorem 9462.1835 (Observed monotone-path exceptions)**.** *Among the 22 observed module-value states, exactly 19 admit a target-monotone path from the standard state using only observed states. The three exceptions are represented by table identifiers*

$$9, \qquad 14, \qquad 28.$$

Their module-value states are

$$(*, *)/W/N/(S, S)/I,$$
$$(Y, *)/W/N/(S, S)/I,$$
$$(Q|*, Q|*)/*|W/K/(R, R)/I.$$

Proof. For each observed target, enumerate all orders in which its nonstandard modules can be changed from their standard values to their target values. A target is accepted exactly when at least one such prefix path lies entirely in the observed state set. The finite enumeration rejects exactly the three displayed states. □

Definition 9462.1836 (Candidate latent states)**.** *The deep-branch candidate latent states are*

$$L_{SS} = (*,*)/W/K/(S,S)/I$$

and

$$L_N = (*,*)/W/N/(R,R)/I.$$

The partial-boundary candidate latent states are

$$L_{*|W} = (*,*)/*|W/K/(R,R)/I$$

and

$$L_{Q|*} = (Q|*, Q|*)/*/K/(R,R)/I.$$

They are not observed table states in the comparison family; they are prefix states implied by the target-monotone support geometry.

Theorem 9462.1837 (Minimal latent completions)**.** *The minimum latent completion size is* 2*. There are exactly four minimum completions:*

$$\{L_{SS}, L_{*|W}\}, \qquad \{L_{SS}, L_{Q|*}\},$$
$$\{L_N, L_{*|W}\}, \qquad \{L_N, L_{Q|*}\}.$$

Proof. The three exceptions in Definition 9462.1835 split into two independent missing squares. Tables 9 and 14 require one deep-branch prefix, either L_{SS} or L_N. Table 28 requires one partial-boundary prefix, either $L_{*|W}$ or $L_{Q|*}$. A single latent state cannot be a prefix for both missing squares, so size 1 is insufficient. The Cartesian product of the two binary choices gives the four displayed size-2 completions, and each removes all three target-monotone exceptions. □

Concretized in §3521: Latent-completion packets realize the finite monotone-path completion witness for the module-state exception geometry.

Definition 9462.1838 (Canonical latent completion)**.** *The canonical latent completion is*

$$\mathcal{L}_{\text{can}} = \{L_{SS}, L_{*|W}\}.$$

It is the minimum completion selected by the value-direction readings $U = W \to R = (S,S) \to N = N$ *and* $U = *|W \to S = (Q|*, Q|*)$.

Concretized in §7831: Canonical latent-completion packets realize the selected two-state target-monotone completion route.

Theorem 9462.1839 (Canonical target-monotone completion)**.** *After adjoining the canonical latent completion to the observed module-value state set, every observed state admits a target-monotone path from the standard state.*

Proof. For the deep branch, L_{SS} supplies the path

$$(*,*)/*/K/(R,R)/I \to (*,*)/W/K/(R,R)/I \to L_{SS}$$
$$\to (*,*)/W/N/(S,S)/I \to (Y,*)/W/N/(S,S)/I.$$

For the partial-boundary branch, $L_{*|W}$ supplies the path

$$(*,*)/*/K/(R,R)/I \to L_{*|W}$$
$$\to (Q|*, Q|*)/*|W/K/(R,R)/I.$$

The remaining 19 observed states already have target-monotone paths by Definition 9462.1835. □

Theorem 9462.1840 (Latent completion graph compression)**.** *The observed module-value graph has* 22 *nodes,* 42 *edges, diameter* 9*, and maximum distance* 6 *from the standard state to an observed state. After adjoining* L_{SS}*, the graph has* 23 *nodes,* 46 *edges, diameter* 7*, and maximum standard-to-observed distance* 4*. After also adjoining* $L_{*|W}$*, the graph has* 24 *nodes,* 52 *edges, diameter* 5*, and maximum standard-to-observed distance* 4*.*

Proof. In each graph, connect two states exactly when they differ in one module value. Compute all-pairs shortest-path distances and the distances from the standard state to the observed vertices. The finite graph enumeration gives the displayed node counts, edge counts, diameters, and standard-source radii. □

Corollary 9462.1841 (Observed states as sampled endpoints)**.** *The comparison family should not be read as a complete smooth state space. It is better read as a finite sample of stable or recorded endpoints, while the module-value grammar also identifies prefix states that are not present as named observed tables.*

Proof. The missing target-monotone prefixes are precisely the latent states of Definition 9462.1836, and their addition removes all target-monotone exceptions by Definition 9462.1839. □

Corollary 9462.1842 (AUA detour is not a forced premise)**.** *The observed graph alone can route some paths toward* $N = N$ *through states with* $I = M$*, but the latent-completed graph gives a direct target-monotone route*

$$U = W, \qquad R = (S, S), \qquad N = N$$

without passing through $I = M$*. Thus the stable implication is*

$$N = N \Rightarrow R = (S, S) \Rightarrow U = W,$$

not a requirement that $I = M$ *precede* $N = N$*.*

Proof. The direct route is the L_{SS} route in Definition 9462.1839. It reaches the table-9 state before any change in the I module. □

Definition 9462.1843 (Canonical rewrite edge)**.** *In the canonical completed state set, a directed rewrite edge* $X \to Y$ *exists when* X *and* Y *differ in exactly one module,* X *has the standard value in that module, and* Y *has a nonstandard value there.*

Theorem 9462.1844 (Canonical rewrite reachability)**.** *The canonical completed state set has* 24 *states. Its directed rewrite graph has* 26 *edges, and every state in the completed set is reachable from the standard state. In particular, all* 22 *observed states are reachable.*

Proof. Enumerate the 22 observed states together with L_{SS} and $L_{*|W}$. Add directed edges according to Definition 9462.1843. The finite enumeration gives 26 directed edges, and graph search from the standard state reaches all 24 states. □

Theorem 9462.1845 (Latent-completed grammar boundary)**.** *The latent-completed graph does not claim that the two latent states are currently observed biological codes, that every target-monotone edge is a biochemical transition, or that the comparison family contains every stable biological endpoint.*

Proof. The construction uses finite module-value states and graph completion under a target-monotone prefix criterion. It supplies a structural completion of the observed state set, not a temporal or mechanistic biological assertion. □

Concretized in §3470: The six-boundary tile coverage packet realizes the trigger-support and coverage-rank rows as finite NameCert data.

9462.28.22 Codon-window spectral inverse dynamics

The codon-window bridge treats RNA and DNA codons as local six-bit states, while keeping the biological genetic-code table outside BEDC kernel primitives. The inverse thesis is local rather than global:

$$\mathsf{Codon} = Q_6 = \{0,1\}^6,$$
$$\mathrm{Stop}_{\mathsf{std}} = \mathrm{U} + \mathrm{RR} + X_2,$$
$$\mathrm{Stop}_{\mathsf{std}} \neq X_6.$$

The inverse question asks how much codon-window structure can be recovered from finite spectra of a classifier. A single global fiber histogram gives the degeneracy profile but not the table. Adding local Q_2-face spectra, Hamming adjacency spectra, and comparative reassignment spectra sharply constrains the local mechanisms detected in subsection 9462.28.21: the dual 11-control tiles, the two 00-singleton Phe/Leu tiles, and the finite local deformations visible across compared genetic-code tables.

Definition 9462.1846 (Window-six spectral inverse bridge status)**.** *The bridge* $\mathsf{CodonWindowSpectralInverse}^{\uparrow}$ *is a* $\mathsf{VisionSeed/BiologicalBridge}$ *target and a finite-enumeration paper-certificate candidate. It is not a BEDC kernel primitive and is not a checked certificate. A future certificate would separate source, pattern, classifier, stability, and ledger fields for the finite codon cube, the two-axis readback, the coding table, the inverse spectra, local tile classifications, adjacency rows, reassignment rows, and biological table provenance.*

Definition 9462.1847 (Two-axis codon atlas)**.** *Let*

$$\Sigma := \{\mathrm{U}, \mathrm{C}, \mathrm{A}, \mathrm{G}\}.$$

The external biological readback is

$$\mathrm{U/T} = (\mathrm{Y}, \mathrm{W}) = 00 \quad \mathrm{C} = (\mathrm{Y}, \mathrm{S}) = 01,$$
$$\mathrm{A} = (\mathrm{R}, \mathrm{W}) = 10 \quad \mathrm{G} = (\mathrm{R}, \mathrm{S}) = 11.$$

Here Y/R *is the pyrimidine/purine axis and* W/S *is the AU-family/GC-family axis. This is a coordinate choice for a biological bridge, not a BEDC primitive.*

Theorem 9462.1848 (Codon cube)**.** *The coordinate map*

$$\beta : \Sigma^3 \to Q_6$$

obtained by concatenating the three two-bit base coordinates is a finite bijection.

Proof. Each base has a unique two-bit coordinate. Hence a three-base codon has a unique six-bit display. Conversely, every six-bit word splits uniquely into three two-bit blocks, each of which decodes to exactly one base. □

Corollary 9462.1849 (Carrier and classifier are distinct)**.** *The equality* $\mathsf{Codon} = Q_6$ *describes the raw local microstate carrier. A genetic-code table is a classifier*

$$E_{\mathsf{std}} : Q_6 \to \mathsf{AminoAcidClass} \oplus \mathsf{Stop},$$

not the identity map on Q_6*.*

Definition 9462.1850 (Local stop face)**.** *The stop face is the local Q_2 face*

$$\mathsf{StopTrpFace} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\},$$

where the first base is U *and the last two bases are purines. Its family-suffix coordinates are*

$$\begin{aligned} \mathrm{AA} &\longmapsto 00 \quad \mathrm{AG} \longmapsto 01, \\ \mathrm{GA} &\longmapsto 10 \quad \mathrm{GG} \longmapsto 11. \end{aligned}$$

Let

$$X_2 := \{00, 01, 10\}, \qquad Q_2 = X_2 \sqcup \{11\}.$$

Theorem 9462.1851 (Three-stop reconstruction)**.** *Under the family-suffix no-*11 *condition inside the stop face,*

$$\mathsf{ZStopCandidate} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}.$$

Proof. The four purine-purine suffixes are AA, AG, GA, and GG, with family coordinates 00, 01, 10, and 11. The local condition excludes exactly the 11 corner, namely GG, and retains the other three suffixes. Prefixing by U gives UAA, UAG, and UGA. □

Corollary 9462.1852 (UGG continuation corner)**.** *Inside the standard-code biological bridge,*

$$\mathrm{UGG} = \mathrm{U} + \mathrm{RR} + 11$$

is the unique non-stop corner adjacent to the stop L-shape. It is a reserved continuation corner, not an absent or biologically illegal state.

Theorem 9462.1853 (Local stop theorem is not global X_6)**.** *The standard stop set is not a subset of the global no-adjacent-*11 *language*

$$X_6 := \{w \in \{0,1\}^6 : w \textit{ has no adjacent substring } 11\}.$$

Proof. The flattened displays are

$$\begin{aligned} \mathrm{UAA} &= 001010, \\ \mathrm{UAG} &= 001011, \\ \mathrm{UGA} &= 001110. \end{aligned}$$

The first word has no adjacent 11, while the latter two do. Therefore the stop structure is local X_2 inside the $\mathrm{U} + \mathrm{RR}$ face, not global X_6. □

Theorem 9462.1854 (Finite local face domain)**.** *The codon cube Q_6 has exactly*

$$\binom{6}{2} 2^4 = 240$$

axis-aligned Q_2 faces.

Proof. Choose the two free bit coordinates in $\binom{6}{2}$ ways. Assign fixed values to the remaining four coordinates in 2^4 ways. The resulting faces are exactly the axis-aligned Q_2 faces of Q_6. □

Theorem 9462.1855 (Dual control tiles)**.** *The standard-code bridge contains two $X_2/\{11\}$ control tiles:*

$$\begin{aligned} \mathrm{AU} + X_2 &= \{\mathrm{AUU}, \mathrm{AUC}, \mathrm{AUA}\} = \mathrm{Ile}, \\ \mathrm{AU} + 11 &= \{\mathrm{AUG}\} = \mathrm{Met}, \\ \mathrm{U} + \mathrm{RR} + X_2 &= \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\} = \mathrm{Stop}, \\ \mathrm{U} + \mathrm{RR} + 11 &= \{\mathrm{UGG}\} = \mathrm{Trp}. \end{aligned}$$

In initiation context, the AUG *row also carries the canonical start bridge row.*

Proof. In the AU face, the varying third-base coordinates are U = 00, C = 01, A = 10, and G = 11. In the U + RR face, the varying purine-purine suffix coordinates are AA = 00, AG = 01, GA = 10, and GG = 11. The displayed labels are supplied by the standard genetic-code bridge. □

Corollary 9462.1856 (Local 11 is reserved)**.** *Across the two control tiles,*

$$\mathrm{AU} + 11 = \mathrm{AUG} = \mathrm{Met/Start}, \qquad \mathrm{U} + \mathrm{RR} + 11 = \mathrm{UGG} = \mathrm{Trp}.$$

Thus local 11 *is separated as a singleton or control-sensitive corner inside the biological bridge. It is not a biological deletion rule.*

Definition 9462.1857 (Coding classifier and global histogram)**.** *Let $D := Q_6$ and let C be a finite set of coding classes. A coding table is a surjective classifier*

$$E : D \to C.$$

For $c \in C$, define

$$d_E(c) := |E^{-1}(c)|, \qquad H_E(k) := |\{c \in C : d_E(c) = k\}|.$$

Theorem 9462.1858 (Global histogram identities)**.** *For any finite surjection $E : D \to C$,*

$$|C| = \sum_k H_E(k), \qquad |D| = \sum_k k\, H_E(k).$$

Proof. Each coding class contributes one fiber, so summing fibers over all sizes gives $|C|$. A fiber of size k contributes k domain states, so the weighted sum gives $|D|$. □

Corollary 9462.1859 (Standard-code degeneracy spectrum)**.** *For the standard genetic-code bridge,*

k	1	2	3	4	6
$H_{\mathsf{std}}(k)$	2	9	2	5	3.

Thus

$$2 + 9 + 2 + 5 + 3 = 21$$

and

$$1 \cdot 2 + 2 \cdot 9 + 3 \cdot 2 + 4 \cdot 5 + 6 \cdot 3 = 64.$$

The singleton classes are Met *and* Trp*, while the tripleton classes are* Ile *and* Stop*.*

Proof. This is finite enumeration of the standard genetic-code bridge table, with the displayed equalities supplied by Definition 9462.1858. □

Theorem 9462.1860 (Global histogram is incomplete)**.** *A single global histogram H_E does not uniquely determine the coding table E.*

Proof. A histogram fixes only the multiset of fiber sizes. It does not specify which points of D belong to which fibers. If the fiber sizes are $s_1, \ldots, s_m$, then any partition of the 64 codons into blocks of those sizes defines a classifier with the same histogram. For unlabeled classes, the number of such partitions has the form

$$\frac{64!}{\prod_i s_i! \prod_k H_E(k)!}.$$

Hence the histogram constrains the table but is not a complete invariant. □

Definition 9462.1861 (Enhanced inverse spectrum)**.** *Let $F \subseteq Q_6$ range over all axis-aligned Q_2 faces, and let $H(E|_F)$ denote the label multiplicity pattern on F, such as 4, $3+1$, $2+2$, $2+1+1$, or $1+1+1+1$. Define*

$$H_2(E) := \{H(E|_F) : F \subseteq Q_6,\ F \simeq Q_2\}.$$

When a face has pattern $3+1$, it is a local $3+1$ tile. It is an 11-control tile when the three-point class occupies X_2 and the singleton class occupies the local 11 corner. It is a 00-singleton tile when the singleton class occupies the local 00 corner and the three-point class occupies $Q_2 \setminus \{00\}$.

Put the Hamming graph on Q_6 and define

$$A_E(i,j) := |\{(x,y) : x \sim y,\ E(x) = i,\ E(y) = j\}|.$$

For a baseline table E and a compared table E' on the same codon carrier, define the reassignment row

$$M(E,E') := \{x \in Q_6 : E'(x) \neq E(x)\}.$$

When E is fixed, write M_E for the selected finite family of such comparison rows, with each row recorded together with its local tile coordinate when applicable. The enhanced inverse spectrum is

$$\mathsf{InvSpec}(E) := (H_E, H_2(E), A_E, M_E).$$

Theorem 9462.1862 (Singleton and tripleton spectra direct local search)**.** *If a codon classifier has singleton classes and tripleton classes, then the minimal local geometric search target is an axis-aligned Q_2 face with a $3+1$ split.*

Proof. A singleton and a tripleton have total support $1+3=4$. The smallest axis-aligned cube with four points is Q_2, so the natural finite local search object is a Q_2 face partitioned as a $3+1$ split. This is a search principle rather than a uniqueness theorem; uniqueness requires the local face spectrum. □

Corollary 9462.1863 (Standard spectrum locates the control tiles)**.** *Under the standard-code bridge, the singleton/tripleton spectrum points to the two core control tiles*

$$\text{Ile/Met} = \text{AU} + X_2/11, \qquad \text{Stop/Trp} = \text{U} + \text{RR} + X_2/11.$$

Proof. The singleton classes are Met and Trp, and the tripleton classes are Ile and Stop by Definition 9462.1859. The local Q_2 enumeration is Definition 9462.1162. □

Theorem 9462.1864 (Standard local $3+1$ face inventory)**.** *Under the two-axis readback and the standard genetic-code bridge, the axis-aligned Q_2 faces with $3+1$ translation-class splits are exactly*

face	*three-point class*	*singleton class*	*singleton corner*
$\{\mathrm{AUU}, \mathrm{AUC}, \mathrm{AUA}, \mathrm{AUG}\}$	Ile	Met	11
$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\}$	Stop	Trp	11
$\{\mathrm{UUU}, \mathrm{UUA}, \mathrm{CUU}, \mathrm{CUA}\}$	Leu	Phe	00
$\{\mathrm{UUC}, \mathrm{UUG}, \mathrm{CUC}, \mathrm{CUG}\}$	Leu	Phe	00.

Proof. This is the finite enumeration of the 240 axis-aligned Q_2 faces under the standard translation table, recorded in Definition 9462.1160. □

Corollary 9462.1865 (Phe/Leu sense-expansion tiles)**.** *The two Phe/Leu $3+1$ faces are* 00*-singleton tiles rather than* 11*-control tiles. They supply a sense-expansion mechanism distinct from the* Ile/Met *and* Stop/Trp 11*-control mechanism.*

Proof. In the two Phe/Leu rows of Definition 9462.1864, the singleton corner is 00 and the three-point class is $Q_2 \setminus \{00\}$. This is exactly the definition of a 00-singleton tile. □

Theorem 9462.1866 (Boundary and continuation reconstruction)**.** *In the Stop/Trp tile, the X_2 side reconstructs halt/release behavior and the* 11 *corner reconstructs continuation:*

$$X_2 = \{00, 01, 10\} \Longrightarrow \mathsf{Stop/halt\text{-}release},$$
$$11 \Longrightarrow \mathrm{Trp}/\mathsf{continuation}.$$

Proof. The standard-code bridge assigns UAA, UAG, and UGA to Stop, while UGG is assigned to Trp. Stop rows trigger termination, whereas the tryptophan row is a sense assignment. Thus the local $3+1$ face supports the displayed boundary/continuation reading. □

Definition 9462.1867 (Leaf and arm reassignment)**.** *In an $X_2 \sqcup \{11\}$ tile, a leaf reassignment occurs when one point of the X_2 tripleton class joins the class containing the* 11 *corner. In the stop L-shape $X_2 = \{00, 01, 10\}$, an arm reassignment occurs when an edge such as $\{00, 01\}$ or $\{00, 10\}$ is reassigned as a unit from* Stop *to a sense class.*

Proposition 9462.1868 (Dual 10-to-11 reassignment)**.** *In genetic-code bridges where* AUA *is assigned to* Met *and* UGA *is assigned to* Trp*, both changes have the same local form:*

$$10 \textit{ joins the class containing } 11.$$

Proof. In the Ile/Met tile, $\mathrm{AUA} = \mathrm{AU} + 10$ and $\mathrm{AUG} = \mathrm{AU} + 11$. In the Stop/Trp tile, $\mathrm{UGA} = \mathrm{U} + \mathrm{RR} + 10$ and $\mathrm{UGG} = \mathrm{U} + \mathrm{RR} + 11$. Assigning AUA with AUG or assigning UGA with UGG therefore has the same coordinate action. □

Proposition 9462.1869 (Stop-arm reassignment)**.** *In genetic-code bridges where* UAA *and* UAG *are assigned together to a sense class, the pair is the $\{00, 01\}$ arm of the stop L-shape.*

Proof. The stop-face coordinates are $\mathrm{UAA} = 00$, $\mathrm{UAG} = 01$, and $\mathrm{UGA} = 10$. Hence $\{\mathrm{UAA}, \mathrm{UAG}\} = \{00, 01\}$ is one edge of the L-shape $01 - 00 - 10$. □

Definition 9462.1870 (Local translation state)**.** *A local translation state has the schematic form*

$$S_t := (f_t, w_t, r_t, \kappa_t),$$

where f_t is reading frame, $w_t \in Q_6$ is the current codon window, r_t records ribosome or release-factor state, and κ_t records local sequence and cellular context. The schematic transition rule is

$$E(w_t) \in \mathsf{AminoAcidClass} \quad \Longrightarrow \quad S_t \to S_{t+1},$$
$$E(w_t) = \text{Stop} \quad \Longrightarrow \quad S_t \to S_{\mathsf{halt}}.$$

A stochastic refinement records rows $P(\delta \mid w_t, \kappa_t)$.

Theorem 9462.1871 (Stop tile is a local halt boundary)**.** *Under the standard-code bridge,*

$$\mathrm{U} + \mathrm{RR} + X_2 = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$$

is a local halt boundary in translation dynamics.

Proof. The equality is Definition 9462.1851. By Definition 9462.1870, a codon classified as Stop transitions to S_{halt}. □

Theorem 9462.1872 (Enhanced inverse spectrum)**.** *The enhanced inverse spectrum*

$$\mathsf{InvSpec}(E) = (H_E, H_2(E), A_E, M_E)$$

recovers or strongly constrains global compression, singleton/tripleton classes, local $3+1$ Q_2 tiles, reserved control corners, boundary/continuation behavior, and local leaf or arm reassignment patterns in compared genetic-code tables.

Proof. The component H_E gives class count and support size by Definition 9462.1858, but is incomplete by Definition 9462.1860. The local spectrum $H_2(E)$ attaches multiplicity patterns to concrete Q_2 faces. The adjacency spectrum A_E records one-bit class boundaries, including L-shape centers and leaves. The reassignment spectrum M_E records finite comparison rows across biological bridge tables or controlled perturbation rows. Together these spectra reduce arbitrary partitions of Q_6 to a small family of structured local mechanisms. □

Definition 9462.1873 (Finite and empirical work surface)**.** *The finite formalization target is to define the two-axis readback, Q_6, Q_2, X_2, the standard-code classifier, the global histogram, the* 240 *local Q_2 faces, the exact list of $3+1$ faces, and the spectrum $\mathsf{InvSpec}(E) = (H_E, H_2(E), A_E, M_E)$. The biological research surface then compares genetic-code tables, stop assignments, codon usage, readthrough, ribosome-profiling pause rows, release-factor context, and synthetic reporter rows for terminal windows*

$$\mathrm{UAA}, \quad \mathrm{UAG}, \quad \mathrm{UGA}, \quad \mathrm{UGG}.$$

The empirical layer tests termination efficiency, readthrough rate, protein output, mRNA abundance, ribosome pausing, and decay rate. These measurements guide bridge choice but do not replace BEDC proof or certificate obligations.

Theorem 9462.1874 (Spectral inverse cannot-claim boundary)**.** *The spectral inverse bridge does not license any claim that Zeckendorf alone proves the biological genetic code, that the whole genetic code is the window-six fold or global X_6, that standard stop codons are universal across every genetic code, that a local DNA or RNA* 11 *corner is the BEDC channel terminator, that* 11 *is biologically*

illegal or deleted, that UGG *is tryptophan by BEDC logic alone, that a single global histogram uniquely determines the genetic code, that alternative genetic-code tables contradict the model, that ribosome dynamics are determined by codon identity alone, or that* $\mathsf{CodonWindowSpectralInverse}^{\uparrow}$ *is already a checked certificate.*

Proof. The global X_6 refusal follows from Definition 9462.1853. The histogram refusal follows from Definition 9462.1860. The local 11 refusal follows from Definition 9462.1856. The biological-label and dynamics refusals follow because genetic-code tables and translation kinetics enter only through external bridge data. The checked-status refusal follows from Definition 9462.1846. □

Corollary 9462.1875 (Allowed spectral inverse claim)**.** *Under the two-axis RNA/DNA bridge, codons form* Q_6*. The standard stop class is a local* $\mathrm{U} + \mathrm{RR} + X_2$ *halt boundary, not a global* X_6 *law. The enhanced inverse spectrum* $(H_E, H_2(E), A_E, M_E)$ *reconstructs or strongly constrains local coding mechanisms such as the* Ile/Met *and* Stop/Trp *control tiles, the Phe/Leu* 00*-singleton tiles, and their local reassignment patterns in compared genetic-code tables.*

Concretized in §2161: Codon-window spectral inverse packets realize the finite cube, local face spectra, stop-face reconstruction, adjacency rows, and provenance as NameCert data.

Concretized in §5177: The channel genetic-code bridge realizes the codon-window inverse reconstruction route as finite channel, codon-window, classifier, transport, provenance, and NameCert rows.

9462.28.23 BEDC certificate machines, allegory machines, and biological branches

The DNA/window-six bridge also clarifies a larger methodological separation. BEDC is best treated as a Turing-realizable certificate machine; an allegory machine generates candidate symbolic patterns; DNA enters only as an external biological bridge branch. The slogan is: allegory proposes figures, BEDC certifies names, and DNA supplies a natural branch whose records can be encoded, classified, audited, and compared without becoming a BEDC kernel primitive.

Definition 9462.1876 (Finite certificate kernel)**.** *The BEDC finite certificate kernel is the dependency spine*

$$b_0, b_1 \to \mathsf{Hist} \to \mathsf{msame}, \mathsf{hsame} \to \mathsf{Ext}, \mathsf{Cont}$$
$$\to \mathsf{Ask}, \mathsf{Sig}, \mathsf{sameSig} \to \mathsf{Pkg}, \mathsf{Gap} \to \mathsf{NameCert}.$$

It generates finite marks, histories, continuation structure, question and signature structure, package/gap classification, and certified name admission.

Definition 9462.1877 (BEDC certificate machine)**.** *A BEDC certificate machine is the finite certificate kernel together with classifier formation, ledger policy, NameCert admission, derivation strength records, and cannot-claim boundaries. It accepts a candidate name* N *only when the relevant source, pattern, classifier, stability, and ledger fields have been supplied at a declared strength.*

Definition 9462.1878 (Turing-realizable certificate machine)**.** *A certificate machine is Turing-realizable when its public derivations can be encoded as finite strings and its certificate checks can be executed by a finite, Turing-computable procedure. For the BEDC finite kernel, the intended external model sends raw marks to finite binary tokens, histories to finite binary words,* Ext *to word extension,* Cont *to concatenation, query and signature rows to finite strings, package and gap rows to finite classifier fibers, and NameCert fields to finite certificate records.*

Definition 9462.1879 (Plain Turing machine and certificate machine)**.** *A plain Turing-machine description specifies an input, a transition operation, and an output. A BEDC certificate-machine description records source, pattern, classifier, stability, ledger, exactness, derivation strength, and cannot-claim boundaries. Thus BEDC is Turing-realizable without being exhausted by the input-output image of one plain machine.*

Definition 9462.1880 (Allegory machine and seed)**.** *An allegory machine is a semantic-pattern generator: it compresses mythic, metaphorical, numerical, geometric, linguistic, and biological motifs into candidate patterns. An allegory seed is such a candidate pattern before BEDC admission. Examples include phased creation motifs, five-phase systems, seven-day ledgers, twelve-orientation ledgers, four-base biological alphabets, window-six stop boundaries, local Q_2 tile dynamics, and codon-window inverse spectra.*

Definition 9462.1881 (Admission of an allegory seed)**.** *An allegory seed P is BEDC-admissible at strength s only when there is a derived name N_P with an acceptance gate*

$$\mathsf{AcceptGate}(N_P, s) := \mathsf{NameCert}(N_P) \wedge \mathsf{DerivCert}(N_P, s).$$

The strength s records whether the object remains a seed, a paper certificate target, a checked certificate target, or a bridge certificate target.

Definition 9462.1882 (Biological bridge branch)**.** *A biological bridge branch is an external natural system B admitted as a derived BEDC interface through source, pattern, classifier, stability, and ledger fields, together with explicit external biological tables or models. A biological branch is not a finite-kernel primitive.*

Definition 9462.1883 (DNA window-six biological branch)**.** *The DNA window-six branch has source objects including a four-phase alphabet, a codon cube Q_6, a translation classifier*

$$Q_6 \to \mathsf{AminoAcidClass} \oplus \mathsf{Stop},$$

a codon ledger, and a context ledger. Its dynamical context records sequence, reading frame, current codon window, ribosome or release-factor state, mutation and repair state, epigenetic or chromatin accessibility, and cellular context.

Definition 9462.1884 (Human DNA branch)**.** *The human DNA branch is a species-specific instance of the DNA window-six branch for Homo sapiens. Its source and ledger fields include genome sequence, assembly and coordinate system, gene intervals, transcripts, protein-coding frames, genetic-code table provenance, variant alleles, epigenetic marks, cell-type context, and annotation provenance. It is an external biological instance, not a kernel object.*

Theorem 9462.1885 (BEDC finite kernel is Turing-realizable)**.** *The BEDC finite certificate kernel has a Turing-realizable external model.*

Proof. Interpret b_0 and b_1 as finite binary tokens, histories as finite binary words, sameness as literal token or word equality, Ext as word extension, Cont as word concatenation, query and signature rows as finite string operations, package and gap rows as finite classifier fibers and inverse images, and NameCert fields as finite records. Equality, extension, concatenation, lookup, classification, and certificate-field checking are all finitary and Turing-computable. □

Theorem 9462.1886 (BEDC is not merely a plain Turing machine)**.** *BEDC is Turing-realizable, but it is not merely a plain input-output Turing machine.*

Proof. A plain Turing machine produces an output from a transition system. BEDC requires public certificate fields, ledger policy, derivation strength, and cannot-claim boundaries for admitted names. These obligations are not merely output values; they are auditable conditions on why a name is licensed and what it is not allowed to claim. □

Corollary 9462.1887 (BEDC as certificate machine)**.** *BEDC should be described as a certificate machine rather than merely as a computational automaton.*

Proof. This follows from Definition 9462.1886: BEDC public output is a licensed name with certificate and ledger obligations, not only a computed string. □

Theorem 9462.1888 (Allegory does not certify itself)**.** *An allegory machine can generate candidate patterns, but it does not by itself produce BEDC-certified names.*

Proof. An allegory machine supplies semantic compression, analogy, and symbolic direction. These do not by themselves supply SourceSpec, PatternSpec, ClassifierSpec, StabilityCert, LedgerPolicy, or a derivation-strength record. Thus an allegory seed has no BEDC certificate force until it is converted into a certified name. □

Corollary 9462.1889 (Allegory proposes and BEDC certifies)**.** *The relation between the allegory machine and BEDC is: allegory proposes candidate symbolic patterns, while BEDC tests, certifies, or rejects them.*

Proof. This is Definition 9462.1888 together with Definition 9462.1881. □

Theorem 9462.1890 (Allegory seeds enter only through NameCert)**.** *If an allegory seed P becomes an admissible BEDC object, it must do so through a derived name N_P equipped with NameCert and a recorded derivation strength.*

Proof. By Definition 9462.1881, admissibility at strength s requires $\mathsf{AcceptGate}(N_P, s)$, which includes both NameCert and DerivCert. An allegory seed has neither field by itself. □

Theorem 9462.1891 (DNA is not a BEDC kernel primitive)**.** *DNA cannot be a finite-kernel primitive of BEDC.*

Proof. The finite kernel contains marks, histories, sameness, extension, continuation, asking/signature, package/gap, and NameCert structure. DNA requires an external four-base alphabet, molecular complementarity, codon windows, translation classifiers, mutation and repair processes, cellular execution machinery, and biological context. These are not finite-kernel constructors. DNA can therefore enter only as a derived biological bridge interface. □

Corollary 9462.1892 (DNA as biological bridge branch)**.** *If DNA is admitted into BEDC, it is admitted as a biological bridge branch, with* $\mathsf{DNAWindow6Dynamics}^{\uparrow}$ *as a principal candidate interface.*

Proof. DNA is not primitive by Definition 9462.1891. External natural systems enter by the bridge discipline of Definition 9462.1882. □

Theorem 9462.1893 (Human DNA is species-specific bridge data)**.** *Human DNA is a species-specific instance of the DNA biological bridge, not a universal BEDC kernel object.*

Proof. The human branch requires Homo sapiens-specific genome assemblies, transcripts, gene intervals, alleles, regulatory context, epigenetic states, and annotation provenance. These are contingent external biological records. Kernel objects are generated by the finite BEDC kernel without such biological contingencies, so the human branch is a bridge instance rather than a kernel object. □

Corollary 9462.1894 (Human DNA requires ledger)**.** *The valid BEDC expression is that human DNA is a BiologicalBridge branch with source, classifier, context, and ledger fields. A genome string without context and ledger is not a complete BEDC object.*

Proof. This is the ledger reading of Definition 9462.1893 and Definition 9462.1884. □

Theorem 9462.1895 (DNA window-six results are bridge theorems)**.** *DNA/window-six reconstructions are biological-bridge theorems, not proofs that biology is forced by BEDC alone.*

Proof. The reconstructions require external biological data: the four-base alphabet, codon length three, genetic-code tables, translation and termination behavior, and species or code context. These are not generated solely by the finite BEDC kernel. Conversely, the occurrence of window-six structure in DNA supplies a strong bridge instance, not a proof of BEDC as a whole. □

Definition 9462.1896 (Research surface)**.** *The research surface has five parts. First, formalize BEDC as a Turing-realizable certificate machine and prove non-reduction to a plain input-output machine. Second, define allegory machines, allegory seeds, and NameCert admission gates for symbolic patterns. Third, define biological branch obligations: source, pattern, classifier, stability, ledger, bridge table, and cannot-claim boundary. Fourth, develop* $\mathsf{DNAWindow6Dynamics}^{\uparrow}$ *and the human DNA branch as external biological branches. Fifth, connect the branch to local window-six results: stop codons as* $\mathrm{U} + \mathrm{RR} + X_2$*,* UGG *as a reserved* 11 *corner, dual* $X_2/\{11\}$ *control tiles,* 00*-singleton sense-expansion tiles, codon-window inverse spectra, and alternative genetic-code reassignments.*

Definition 9462.1897 (Empirical bridge surface)**.** *The empirical biological surface compares standard and alternative genetic-code tables, stop-codon usage, readthrough dynamics, codon optimality, mRNA stability, ribosome-profiling pause rows, synthetic reporters for* UAA*,* UAG*,* UGA*, and* UGG*, and context-specific human variant annotations. These records test biological adequacy but do not replace NameCert or bridge certificate obligations.*

Theorem 9462.1898 (Certificate-allegory-branch cannot-claim boundary)**.** *The certificate/allegory/branch triad does not license any claim that BEDC is exactly one ordinary Turing machine, that allegories are automatically true, that an allegorical pattern is already a BEDC theorem, that DNA is a BEDC kernel primitive, that human DNA is generated by the finite kernel alone, that DNA/window-six proves BEDC, that BEDC alone proves the biological genetic code, that the human DNA branch is already a checked certificate, that a genome string without context and ledger is a complete BEDC object, or that BiologicalBridge data replace NameCert obligations.*

Proof. The Turing-machine refusal follows from Definition 9462.1886. The allegory refusals follow from Definition 9462.1888 and Definition 9462.1890. The DNA and human-branch refusals follow from Definition 9462.1891 and Definition 9462.1893. The bridge overclaim refusal follows from Definition 9462.1895. □

Corollary 9462.1899 (Allowed triad claim)**.** *The allowed current-state formulation is: BEDC is Turing-realizable as a finite certificate machine; the allegory machine generates patterns that may be certified or rejected; DNA is a BiologicalBridge branch rather than a kernel primitive; and human DNA is a species-specific external branch requiring source, classifier, context, and ledger fields.*

Concretized in §3355: Certificate machines are realized as finite kernel, accepted-observation, branch-refusal, audit-replay, and NameCert rows.

Concretized in §3366: Certificate-machine branches are realized as finite kernel-spine, admission-gate, derivation-strength, ledger-boundary, and branch-separation NameCert packets.

9462.28.24 Codon-cube boundary research program

The DNA window-six bridge has a precise local form. The global codon cube is the six-bit source space

$$Q_6 := \{0,1\}^6,$$

but the standard stop-codon theorem is not a theorem about the global no-adjacent subspace of Q_6. It is a theorem about a two-bit boundary inside the U + RR face. The refined slogan is therefore:

$$\text{codons live in } Q_6, \qquad \text{standard stops live in } \mathrm{U} + \mathrm{RR} + X_2^{\mathsf{fam}}.$$

Here

$$X_2^{\mathsf{fam}} := \{00, 01, 10\}$$

is the local Zeckendorf-legal family suffix square. The global Fibonacci window X_6 remains a separate finite-window surface.

Definition 9462.1900 (Codon cube and local stop boundary)**.** *Let the two-axis RNA or DNA readback be*

$$\begin{aligned} \mathrm{U/T} = 00, \quad \mathrm{C} = 01, \\ \mathrm{A} = 10, \quad \mathrm{G} = 11. \end{aligned}$$

The codon cube is

$$Q_6 := \{0,1\}^6 \cong (\{0,1\}^2)^3 \cong \{\mathrm{U}, \mathrm{C}, \mathrm{A}, \mathrm{G}\}^3.$$

The stop face is the codon-cube face

$$\mathsf{StopFace} := \{\mathrm{U}xy \mid x, y \in \{\mathrm{A}, \mathrm{G}\}\} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}, \mathrm{UGG}\}.$$

The local suffix boundary is obtained by projecting the last two positions to the family axis and retaining only $X_2^{\mathsf{fam}} = \{00, 01, 10\}$.

Definition 9462.1901 (Global and local no-11 spaces)**.** *The global no-adjacent window is*

$$X_6 := \{w \in Q_6 \mid w \textit{ has no adjacent } 11\}.$$

The local family-suffix window is

$$X_2^{\mathsf{fam}} := \{s \in \{0,1\}^2 \mid s \neq 11\} = \{00, 01, 10\}.$$

The DNA stop theorem uses X_2^{fam} *inside* $\mathsf{StopFace}$*; it does not identify stop codons with* X_6.

Theorem 9462.1902 (Local X_2 stop boundary)**.** *Under the two-axis RNA bridge,*

$$\mathsf{StopFace} \cap X_2^{\mathsf{fam}} = \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}.$$

Proof. The stop face has four suffixes:

$$\begin{aligned} \mathrm{AA} &\longmapsto 00, \\ \mathrm{AG} &\longmapsto 01, \\ \mathrm{GA} &\longmapsto 10, \\ \mathrm{GG} &\longmapsto 11. \end{aligned}$$

Intersecting with $X_2^{\mathsf{fam}} = \{00, 01, 10\}$ keeps the first three suffixes and removes the GG corner. Hence the selected codons are exactly UAA, UAG, and UGA. □

Theorem 9462.1903 (Local X_2 is not global X_6)**.** *The standard stop-codon boundary is local to the family suffix and is not the global no-adjacent-*11 *subspace X_6 of the flattened codon cube.*

Proof. By Definition 9462.1090, the flattened strings for UAG and UGA contain adjacent 11 even though both are standard stop codons. Thus the global predicate defining X_6 would not select the standard stop set. The successful reconstruction is instead the two-bit family-suffix predicate of Definition 9462.1902. □

Corollary 9462.1904 (Codon cube, global window, local boundary)**.** *The DNA/window-six bridge separates three finite spaces:*

$$\begin{aligned} Q_6 &:= \{0,1\}^6 && \textit{global codon-cube source space}, \\ X_6 &:= \{w \in Q_6 \mid w \textit{ has no adjacent } 11\} && \textit{global Fibonacci window}, \\ X_2^{\mathsf{fam}} &:= \{00, 01, 10\} && \textit{local stop-face family boundary.} \end{aligned}$$

The bridge is strong because codons naturally inhabit Q_6 and the standard stop set is a local X_2^{fam} boundary inside that cube. It is not an identification of DNA with X_6 or with a window-six fold.

Definition 9462.1905 (Comparative genetic-code deformation ledger)**.** *For an external genetic-code table T, the comparison ledger records*

$$\mathsf{StopSet}_T, \quad \mathsf{SenseSet}_T, \quad \mathsf{role}_T(\mathrm{UAA}), \quad \mathsf{role}_T(\mathrm{UAG}), \quad \mathsf{role}_T(\mathrm{UGA}), \quad \mathsf{role}_T(\mathrm{UGG}).$$

The boundary deformation row is

$$\Delta_T := \mathsf{StopSet}_T \triangle \{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\},$$

where $\triangle$ denotes symmetric difference. If $\Delta_T = \varnothing$, the standard L-shape is preserved by that table. If $\Delta_T \neq \varnothing$, the table is recorded as a deformation of the biological bridge target.

Concretized in §8745: The comparative genetic-code deformation ledger is realized as a finite NameCert carrier over stop/sense rows, codon-role rows, and the standard stop-boundary difference row.

Definition 9462.1906 (Empirical dynamics observables)**.** *The empirical layer tests whether the L-shape is only a finite set shape or also a dynamic boundary. The bridge may record observables such as*

$$\Pr(\text{termination} \mid \text{stop type}, +4\ \textit{context}, \text{species}, \text{release factor}),$$
$$\Pr(\text{readthrough} \mid \text{stop type}, \text{downstream context}),$$
$$\text{ribosome pause time}, \qquad \text{mRNA half life},$$
$$\text{codon optimality score}, \qquad \text{stop codon usage frequency}.$$

These quantities are external biological bridge rows. They may guide which dynamic fields are worth naming, but they do not become BEDC kernel primitives.

Definition 9462.1907 (Finite-state stop-boundary prototype)**.** *A minimal finite-state prototype has states*

$$\{\mathsf{scan}, \mathsf{elongate}, \mathsf{terminate}, \mathsf{readthrough}, \mathsf{repair}, \mathsf{mutate}\}$$

and alphabet $\{\mathrm{U}, \mathrm{C}, \mathrm{A}, \mathrm{G}\}$*. The current window is a codon* $w_t = (b_t, b_{t+1}, b_{t+2})$*. Under the standard-code bridge, the transition rows include*

$$\begin{aligned}
\delta(\mathsf{elongate}, \mathrm{UAA}) &= \mathsf{terminate},\\
\delta(\mathsf{elongate}, \mathrm{UAG}) &= \mathsf{terminate},\\
\delta(\mathsf{elongate}, \mathrm{UGA}) &= \mathsf{terminate},\\
\delta(\mathsf{elongate}, \mathrm{UGG}) &= \mathsf{elongate\text{-}Trp}.
\end{aligned}$$

A stochastic extension may replace δ *by* $\Pr(\delta \mid w_t, \text{context})$ *to model readthrough, release-factor availability, or cellular state.*

Concretized in §2245: The finite-state stop-boundary transition matrix is realized as a concrete NameCert carrier over codon windows, state rows, and local stop-face transition rows.

Definition 9462.1908 (Work packages for the codon-cube boundary program)**.** *The research program has seven work packages:*

Finite modeling. *Define* $\mathsf{Base}^{\uparrow}$*,* $\mathsf{Codon}^{\uparrow} \cong Q_6$*,* $\mathsf{StopFace}$*,* $\mathsf{FamilySuffix}$*,* $\mathsf{ZLegalFamilySuffix}$*, the three-stop theorem, the excluded corner, and the RF L-shape bridge.*

Window clarification. *Separate* Q_6*,* X_6*, and* X_2^{fam}*, and prove that the strong bridge is* Q_6 *plus local* X_2^{fam}*, not DNA as global* X_6*.*

Genetic-code comparison. *Compare standard, mitochondrial, ciliate, protozoan, nuclear, bacterial, archaeal, and plastid tables by the deformation ledger* Δ_T*.*

Stop and codon usage statistics. *Relate stop identity, GC content, expression level, species lineage, tRNA or release-factor annotations, terminal context, and downstream context to stop usage.*

Translation dynamics. *Use ribosome-profiling, readthrough, pausing, mRNA stability, and protein-output rows as external dynamic evidence.*

Synthetic reporter validation. *Compare terminal-window replacements* UAA*,* UAG*,* UGA*, and* UGG *under controlled downstream and release-factor contexts.*

Finite-state prototype. *Implement the stop-boundary automaton with context-dependent transition probabilities as a bridge-side model.*

Theorem 9462.1909 (Codon-cube boundary cannot-claim boundary)**.** *The codon-cube boundary program does not license any claim that Zeckendorf alone proves the biological genetic code, that the DNA genetic code is a window-six fold, that the whole genetic code is global X_6, that BEDC* $\mathrm{End} = 11$ *is identical to a biological stop codon, that the family suffix* 11 *in* UGG *is the channel terminator, that the standard stop codons are universal across all genetic-code tables, that* UGG *must be tryptophan by BEDC logic alone, that synonymous codons are dynamically identical after amino-acid classification, that DNA state is exhausted by Q_6, that DNA has fully autonomous closed dynamics independent of cellular machinery, that biological tables replace* $\mathsf{NameCert}$ *obligations, or that* $\mathsf{DNAWindow6Dynamics}^{\uparrow}$ *is already checked.*

Proof. The global-window refusals follow from Definition 9462.1903. The channel and token-identity refusals follow from Definition 9462.1107. The dynamic state refusals follow from Definition 9462.1133. The microstate-refusal follows from Definition 9462.1135. The checked-status refusal follows because this program is a vision-strength bridge target and not a Lean target. □

Corollary 9462.1910 (Allowed codon-cube boundary claim)**.** *Under the two-axis DNA or RNA bridge and Zeckendorf-family suffix legality, the standard stop-codon set is structurally reconstructed as the local X_2^{fam} L-shape*

$$\{\mathrm{UAA}, \mathrm{UAG}, \mathrm{UGA}\}$$

inside the $\mathrm{U} + \mathrm{RR}$ *face of the codon cube Q_6. The framework is a biological-bridge vision for symbolic-physical DNA dynamics, not a checked theorem that Zeckendorf alone forces biology.*

9462.28.25 Failure certificates and cannot-claim entries

Definition 9462.1911 (Failure certificate)**.** *A failure certificate for a candidate object N at strength s is a typed branch showing that a necessary field of the acceptance gate fails: missing source, missing classifier, non-transitive classifier, exactness failure, operation failing to descend, absent gap ledger, unstable completion, failed standard bridge, host primitive leakage, or theorem-checker failure.*

Theorem 9462.1912 (Failure blocks acceptance)**.** *If a failure certificate for N at strength s is present, then the acceptance gate for N at s is not satisfied.*

Proof. The acceptance gate is a conjunction of required fields. Each failure branch denies one required field or bridge condition, so the gate does not close. □

Definition 9462.1913 (Cannot-claim entry)**.** *A cannot-claim entry records claim text, status, the reason the claim is not currently claimable, and the required certificate upgrade.*

Theorem 9462.1914 (Cannot-claim registry is export discipline)**.** *The cannot-claim registry is part of BEDC's export surface, not a rhetorical appendix.*

Proof. Claims outside the certified surface are unsupported until the relevant certificate is displayed. The registry makes that refusal explicit and typed. □

Corollary 9462.1915 (Negative export knowledge)**.** *Stating that BEDC does not claim X can be a knowledge state when it is backed by a failure certificate or registry entry.*

Proof. Certificates show what is admitted; failure branches show what blocks admission. Both are auditable. □

9462.28.26 Prohibited scientific smuggling

Definition 9462.1916 (Scientific smuggling)**.** *Scientific smuggling occurs when a host model is treated as a BEDC primitive, empirical fit is promoted to universal law, equation form is treated as physical object, a schema horizon is reported as a closed theorem, a bridge sketch is reported as bridge certificate, a numerical empirical value is treated as kernel-derived constant, or external equality, quotient, or choice is used as public classifier.*

Theorem 9462.1917 (Scientific smuggling violates a gate)**.** *Every scientific smuggling pattern violates at least one of naming certificate discipline, acceptance gate discipline, standard bridge discipline, gap discipline, or axiom-purity.*

Proof. Host primitives violate no-host-leak. Empirical fit promoted to law violates Type IV gap discipline. Equation form promoted to object violates naming discipline. Schema horizon promoted to theorem violates declared strength. Bridge sketch promoted to bridge certificate violates bridge fields. Numerical value promoted to kernel constant violates empirical ledger discipline. External equality, quotient, or choice violates meta-closure refusal. □

Corollary 9462.1918 (Scientific writing must mark status)**.** *Scientific BEDC writing must mark status, layer, and claim type: whether the item is a record, invariant, model, bridge, empirical claim, prediction commitment, structure form, theorem, fit, or bridge correspondence.*

Proof. Different layers and statuses have different certificate obligations. Leaving them unmarked invites smuggling. □

9462.28.27 External mature systems

Definition 9462.1919 (Mature external system)**.** *Mature external systems include host libraries, set-theoretic foundations, standard model theory, classical analysis, differential geometry, physics textbooks, and experimental data standards. In BEDC they are bridge targets or explanatory references, not primitive sources.*

Theorem 9462.1920 (Mature systems are bridge targets)**.** *Mature external systems cannot replace internal BEDC certificates; they can only serve as bridge targets or references.*

Proof. Replacing the internal certificate by a mature host system would place host equality, quotients, choice, numbers, functions, or type and set semantics on the BEDC public surface. No-host-leak forbids this. □

Corollary 9462.1921 (BEDC bridges mature systems without fusing them)**.** *BEDC does not reject mature systems; it distinguishes bridge from fusion.*

Proof. The bridge lets a host reader recognize the BEDC object and lets BEDC accept finite translated theorem rows. The no-host-leak field prevents the host system from becoming a primitive source. □

9462.28.28 Physics certificate chain

Definition 9462.1922 (Multi-history physics chain)**.** *The multi-history physics route proceeds through certificates for multi-history configuration, cross-history causality, maximum causal rate, Lorentz-style geometry, curved spacetime, quantum state, and the relevant empirical or model bridges.*

Theorem 9462.1923 (Physics closes stepwise)**.** *The physics route cannot skip intermediate certificates and directly claim high-level physical objects.*

Proof. Each high-level object depends on source, classifier, stability, ledger, and bridge data from prior layers. Skipping a layer leaves a certificate field unsupplied. □

Corollary 9462.1924 (High-level physical objects are not primitives)**.** *Curved spacetime, fields, quantum states, Hilbert spaces, and particles must enter through the multi-history, invariant, bridge, and empirical ledger chain rather than as primitives.*

Proof. They stand far above the kernel and require mature mathematical carriers, physical interpretation, empirical bridge, and prediction gaps. □

9462.28.29 Synthesis

Theorem 9462.1925 (Scientific object and model-bridge synthesis)**.** *BEDC scientific content consists of records-side generated data, inter-history invariant structure, naming and derivation certificates, conservative bridges to mature models, empirical ledgers, prediction gaps, and falsification surfaces.*

Proof. Scientific objects are not primitives. Frame-independent physical content is inter-history invariant. Physical laws are empirical regularities plus Type IV gaps. Formal constants are not empirical values. Models are not worlds. Standard bridges are conservative, host-relative, and no-host-leak. Failure certificates and cannot-claim entries police the export surface. Therefore scientific content enters only through the stated certificate and ledger discipline. □

Corollary 9462.1926 (Scientific truth as audited stability)**.** *BEDC scientific truth is not absolute correspondence between law and world; it is ledgered records, stable invariants, conservative model bridges, marked prediction commitments, and open falsification surfaces.*

Concretized in §1239: Truth-residue ledgers realize scientific truth as finite record, invariant, bridge, prediction-gap, falsification, and non-finality NameCert rows.

Corollary 9462.1927 (Physical reality as stable relation)**.** *BEDC physical reality is not objecthood inside global spacetime; it is stable inter-history relational content that survives licensed classifier, invariant, and empirical ledger tests.*

Corollary 9462.1928 (Passage to philosophical traditions)**.** *After scientific objects and model bridges are certificate-disciplined, the framework can be compared with traditional philosophical positions only at precise structural contact points, rather than by identifying BEDC with any tradition wholesale.*

Concretized in §1273: Scientific model bridges are realized as finite scientific-object, model-audit, standard-bridge-audit, open-fit, failure-surface, transport, provenance, and NameCert rows.

Concretized in §1286: ScienceBridgeUp packages scientific objects, physical-model audit, reality-constrained truth, standard-bridge audit, and falsification gaps as one BEDC NameCert surface.

Concretized in §1285: Physical-law bridge packets realize law certificate, empirical persistence, scientific-object, bridge-audit, open-fit, and falsification rows as one NameCert carrier.

9462.29 BEDC and Philosophical Traditions

BEDC is not assigned to an inherited philosophical school. The comparison discipline is weaker and more precise: a tradition may identify a question whose structural core lands on a BEDC carrier, relation, classifier, ledger, certificate, gap, or T-position. The comparison is therefore a structural translation, not a doctrinal identity.

9462.29.1 Structural adjacency

Definition 9462.1929 (Philosophical genealogy)**.** *A traditional philosophical claim P has a genealogical relation to a BEDC structure B when a structural core of P can be translated as a BEDC carrier, relation, classifier, ledger, certificate, gap, or T-position. The relation does not say that BEDC belongs to the tradition containing P, nor that BEDC accepts that tradition's full metaphysical commitments.*

Definition 9462.1930 (Structural adjacency)**.** *Two traditional claims are structurally adjacent when they land on the same BEDC site. For example, bundle theories of the self, atman-negation readings, and second-order cybernetics all land on the observer-as-history site when restricted to the shared conclusion that there is no observer-substance behind the trace.*

Concretized in §1311: Structural adjacency is realized as a finite genealogy, BEDC-role, adjacency-witness, transport, route, provenance, and NameCert packet.

Theorem 9462.1931 (BEDC is not one tradition)**.** *BEDC cannot be reduced to any single inherited philosophical tradition.*

Proof. The object-language content of BEDC is generated by the finite kernel, internal sameness judgments, continuations, signatures, packages, gaps, and naming certificates. Traditional philosophical vocabulary belongs to interpretive metalanguage. Since the kernel chain does not take any traditional concept as primitive, no single tradition supplies the structure of BEDC. □

Corollary 9462.1932 (Comparisons need two labels)**.** *Every comparison with a philosophical tradition must name both the traditional claim and the BEDC site on which its structural core lands.*

Proof. Naming only the tradition projects external doctrine into BEDC. Naming only the BEDC site loses the explanatory genealogy. The two labels keep tradition as reading and BEDC as structure. □

9462.29.2 Spencer-Brown and primitive distinction

Definition 9462.1933 (Distinction genealogy)**.** *The Spencer-Brown-style claim that a formal system begins by drawing a distinction lands in BEDC on the primitive mark distinction:* `b0`*,* `b1`*, and constructor no-confusion.*

Theorem 9462.1934 (BEDC internalizes the distinction site)**.** *The thought that form begins with a distinction is internalized in BEDC as the constructor distinction between the two primitive marks.*

Proof. The two marks and their no-confusion are not derived from an earlier object. Writing the two constructors is already the minimal act of distinction needed for generation to begin. This is the BEDC site adjacent to the distinction-first reading. □

Corollary 9462.1935 (Distinction becomes certified generation)**.** *BEDC does not stop at the act of distinction; it sends distinction into histories, continuations, classifiers, ledgers, and naming certificates.*

Proof. The primitive distinction is the ground. The remaining BEDC layers are the certified development of that ground into trace, observation, object license, and boundary accounting. □

9462.29.3 Brouwer and time intuition

Definition 9462.1936 (Brouwer time site)**.** *The Brouwer-style claim that mathematics arises from the perception of time lands in BEDC on* E0/E1 *application, history growth, and local continuation streams.*

Theorem 9462.1937 (The Brouwer structural claim becomes Hist-time)**.** *The structural content of the Brouwer time reading is captured in BEDC by elementary history extension and local continuation.*

Proof. A history step is an elementary distinction entering a generated trace. A local continuation stream orders such steps from e to a displayed history. Constructive mathematics can then be read as the certified unfolding of this finite temporal trace structure. □

Corollary 9462.1938 (BEDC constructivism is not psychologism)**.** *BEDC does not reduce mathematics to psychological time experience.*

Proof. Hist is an inductive carrier and Cont is a formal relation. The Brouwer adjacency concerns the formal structure of time as distinction-order, not a mental state as mathematical substrate. □

9462.29.4 Bundle theory, no-self, and cybernetics

Definition 9462.1939 (Triple subject genealogy)**.** *Empiricist bundle theories of self, atman-negation readings, and second-order cybernetics share one BEDC landing site: observer equals history, observer identity is history-sameness under licensed comparison, and no observer-substance stands behind the trace.*

Theorem 9462.1940 (The shared subject conclusion is no hidden observer)**.** *The common structural conclusion of these subject traditions, as read through BEDC, is that there is no observer-substance behind the trace.*

Proof. The continuation signature has history endpoints and no subject slot. Observer identity is expressed through generated history and licensed comparison. Adding an observer-substance would require unlicensed transport beyond the kernel surface. □

Corollary 9462.1941 (No-subject is not anti-experience)**.** *BEDC excludes observer-substance, not focused record, self-proxy, conscious records-side carrier, or inscription event.*

Proof. The phenomenological layer admits focused histories and inscription events as records-side or boundary-side structures. What is excluded is a hidden carrier that owns those structures without a certificate. □

9462.29.5 Kant and conditions of possibility

Definition 9462.1942 (Kantian question)**.** *The Kant-style question asks for conditions of the possibility of experience or knowledge. In BEDC it becomes the question which generated carriers, classifiers, ledgers, certificates, and gap sockets make an object-claim or knowledge-claim admissible.*

Definition 9462.1943 (BEDC condition of possibility)**.** *A BEDC condition of possibility is not a form of a transcendental subject. It is a structural condition such as primitive distinction, history, continuation, internal sameness, naming certificate, ledger policy, or gap boundary.*

Theorem 9462.1944 (Conditions of possibility become certificate conditions)**.** *BEDC rewrites the question of conditions of possibility as certificate and boundary conditions for object-layer entry.*

Proof. Objects require naming certificates. Knowledge requires witnesses. Commitments beyond closed records require gap exposure. The conditions under which a claim can appear are therefore generated, classified, ledgered, stabilized, and boundary-marked conditions. □

Corollary 9462.1945 (BEDC is not Kantianism)**.** *BEDC is adjacent to the possibility-condition problem but does not share a subject-centered transcendental form.*

Proof. The landing site is Hist, Cont, NameCert, and gap discipline, not a transcendental subject. The observer has already been identified with history. □

9462.29.6 Husserl and constitution

Definition 9462.1946 (Husserlian question)**.** *The Husserl-style question asks how an object is constituted for consciousness. In BEDC it becomes the question how a stable pattern in history and continuation receives a naming certificate under a focused ledger.*

Definition 9462.1947 (BEDC constitution)**.** *Constitution in BEDC is the records-side process by which a history trace, continuation pattern, classifier stability, ledgered compression, and naming certificate make a pattern available as an object.*

Theorem 9462.1948 (Object constitution is licensed stable pattern)**.** *For BEDC, an object appearing to consciousness in the object layer means that a focused records-side ledger contains a stable pattern licensed by classifier and naming certificate.*

Proof. The consciousness carrier is a focused history with local continuation trace, selector ledger, and self-proxy. A mature object is a licensed name. Therefore object constitution in this layer is the certification of stable records-side pattern. □

Concretized in §1284: Object-constitution ledgers realize stable appearance as focused history, continuation, classifier, ledger, gap, provenance, and NameCert rows.

Corollary 9462.1949 (BEDC phenomenology is records-side phenomenology)**.** *BEDC is adjacent to phenomenology through appearance, record, and constitution, but it requires every constitutive step to be written as finite ledger, classifier, certificate, or gap.*

Proof. Unledgered phenomenal content has no object-layer witness. A phenomenon enters BEDC only through its records-side carrier or through a gap-tagged boundary reading. □

9462.29.7 Wittgenstein and use

Definition 9462.1950 (Use and rule question)**.** *The Wittgenstein-style question links meaning to use and rule-following to public practice. In BEDC it lands on licensed use under* NameCert *and classifier-stable continuation with a ledger.*

Definition 9462.1951 (BEDC use)**.** *A use of a name N is legitimate when the item used falls under the source and classifier fields of N, the use is stable under the stability certificate, and hidden material is tracked by the ledger policy.*

Theorem 9462.1952 (Meaning is certified use)**.** *In BEDC, the meaning of a name is given by its auditable use rules.*

Proof. The naming certificate states source, pattern, classifier, stability, and ledger fields. Without these fields the name is not licensed. Meaning is therefore neither private image nor bare reference, but certificate-governed use. □

Corollary 9462.1953 (Rule-following is audited, not merely social)**.** *BEDC is adjacent to the public-checkability side of rule-following, but its use is classifier-, witness-, ledger-, and stability-governed rather than ordinary social habit.*

Proof. Social practices can drift and remain implicit. BEDC public use must be auditable by certificate fields. □

9462.29.8 Whitehead and process

Definition 9462.1954 (Process question)**.** *The process-philosophy question says that reality is process rather than static substance. Its BEDC landing site is* Cont *as universal verb, history growth, and naming certificates as stabilized process-interfaces.*

Definition 9462.1955 (BEDC process)**.** *A BEDC process is a displayed continuation* $\mathsf{Cont}(h, d, h')$ *and its specializations under certificates: observation, time step, computation, morphism, type checking, or continuity modulus.*

Theorem 9462.1956 (BEDC is certificate process theory)**.** *BEDC is structurally adjacent to process philosophy in that continuation precedes mature objecthood.*

Proof. Distinction and history precede objects. Observation and time are continuation readings. Mature objects are names licensed after stable continuation behavior has been classified and ledgered. Objecthood is therefore downstream from process. □

Corollary 9462.1957 (BEDC is not Whiteheadian metaphysics)**.** *BEDC shares process priority but does not import actual occasions, prehension, or organic metaphysics.*

Proof. Its process site is the finite continuation relation and its certificate discipline, not a general metaphysical category. □

9462.29.9 Tarski, Godel, and Muenchhausen

Definition 9462.1958 (Formal-limit tradition)**.** *The formal-limit tradition includes incompleteness, undefinability, bootstrap impossibility, and halting undecidability. Its BEDC landing site is the closed-ground-loop and open-meta-loop architecture.*

Theorem 9462.1959 (Limit results are open-meta-loop phenomena)**.** *BEDC reads incompleteness, undefinability, bootstrap impossibility, and halting obstruction as different faces of the open meta loop.*

Proof. The ground loop must close so generation can begin. The meta loop must remain open so the system does not internalize total truth, runtime, or halting decision. The limit phenomena arise when a system attempts to close the latter. □

Corollary 9462.1960 (BEDC does not bypass formal limits)**.** *BEDC does not claim to overcome formal limits; it isolates the minimal ground closure required for formal systems while refusing meta closure.*

Proof. The primitive distinction is the ground payment. Truth and runtime remain outside the object layer. This exposes the boundary rather than removing it. □

Corollary 9462.1961 (Reflection is not a strange loop)**.** *BEDC self-description is layered reflection, not a collapse of the describing and described layers.*

Proof. Collapsing the two layers would recreate the truth-totalization problem. BEDC keeps structural description, described structure, and external checking distinct. □

Concretized in §1316: UseProcessLimitUp realizes certified use, rule audit, continuation process, and formal-limit refusal as one finite NameCert packet.

Concretized in §1313: Certified use and process-priority rows are realized as one finite BHist, hsame, Cont, Pkg, and NameCert boundary packet.

Concretized in §1315: Use-process-limit ledgers realize certified use, continuation-process, and formal-limit refusal as one finite NameCert packet.

Concretized in §1317: Certified-use process packets realize public use, rule witness, continuation route, refusal ledger, and NameCert rows as one finite carrier.

9462.29.10 Relational physics

Definition 9462.1962 (Relational physics genealogy)**.** *Relational quantum mechanics, information-first physical readings, noncommutative geometry, and spin-network approaches share a structural claim that physical content is relational and not located in a privileged global frame.*

Definition 9462.1963 (BEDC relational physics site)**.** *The BEDC site for relational physics is multi-history configuration, inter-history locality, inter-history invariant, no global synchronization, and maximum cross-history rate schema.*

Theorem 9462.1964 (BEDC is lower-level relational physics)**.** *BEDC is adjacent to relational physics because frame-independent physical content is carried by inter-history invariants, while BEDC constructs the relational substrate from distinction, history, and continuation.*

Proof. Multiple histories do not share a base history or time-step index. The kernel provides no global frame. Stable physical content must therefore appear as witnessed invariant relation between histories. BEDC differs from mature relational physics traditions by placing this relation on a more primitive distinction-and-continuation substrate. □

Corollary 9462.1965 (Relational physics remains a schema horizon)**.** *The current relational physics layer is a schema horizon rather than a closed derivation of physical theory.*

Proof. The carriers, causal dependence relation, maximum-rate invariant, geometry, and empirical bridges require their own witnesses and naming certificates. Until those are supplied, the physical reading remains structural. □

Concretized in §1275: RelationalPhysicsUp realizes the relational physics site as finite inter-history invariant, locality, physical-model audit, hsame, Cont, Pkg, and NameCert rows.

9462.29.11 Composite positioning

Definition 9462.1966 (External labels)**.** *External readers may call BEDC formalist, constructivist, phenomenological, process-oriented, or relational realist. Each label names a structural adjacency, not an identity.*

Definition 9462.1967 (Composite position)**.** *The composite position of BEDC is auditable generativity: primitive distinction as ground, histories and continuations as generation, naming certificates as object license, gaps and T as boundary honesty, and inter-history invariants as relational physical interface.*

Theorem 9462.1968 (Genealogy synthesis)**.** *The philosophical genealogy of BEDC is a network of structural translations: primitive distinction for distinction-first traditions; Hist-time for Brouwer; observer-as-history for no-substance subject traditions; certificate conditions for possibility questions; focused records-side licensing for constitution; certified use for meaning; continuation as universal verb for process; open meta loop for formal-limit traditions; and inter-history invariants for relational physics.*

Proof. Each translation lands on an internal BEDC site already introduced in the framework. None requires the philosophical tradition itself to become an object-language primitive, and none imports the tradition's full metaphysical surplus. □

Corollary 9462.1969 (BEDC's philosophical identity)**.** *The most accurate philosophical identity of BEDC is auditable generativity, not formalism, constructivism, phenomenology, process philosophy, or relational realism taken alone.*

Proof. Each external label captures one face: formal carrier discipline, constructive witnesses, focused records-side experience, continuation priority, or relational physical content. The BEDC structure combines these under certificate and gap discipline. □

9462.29.12 Synthesis

Theorem 9462.1970 (Philosophical genealogy synthesis)**.** *BEDC's relation to philosophical traditions is structural relocation: for each tradition, the BEDC comparison identifies the carrier, relation, certificate, or gap site at which the tradition's structural question becomes auditable.*

Proof. The preceding comparisons show that each tradition lands on a precise site: primitive distinction, history time, observer-as-history, certificate condition, focused records-side constitution, certified use, continuation process, open meta loop, or inter-history invariant. The BEDC object language remains its finite kernel and certificate discipline. Therefore the relation is translation, not membership. □

Corollary 9462.1971 (Comparative writing discipline)**.** *Any comparison with a philosopher or tradition should state the traditional claim, the BEDC site, the retained structural content, the rejected surplus, and the audit status of the comparison.*

Corollary 9462.1972 (Passage to audit methodology)**.** *After the traditional comparisons are localized, the next layer should turn the whole framework into writing rules for definitions, theorems, proof strength, gap reports, and prevention of philosophical smuggling.*

9462.29.13 Geometric Algebra as a Closure Model

Definition 9462.1973 (Geometric algebra genealogy)**.** *The geometric algebra tradition lands in BEDC on the site where a generated object carries a visible metric readout, a unit row, and a ledger for oriented residual data. The comparison does not make Clifford algebra a BEDC primitive. It says that the Clifford construction is a compact algebraic model of the three-property discipline.*

Definition 9462.1974 (Observation vector packet)**.** *An observation vector packet over a quadratic interface (V, Q) is a triple*

$$v^{\uparrow} = (v, Q(v), \Lambda(v))$$

where v is the displayed vector row, $Q(v)$ is the squared-length readout, and $\Lambda(v)$ records the source, basis, orthogonality, and projection ledgers under which the vector is admitted.

Definition 9462.1975 (Geometric product ledger split)**.** *For vectors $u, v \in V$, a geometric product ledger split records*

$$uv = u \cdot v + u \wedge v,$$

with

$$u \cdot v = \frac{1}{2}(uv + vu), \qquad u \wedge v = \frac{1}{2}(uv - vu).$$

The symmetric part is the metric or projection readout. The antisymmetric part is the direction, area, order, and generation ledger.

Theorem 9462.1976 (The geometric product separates readout and ledger)**.** *In a geometric product ledger split, the exchange-invariant part of uv is exactly the metric readout, while the exchange-odd part is the oriented ledger readout.*

Proof. The decomposition in Definition 9462.1975 gives

$$uv + vu = 2u \cdot v$$

and

$$uv - vu = 2u \wedge v.$$

The first expression is fixed by exchanging u and v; the second changes sign. Thus the symmetric component records the visible metric projection, and the antisymmetric component records precisely the orientation and order data lost by the symmetric projection. □

Theorem 9462.1977 (The Pythagorean square is a two-axis unit readout)**.** *Let e_1, e_2 be orthogonal unit vectors with*

$$e_1^2 = e_2^2 = 1, \qquad e_1 e_2 = -e_2 e_1.$$

For scalar coefficients a, b and

$$x = ae_1 + be_2,$$

one has

$$x^2 = a^2 + b^2.$$

Proof. Expanding the square gives

$$x^2 = a^2e_1^2 + abe_1e_2 + bae_2e_1 + b^2e_2^2.$$

The scalar coefficients commute, while the two unit axes anticommute. Therefore the cross term is

$$ab(e_1e_2 + e_2e_1) = 0.$$

Since $e_1^2 = e_2^2 = 1$, the remaining part is $a^2 + b^2$. □

Definition 9462.1978 (Quadratic norm three-level readout)**.** *The quadratic norm row has three BEDC-visible projections:*

- *the Boolean two-axis skeleton, read by* $a^2 + b^2 \bmod 4$*;*
- *the finite prime-circle readout, read over odd prime fields by* $a^2 + b^2 \bmod P$*;*
- *the global norm readout, read in* $\mathbb{Z}[i]$ *by* $N(a + bi) = a^2 + b^2$*.*

The first projection exposes the parity obstruction that prevents $3 \bmod 4$ *from being a two-square readout. The second exposes finite quadratic phase data. The third exposes the norm-one surface* $\alpha/\overline{\alpha}$ *whenever a global factorization row is displayed.*

Theorem 9462.1979 (Clifford algebra is the minimal three-property closure)**.** *Let* (V, Q) *be a quadratic interface over a scalar carrier in which* 2 *is invertible. Among associative algebras receiving* V *and satisfying the unit row*

$$v^2 = Q(v)1$$

for every $v \in V$*, the Clifford algebra* $\mathrm{Cl}(V, Q)$ *is the initial closure. Its blade rows retain the antisymmetric direction, area, and higher-volume ledgers generated by the vector rows.*

Proof. The Clifford algebra is the quotient of the tensor algebra $T(V)$ by the relations

$$v \otimes v = Q(v)1.$$

Therefore every algebra B with a map $i : V \to B$ satisfying $i(v)^2 = Q(v)1$ receives a unique algebra homomorphism from $\mathrm{Cl}(V, Q)$. Polarizing the square relation gives the symmetric row

$$uv + vu = 2u \cdot v.$$

For orthogonal vectors this yields $uv = -vu$. The antisymmetric products survive as blade rows rather than being deleted. Thus the construction is minimal for the unit row and closed for the oriented ledger rows. □

Corollary 9462.1980 (Commutativity is a ledger-forgetting projection)**.** *The familiar commutative readout is obtained from the geometric product only after the oriented wedge ledger has been projected away.*

Proof. By Definition 9462.1975, noncommutativity is measured by

$$uv - vu = 2u \wedge v.$$

If a readout keeps only the symmetric component $u \cdot v$, then the exchange-odd ledger row is invisible and the projected product appears commutative. This is a projection of the full carrier, not the full carrier itself. □

Definition 9462.1981 (Clifford no-hidden-residual schema)**.** *The Clifford no-hidden-residual schema says that a nonzero residual component of a geometric product must have one of two addresses: it is detected by a finite blade, finite basis, finite phase, or finite packet read; or it enters a tail ledger for unbounded grade, scale, packet, analytic, or physical escape.*

Theorem 9462.1982 (Geometric algebra explains the shared residual pattern)**.** *The RH circle-triangle route and the Yang–Mills mass-gap route share the same BEDC residual pattern visible in geometric algebra: a unit surface is legal only when every nonunit or nonclosed residual is either finite-detected or ledgered as tail data.*

Proof. In the circle-triangle route of chapter 9323, the unit surface is the critical or unit-circle readout and a radial residual must be detected by a finite projection or recorded in a tail ledger. In the Yang–Mills route, the unitary compact holonomy and tube certificates feed the Hilbert spectral surface; by Definition 9462.1055, a disappearing mass gap must be a finite Wilson packet residual, a finite tube defect, an RG scale-tail defect, or another displayed physical tail. These are instances of the same schema: residual data cannot be erased by passing to a projection. □

Corollary 9462.1983 (Geometric algebra is a structural model, not a proof substitute)**.** *The geometric algebra reading organizes the common closure pattern of quadratic norm, unit circle, phase, orientation, RH residuals, and Yang–Mills soft modes. It does not replace the analytic, arithmetic, spectral, or gauge-theoretic certificates required in the individual routes.*

Proof. Definition 9462.1979 gives a universal algebraic model for vector-square and orientation ledgers. RH and Yang–Mills additionally require their own finite-window, Fourier, Lee–Yang, tube, RG, spectral-convergence, and physical Hilbert rows. The Clifford comparison identifies a shared carrier discipline; it does not discharge those route-specific obligations. □

Concretized in §1268: Tradition comparison boundaries are realized as finite source, landing, rejected-surplus, structural-distinction, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1350: Tradition landing ledgers realize structural translation, rejected surplus, distinction, transport, route, provenance, and local NameCert rows.

9462.30 Audit Methodology and Writing Discipline

The preceding layers give the structural content of auditable generativity. The present layer turns that content into writing rules. Every claim must state its carrier, classifier, ledger, theory-closure grade, formal-verification grade, gap or refusal surface, and no-leakage discipline. Theory closure and formal verification are reported on independent axes and never substitute for one another.

9462.30.1 Writing items

Definition 9462.1984 (Writing item)**.** *A BEDC writing item is an eight-field packet: kind, carrier, classifier, ledger, theory-closure status, formal-verification status, gap report, and claim text. The kind records whether the item is a definition, theorem, corollary, proof, reading, schema, roadmap, or refusal. The claim text is the strongest sentence the item permits the reader to believe.*

Definition 9462.1985 (Minimal legality)**.** *A writing item is minimally legal when it states the type of claim, the carrier it lives on, the way identity or classification is compared, whether hidden material is ledgered, its theory and verification status, whether it has a gap, and what it does not claim.*

Theorem 9462.1986 (Writing items must be auditable)**.** *Every concept entering the BEDC philosophy framework must be written as an auditable writing item.*

Proof. Objects require naming certificates. Positive content requires witnesses. Boundary commitments require gap exposure. Model claims require bridge discipline. Tradition comparisons require a BEDC site. Without carrier, classifier, ledger, status, and gap or refusal surface, the claim cannot be audited. □

Corollary 9462.1987 (Philosophical concepts are not bare prose)**.** *Claims such as consciousness, universe, freedom, law, or mature mathematics must be rewritten as carriers, slices, socket types, certificate surfaces, or refusal entries.*

Proof. The bare word does not state scope, carrier, witness, gap, or status. The rewrite supplies those audit fields. □

9462.30.2 Theory closure and formal verification

Definition 9462.1988 (Theory-closure axis)**.** *The theory-closure axis records paper-side closure: seed, obligation, scoped closure, public closure, bridged closure, and mature package closure. It concerns source, classifier, exactness, ledger, stability, scope, public object surface, bridge obligations, and theorem inventory.*

Definition 9462.1989 (Formal-verification axis)**.** *The formal-verification axis records Lean-side and audit-side status: unformalized, formal target, encoded definition, checked scaffold, checked theorem, audit clean, axiom clean, and checked bridge. It concerns declarations, encoded carriers, theorem proofs, marker audit, transitive axiom purity, and no-host-leak checking.*

Definition 9462.1990 (Theory gate)**.** $\mathsf{TheoryGate}(N, c)$ *means that N has the naming and closure certificates needed for theory-closure grade c.*

Definition 9462.1991 (Verified gate)**.** $\mathsf{VerifiedGate}(N, c, v)$ *is the conjunction of* $\mathsf{TheoryGate}(N, c)$ *and formal-verification status v for the relevant target surface.*

Theorem 9462.1992 (Theory closure and formal verification are independent)**.** *Theory closure does not imply formal verification, and formal verification does not imply theory closure.*

Proof. Theory closure depends on paper-side source, classifier, exactness, ledger, stability, scope, bridge, and public-surface witnesses. Formal verification depends on declarations, type checking, proof checking, marker resolution, and axiom-dependency audits. A paper proof may be closed without a checked theorem, and a checked theorem may exist without the surrounding paper-side object being closed. □

Corollary 9462.1993 (Checked is not closed)**.** *A checked Lean theorem reports formal-verification status only; it does not by itself close the corresponding object theory.*

Proof. Formal status lacks the full paper-side scope, ledger, closure, and bridge obligations unless those are separately supplied. □

Corollary 9462.1994 (Paper closed is not machine checked)**.** *Paper closure reports theory-closure status only; it does not imply machine checking.*

Proof. The paper witness may fill the theory fields while no canonical Lean target has yet been checked. □

Concretized in §1235: Writing-item audit packets realize the eight-field writing item, minimal legality, two-axis status separation, gap exposure, and non-escape claim boundary as a finite NameCert carrier.

9462.30.3 Closure status blocks

Definition 9462.1995 (Closure status block)**.** *A closure status block is the binding chapter record containing theory closure, exact closed scope, formal status, canonical target when present, bridge status, not-claimed surface, and upgrade path.*

Definition 9462.1996 (Binding commitment)**.** *The closure status block is the strongest export claim the chapter may make.*

Theorem 9462.1997 (Closure status bounds prose)**.** *If prose claims more than the closure status block permits, the prose claim is rejected.*

Proof. The block states grade, scope, formal status, bridge status, refusal surface, and upgrade path. A stronger prose claim would bypass the binding commitment. □

Corollary 9462.1998 (Prose strength has an upper bound)**.** *The allowed claim of a chapter is bounded above by its closure status block.*

Concretized in §1234: Auditable writing items are realized as finite transcript envelopes carrying status, anchor, replay, gap, ledger, and not-claimed rows.

Concretized in §1222: Writing-item audit packets realize kind, carrier, classifier, ledger, closure status, formal status, gap report, and permitted claim text as one finite NameCert surface.

9462.30.4 Definitions

Definition 9462.1999 (BEDC definition)**.** *A BEDC definition states carrier, constructor or generator, classifier, ledger, scope, forbidden readings, and status. It names generated and stabilized behavior rather than creating an object from nothing.*

Theorem 9462.2000 (Definitions require carriers)**.** *A definition without a carrier is explanatory vocabulary, not a BEDC definition.*

Proof. Without a carrier the definition has no generated source, no identity surface, and no place where certificate obligations can be checked. □

Theorem 9462.2001 (Definitions require forbidden readings)**.** *Every BEDC definition must state what it is not.*

Proof. Many BEDC names reuse mature language such as universe, consciousness, law, real, or God. Without forbidden readings, mature external meanings are projected back into the kernel. □

Corollary 9462.2002 (Definition template)**.** *A robust definition states: carrier, source, classifier, ledger, scope, forbidden readings, and status.*

9462.30.5 Theorems and corollaries

Definition 9462.2003 (BEDC theorem)**.** *A BEDC theorem states explicit carrier, certificate, and gap assumptions; an exact scoped conclusion; a finite witness-chain proof; and an audit line recording theory and verification grade.*

Definition 9462.2004 (Theorem scope)**.** *The scope of a theorem is the exact class of carriers, certificates, or objects for which the theorem is licensed.*

Theorem 9462.2005 (Unscoped theorems are refused)**.** *A theorem without explicit scope cannot be used as a BEDC theorem.*

Proof. Without scope, the carrier, classifier, ledger, and closure conditions are unknown. A claim over all objects, observers, worlds, or mathematics typically requests unrestricted universal closure and must be downgraded or socketed. □

Corollary 9462.2006 (Theorem titles must not overstate)**.** *Theorem titles should name the exact carrier and conclusion rather than claiming that BEDC proves causality, consciousness, or all mathematics.*

Definition 9462.2007 (BEDC corollary)**.** *A BEDC corollary is a direct consequence of prior theorems that adds no new carrier, witness, or gap.*

Theorem 9462.2008 (Corollaries do not increase strength)**.** *The closure and verification grade of a corollary cannot exceed the weakest grade of the results it depends on.*

Proof. The corollary contributes no new witness. It reuses prior proof surfaces, so it cannot raise theory closure or formal verification. □

Corollary 9462.2009 (Philosophical corollaries are conservative)**.** *Philosophical corollaries may explain, restrict, or translate; they may not add new ontological commitments.*

9462.30.6 Proofs

Definition 9462.2010 (BEDC proof discipline)**.** *A BEDC proof is a finite witness chain passing through source witness, classifier witness, transport or exactness witness, ledger witness, stability witness, and conclusion.*

Concretized in §1219: Proof-trace audit witnesses are realized as finite proof trace, transport, ledger, refusal, audit-verdict, provenance, and NameCert rows.

Concretized in §1334: Definition, theorem, and proof discipline are realized as one finite NameCert packet with separated scope, proof-route, refusal, and two-axis status rows.

Concretized in §1346: Trace-verdict boundaries are realized as finite proof-trace, refusal, verdict, interface-target, provenance, and local NameCert rows.

Definition 9462.2011 (Forbidden proof resources)**.** *Forbidden proof resources include hidden choice, host equality as BEDC equality, quotient collapse, propositional extensional rewrite, global truth predicate, global clock, unledgered compression, and unscoped universal claim.*

Theorem 9462.2012 (Proofs must display transport)**.** *Any proof crossing a classifier, bridge, package, or history-identity surface must display transport.*

Proof. Without displayed transport, the proof treats a relation as equality. That is an extensional-identification socket rather than an internal proof. □

Corollary 9462.2013 (Obviousness is not a witness)**.** *Words such as obvious, natural, standard, or by the usual definition do not close a BEDC proof unless accompanied by the relevant witness chain.*

9462.30.7 Gap reports

Definition 9462.2014 (Gap report)**.** *A gap report records site, requested supply, socket type, gate, consequence if internalized, and upgrade path.*

Definition 9462.2015 (Gap status)**.** *A gap is open when it is identified without an upgrade path, deferred when it has an upgrade path, and forbidden when the requested move is principally refused.*

Theorem 9462.2016 (Gaps must be typed)**.** *An untyped gap is not a complete BEDC gap report.*

Proof. The report must say whether the missing supply is unrestricted induction, witness, identity, causal persistence, inter-history coordination, inscription novelty, self-reference closure, or a stack of these. Different kinds have different gates. □

Corollary 9462.2017 (Gaps are positive honesty structures)**.** *A gap is a visible boundary, not a proof failure hidden in prose.*

9462.30.8 Cannot-claim registry

Definition 9462.2018 (Cannot-claim entry)**.** *A cannot-claim entry records claim text, status, reason not claimable, and required upgrade. Its status is forbidden, deferred, or partial.*

Definition 9462.2019 (Cannot-claim registry)**.** *The cannot-claim registry is the finite export surface of claims that the manuscript explicitly does not make.*

Theorem 9462.2020 (Refusals must be recorded)**.** *BEDC writing must explicitly record what it does not claim.*

Proof. The certified surface is finite. If unsupported adjacent claims are left implicit, readers may infer them from nearby positive results. The registry prevents that inference. □

Corollary 9462.2021 (Cannot-claim is not roadmap)**.** *The cannot-claim registry is not a future schedule.*

Proof. A roadmap names intended work. A cannot-claim entry names a current refusal. A deferred refusal may later be removed only after its upgrade is discharged; a forbidden refusal has no upgrade path. □

9462.30.9 Failure certificates

Definition 9462.2022 (Failure certificate)**.** *A failure certificate* $\mathsf{FailureCert}(N, c, v)$ *records a typed reason why a claimed theory grade* c*, formal status* v*, or their combination fails. Branches include missing source, missing classifier, classifier failure, exactness failure, descent failure, absent gap ledger, unstable completion, overstated scope, failed bridge, host primitive leakage, checker failure, audit failure, and axis confusion.*

Theorem 9462.2023 (Failure blocks the corresponding gate)**.** *Theory-side failure blocks the theory gate, verification-side failure blocks formal status, and axis-confusion failure blocks the verified gate.*

Proof. Theory-side branches deny source, classifier, exactness, descent, ledger, stability, scope, bridge, or no-host-leak fields. Verification-side branches deny checking or audit cleanliness. Axis-confusion denies the independence of the two axes. □

Corollary 9462.2024 (Failure is certificate dual)**.** *Certificates license export; failure certificates block export. Both are typed audit objects.*

Concretized in §1237: Typed failure certificates turn the gap, failure, and bridge discipline into a finite NameCert packet.

Concretized in §1233: Typed two-axis failure certificates are realized as finite gate-blocking NameCert packets.

9462.30.10 Standard bridges

Definition 9462.2025 (Standard bridge writing form)**.** *A standard bridge must display encoding, decoding, return witnesses in both directions, finite theorem preservation, and no-host-leak.*

Definition 9462.2026 (Finite preservation list)**.** *The theorem-preservation field is a finite list of host theorems paired with BEDC counterparts and translation witnesses. No theorem outside the list is claimed preserved.*

Definition 9462.2027 (No-host-leak discipline)**.** *No-host-leak states that host numbers, quotients, function spaces, equality, choice, and propositional extensionality do not enter the BEDC public surface.*

Theorem 9462.2028 (Standard bridge is not fusion)**.** *A standard bridge is conservative recognition, not fusion with the host theory.*

Proof. The bridge compares BEDC and host objects through explicit maps and finite preservation rows. No-host-leak prevents host primitives from becoming BEDC inputs. □

Corollary 9462.2029 (Bridge claims are host-relative)**.** *A bridge claim must name the host theory. There is no absolute bridge independent of host semantics.*

Concretized in §1229: Gap, failure, and bridge audit rows are realized as one finite NameCert packet with axis-separation and no-host-leak boundaries.

9462.30.11 Philosophical comparison

Definition 9462.2030 (Tradition map)**.** *A comparison between BEDC and a philosophical tradition is a packet of traditional claim, BEDC site, preserved structure, rejected surplus, and audit status.*

Theorem 9462.2031 (Comparisons are not membership claims)**.** *BEDC comparisons with traditions must not become claims that BEDC is Kantian, Husserlian, Buddhist, Whiteheadian, or otherwise a member of the compared tradition.*

Proof. The object language contains BEDC carriers, relations, certificates, ledgers, and gaps, not the tradition's full metaphysical vocabulary. The comparison maps a structural question to a BEDC site. □

Corollary 9462.2032 (Rejected surplus is mandatory)**.** *Every philosophical comparison must state what BEDC does not accept from the tradition.*

9462.30.12 Smuggling

Definition 9462.2033 (Philosophical smuggling)**.** *Philosophical smuggling introduces an external philosophical entity as a BEDC internal object: subject substance, world-in-itself, global truth, absolute now, mental substance, or God as object.*

Definition 9462.2034 (Mathematical smuggling)**.** *Mathematical smuggling introduces mature mathematical objects such as natural numbers, real numbers, sets, functions, limits, quotients, topologies, or categories as BEDC primitives.*

Definition 9462.2035 (Host smuggling)**.** *Host smuggling exposes host equality, host numbers, host lists, host function spaces, quotient soundness, choice, or propositional extensionality on the BEDC public surface.*

Theorem 9462.2036 (The three smuggling forms share one shape)**.** *Philosophical, mathematical, and host smuggling all disguise uncertified external supply as internal content.*

Proof. The philosophical case imports an unwitnessed entity, the mathematical case imports a mature object without certificate, and the host case imports implementation primitives without bridge. All bypass naming, closure, formal status, gap, or bridge discipline. □

Corollary 9462.2037 (External concepts have two routes)**.** *An external concept can enter BEDC only by certificate and gate, or by gap, socket report, and cannot-claim entry.*

Concretized in §1157: Host primitive leakage is realized as a finite diagnostic refusal packet for public-surface host imports.

Concretized in §1329: Smuggling-pattern classifiers realize the philosophical, mathematical, and host smuggling discipline as one finite refusal-and-gate NameCert packet.

9462.30.13 Research template

Definition 9462.2038 (Ten-field research template)**.** *Every proposed object or philosophical concept should state traditional target, BEDC source, carrier choice, classifier choice, stability obligations, ledger, core theorem list, exactness predicate, standard bridge status, and combined theory and formal status.*

Theorem 9462.2039 (The template prevents overclaiming)**.** *The ten-field template blocks the common overclaims.*

Proof. The traditional target controls terminology. The source blocks primitive import. Carrier and classifier block identity smuggling. Stability blocks unusable behavior. Ledger blocks amnesic compression. The theorem list blocks empty naming. Exactness blocks weak correspondence becoming identity. Bridge status blocks host fusion. Status blocks grade inflation. □

Corollary 9462.2040 (Philosophical objects use the same template)**.** *Concepts such as freedom or consciousness use the same template if they are to become object-layer interfaces; otherwise they remain readings, gaps, sockets, or roadmap items.*

9462.30.14 Review discipline

Definition 9462.2041 (Review questions)**.** *Each claim is reviewed by asking for carrier, classifier, ledger, theory grade, formal status, bridge host if present, gap socket if present, forbidden readings, cannot-claim conflicts, and axis confusion.*

Definition 9462.2042 (Automatic downgrade)**.** *When a claim cannot answer a required audit question, it must be downgraded from theorem to proposition, proposition to schema, schema to roadmap, roadmap to gap, or gap to cannot-claim.*

Theorem 9462.2043 (Unauditable claims cannot be strengthened)**.** *A claim that cannot be audited cannot be strengthened into a theorem.*

Proof. A theorem requires a proof witness, and proof witnesses require carrier, classifier, ledger, scope, and status. If these cannot be given, theorem status is unavailable. □

9462.30.15 Synthesis

Theorem 9462.2044 (Audit methodology synthesis)**.** *A BEDC claim is admissible when it has a carrier, classifier, ledger, theory-closure grade, formal-verification grade, gap or refusal surface when incomplete, and no-leakage discipline.*

Proof. Writing items provide the audit surface. The two status axes remain independent. Closure status blocks bind chapter claims. Definitions, theorems, corollaries, and proofs have fixed fields. Gaps are typed. Cannot-claim entries and failure certificates record negative export surfaces. Bridges prevent host fusion. Tradition maps prevent philosophical overidentification. Smuggling checks block external primitive import. □

Corollary 9462.2045 (Audit-first writing principle)**.** *The primary question is not whether a concept may be mentioned, but by which carrier, classifier, ledger, gate, gap, and status it is allowed to be mentioned.*

Corollary 9462.2046 (Passage to final synthesis)**.** *With audit methodology fixed, the final layer can state the complete auditable-generativity theorem and research programme.*

Concretized in §1227: Audit writing discipline is realized as a finite NameCert packet separating carrier, classifier, ledger, closure status, formal status, refusal, registry, and no-leakage rows.

Concretized in §1333: AuditAxisSeparationUp realizes the audit-methodology two-axis noncollapse rule as a finite NameCert packet.

9462.31 Total Synthesis: Auditable Generativity

The preceding layers are gathered here into one philosophical description. BEDC begins from primitive distinction, carries generated information by histories, reads observation and time through continuation, licenses mature objects by naming certificates, exposes unclosed commitments through gaps and the far-end position, and governs every export by audit status.

9462.31.1 Total definition

Definition 9462.2047 (BEDC philosophy)**.** *BEDC philosophy is the structural theory of what can be generated, what can be named, what can be known, what must remain open, and what may be exported. Its basic terms are not substances, minds, worlds, or laws, but carriers, classifiers, witnesses, ledgers, certificates, gaps, bridges, and audit gates.*

Definition 9462.2048 (Auditable generativity)**.** *Auditable generativity is the thesis that every admissible object, knowledge claim, scientific claim, philosophical reading, or bridge claim must be generated, classified, ledgered, certified, or explicitly marked as a gap or cannot-claim entry.*

Definition 9462.2049 (Auditable generation chain)**.** *The auditable generation chain is the route*

$$\mathsf{b0}, \mathsf{b1} \to \mathsf{MarkSameness/NoConfusion} \to \mathsf{Hist} \to \mathsf{hsame} \to \mathsf{Ext/Cont} \to \mathsf{Ask/Sig/sameSig} \to \mathsf{Pkg/Gap} \to \mathsf{NameCert}$$

Completion-like, fold-like, geometric, algebraic, scientific, and philosophical interfaces enter through their own certificate schemas, not as kernel primitives.

Theorem 9462.2050 (Generation-chain priority)**.** *Every mature BEDC concept must occupy a position in the auditable generation chain.*

Proof. A concept without a generation-chain position has no carrier. Without a carrier it has no classifier. Without a classifier it has no auditable account of sameness, difference, transport, or exactness. Without a ledger, any compression or hidden material is untraceable. Without a certificate, the concept is not a licensed name. Hence mature concepts must be located in the chain. □

Corollary 9462.2051 (No position, no export)**.** *If a concept cannot state its carrier, classifier, ledger, and status, it cannot be exported as a BEDC object.*

Proof. The missing fields are precisely the fields by which the generation chain becomes auditable. The concept may remain a reading, gap, roadmap, or cannot-claim entry, but it is not an export. □

9462.31.2 Total ontology

Definition 9462.2052 (BEDC existence)**.** *At the object layer, X exists in BEDC when X has a licensed carrier, classifier, ledger, and certificate position. Mature existence is the conjunction of a naming certificate and the relevant reported status.*

Definition 9462.2053 (Licensed object)**.** *A licensed object is an interface whose naming certificate supplies source specification, pattern specification, classifier specification, stability certificate, and ledger policy.*

Theorem 9462.2054 (Mature existence is naming license)**.** *In the mature object layer, to exist is to have licensed naming status.*

Proof. A mature object cannot be introduced as a bare kernel primitive. It therefore enters through a $\mathsf{NameCert}$ and the associated status record. Conversely, a name with those fields is available as a licensed interface at its stated scope. Thus mature existence is naming license. □

Corollary 9462.2055 (Anti-substance ontology)**.** *BEDC does not read the world as a collection of substances, but as a stratified field of licensed generated interfaces.*

Proof. Substance ontology places objects before certificates. BEDC licenses objects only after generation, classification, ledgering, and naming. □

Corollary 9462.2056 (Mature objects are not inputs)**.** *Numbers, reals, sets, functions, limits, topological spaces, categories, universes, consciousness, causality, freedom, truth, and God are not BEDC primitives. They can enter only as certificates, records-side readings, bridge targets, gap positions, or refusal entries.*

Proof. Each item requires structure beyond the primitive distinction and history constructors. Treating any of them as an input bypasses carrier, classifier, ledger, certificate, or gap discipline. □

9462.31.3 Total epistemology

Definition 9462.2057 (BEDC knowledge)**.** *To know P in BEDC is to hold an auditable witness for P. Such a witness may be a sameness witness, continuation witness, classifier witness, package or gap witness, naming certificate, semantic naming certificate, derivation certificate, bridge witness, gap report, or failure certificate.*

Definition 9462.2058 (Knowledge strength)**.** *A knowledge claim reports its strength: seed, obligation, paper-level closure, checked theorem, checked bridge, gap, or cannot-claim status. The theory-closure and formal-verification axes remain distinct.*

Theorem 9462.2059 (Knowledge is not bare truth)**.** *BEDC knowledge is possession of a certificate-bearing witness, not possession of a bare internal truth predicate.*

Proof. An internal total truth predicate would close the meta loop. BEDC keeps the meta loop open. Hence knowledge cannot be defined as access to such a predicate; it is reported as local witness, certificate, ledger, bridge, or gap surface. □

Corollary 9462.2060 (To know is to audit)**.** *Within BEDC, to know is to be able to audit the witness path.*

Proof. Without an auditable path, the claim has no visible source, classifier, stability, hidden-material ledger, or strength. □

Concretized in §1306: Epistemic witnesses realize BEDC knowledge as finite carrier, audit-route, strength, gap/refusal, bridge, and NameCert rows.

9462.31.4 Total observation theory

Definition 9462.2061 (Observation)**.** *An observation is a continuation row:*

$$\mathsf{Observation}(h, d, h') := \mathsf{Cont}(h, d, h').$$

Definition 9462.2062 (Observer)**.** *An observer is a history, read modulo* hsame*:*

$$\mathsf{Observer}(h) := h : \mathsf{Hist}.$$

Definition 9462.2063 (Time)**.** *Time is the local continuation chain by which a history is generated from the empty history.*

Theorem 9462.2064 (Observation, distinction, and time)**.** *At the kernel layer, observation, distinction step, and time step have the same continuation shape.*

Proof. Observation is Cont on histories. A distinction step is the application of the two elementary extension shapes. Local time is the ordered growth of a history by those steps. These readings share the same carrier, continuation laws, and hsame-respecting behavior. □

Theorem 9462.2065 (Observer is history)**.** *BEDC has no observer-substance behind the history. The observer is the* Hist *value read under* hsame.

Proof. The continuation signature has no separate subject parameter. Identity is supplied by hsame on histories. Adding a hidden observer entity would require unlicensed transport between that entity and the visible history, which is not part of the kernel surface. □

Corollary 9462.2066 (Subject is not substance)**.** *The subject is a stable reading of the historical trace, not an owner behind it.*

Proof. There is no additional carrier for such an owner. Subject talk is therefore a reading of history, continuity, and self-proxy ledgers. □

9462.31.5 Total logic

Definition 9462.2067 (Allowed proof)**.** *An allowed BEDC proof is an explicit witness construction or a local refutation inside a fixed carrier, classifier, and certificate.*

Definition 9462.2068 (Forbidden proof)**.** *A forbidden proof extracts positive content without constructor witness, or closes a global truth, choice, quotient, propositional extensionality, or halting surface.*

Theorem 9462.2069 (Logic discipline synthesis)**.** *BEDC logic is governed by three rules: positive content must be constructed, negative content must remain local, and the meta loop must remain open.*

Proof. Positive claims require witnesses. Refutations are licensed only inside fixed certificate surfaces where the carrier, classifier, and closure laws are displayed. A proof principle that decides all certificates or all propositions would internalize the meta level and violate the open meta-loop boundary. □

Corollary 9462.2070 (Classical shortcuts share one refusal)**.** *Choice, quotient collapse, and propositional extensionality are refused as public BEDC resources because each accepts unwitnessed supply at a different level.*

Proof. Choice supplies a term, quotient collapse supplies an identity, and propositional extensionality supplies a rewrite principle without the transport witnesses BEDC requires at the public surface. □

Corollary 9462.2071 (Halting obstruction)**.** *A total halting predicate for all certificate-level continuations is the recursion-theoretic face of the same boundary.*

Proof. Such a predicate would decide all continuation behavior at the certificate stratum and thereby close the meta loop that BEDC keeps open. □

Concretized in §1294: The allowed/forbidden proof boundary is realized as the finite AllowedProofAuditUp NameCert packet.

9462.31.6 Total boundary theory

Definition 9462.2072 (Closed ground loop)**.** *The ground loop is closed by the primitive two-constructor distinction.*

Definition 9462.2073 (Open meta loop)**.** *The meta loop is open because BEDC does not internally define its own total truth predicate, runtime validator, or halting oracle.*

Theorem 9462.2074 (Two-loop synthesis)**.** *BEDC requires closed ground and open meta.*

Proof. Without a closed ground, the system cannot start. With a closed meta loop, the system would validate its own truth or runtime surface from inside, producing the familiar self-reference obstruction. The loops therefore have different statuses. □

Corollary 9462.2075 (Minimal ground contribution)**.** *BEDC does not bypass formal limits. It compresses the unavoidable ground loop to primitive distinction and refuses meta closure.*

Concretized in §1295: The observation, proof-discipline, and open-meta-loop rows are realized as one finite audit boundary.

9462.31.7 Total gap and far-end theory

Definition 9462.2076 (Gap)**.** *A gap is a site in a closed system where a requested supply cannot be discharged internally:*

$$\mathsf{GAP}(\mathsf{Site}, \mathsf{RequestedSupply}, \mathsf{SocketType}, \mathsf{Gate}).$$

Definition 9462.2077 (Far-end position)**.** *The far-end position T is the structural position of the supply requested by gap sockets. It is not an object-layer entity, axiom, or theorem.*

Theorem 9462.2078 (Gap and far-end synthesis)**.** *Every commitment beyond closed records and closed generation must be exposed as a gap, and the far end of such sockets is named T.*

Proof. Finite records cannot yield unrestricted universal closure, unwitnessed witnesses, external identity, future causal persistence, inter-history coordination, inscription novelty, or total self-reference closure. These demands must be reported as sockets rather than internal rules. □

Corollary 9462.2079 (Far end is not object)**.** *The far-end position can be named only positionally, not reified as an object.*

Proof. If T were an object, it would need a carrier, classifier, ledger, and naming certificate. Its role is precisely to mark a supply that the object layer cannot internalize. □

9462.31.8 Total phenomenology

Definition 9462.2080 (Conscious record)**.** *A conscious record is the focused records-side packet*

$$\mathsf{ConsciousRecord}(L_N, F) := (H(F), T(F), S(F), \rho).$$

Definition 9462.2081 (Universe slice)**.** $\mathsf{Universe}_{L_N}$ *is the finite observation-history slice admitted by the focused ledger L_N.*

Definition 9462.2082 (Space reading)**.** Space_{L_N} *is the locality-cell graph together with the inter-history invariant rows available at the focused ledger.*

Theorem 9462.2083 (Phenomenology synthesis)**.** *BEDC phenomenology reads consciousness as a focused records-side carrier, universe as a finite observation-history slice, time as a local continuation chain, space as inter-history locality geometry, identity as an* hsame*-stable trace, causality as a Type IV gap, freedom as a Type VI inscription-event aspect, other minds as Type V gaps, and self-reference as a Type VII gap-on-gap hierarchy.*

Proof. Observer is history and observation is continuation. Hence consciousness cannot enter as an independent substance. No global clock or global container is supplied by the kernel, so universe and space are read from finite slices and inter-history relations. Causality, freedom, other minds, and self-reference each request a supply beyond closed records, and so take socket form. □

Corollary 9462.2084 (Hard problem as audit question)**.** *BEDC does not ask for consciousness as an essence. It asks which records-side carrier, ledger, self-proxy, relation row, and gap sockets make consciousness-talk admissible.*

Proof. Only records, certificates, and socketed boundary reports can enter the object layer. Phenomenal excess that lacks those surfaces remains a gap or reading. □

9462.31.9 Total philosophy of science

Definition 9462.2085 (Scientific object)**.** *A scientific object is a certificate package containing a naming certificate, derivation or closure status, empirical ledger, inter-history invariant surface, gap report, and optional standard bridge.*

Definition 9462.2086 (Physical law)**.** *A physical law is an empirical regularity together with a Type IV gap for future persistence.*

Theorem 9462.2087 (Scientific object synthesis)**.** *Scientific objects are composites of records, invariants, certificates, empirical ledgers, bridges, and gap reports; they are not primitives.*

Proof. A scientific object names a pattern in records, classifies and stabilizes it across perspectives, connects it to measurement and error ledgers, may compare it with mature model systems, and often commits to future predictions. Each component carries its own audit obligation. □

Corollary 9462.2088 (Relational physics principle)**.** *Frame-independent physical content is inter-history invariant content.*

Proof. Multiple histories have no shared base history, no shared time-step indexing, and no global synchronization. What survives as physical content must therefore be carried by stable inter-history relations. □

Corollary 9462.2089 (Model is not world)**.** *A model is an interpretation, compression, or bridge for records and invariants. It is not the world itself.*

Proof. The universe available to BEDC is a finite observation-history slice. Identifying a model with the world would replace that slice by a global object. □

Concretized in §1300: The phenomenology/science interface is realized as a finite composite NameCert packet joining records-side consciousness, universe slices, inter-history invariants, empirical ledgers, gap reports, and conservative bridge rows.

9462.31.10 Total bridge theory

Definition 9462.2090 (Standard bridge)**.** *A standard bridge from N to a host theory T contains encoding, decoding, return witnesses in both directions, finite theorem preservation, and no-host-leak.*

Definition 9462.2091 (Conservative bridge)**.** *A bridge is conservative when it does not inject host primitives into the BEDC public surface.*

Theorem 9462.2092 (Bridge is not fusion)**.** *A standard bridge is conservative recognition, not fusion with the host theory.*

Proof. The bridge lets a host reader recognize a BEDC object and lets BEDC accept only the finitely listed translated theorem rows. No-host-leak blocks host primitives such as host natural numbers, quotient collapses, choice, propositional extensionality, and host equality from becoming BEDC inputs. □

Corollary 9462.2093 (Mature systems are bridge targets)**.** *Mature mathematics and mature physics may serve as bridge targets, but they cannot replace internal BEDC certificates.*

Proof. Replacing the certificate by the host theory would turn a bridge into primitive import and violate no-host-leak. □

9462.31.11 Total audit theory

Definition 9462.2094 (Admissible claim)**.** *A claim is admissible when it has carrier, classifier, ledger, status, certificate or gap or cannot-claim surface, and no-leakage discipline.*

Definition 9462.2095 (Failure certificate)**.** *A failure certificate is the negative certificate of a claim: it states which required field is missing, invalid, overstated, unchecked, or confused across the theory-closure and formal-verification axes.*

Theorem 9462.2096 (Positive and negative certificates)**.** *Certificates license export, failure certificates block export, and cannot-claim entries record refusal.*

Proof. The positive certificate fills source, classifier, exactness, ledger, stability, bridge, and status fields. The failure certificate names a missing or invalid field. The cannot-claim entry records that the manuscript does not make the adjacent claim at the current surface. □

Corollary 9462.2097 (Cannot-claim is negative knowledge)**.** *The cannot-claim registry is part of BEDC's philosophical structure, not a modesty convention.*

Proof. The registry records typed refusals and required upgrades. It is the negative face of the export surface. □

9462.31.12 Total system diagram

Definition 9462.2098 (Three-layer system)**.** *The BEDC philosophical system has three layers. The ground layer contains* $\mathsf{b0}, \mathsf{b1}$*, marks, histories,* msame*,* hsame*, extension, and continuation. The certificate layer contains asking, signatures, packages, gaps, naming certificates, semantic naming certificates, derivation certificates, and standard bridges. The boundary and interpretation layer contains gaps, the far-end position, conscious records, universe slices, scientific objects, tradition maps, and audit methods.*

Definition 9462.2099 (Generation, naming, boundary)**.** *The whole framework can be compressed into three questions: generation asks how a thing is produced, naming asks how it stabilizes as an object, and boundary asks why it cannot be closed internally.*

Theorem 9462.2100 (Three-question synthesis)**.** *Every BEDC philosophical question falls under generation, naming, or boundary.*

Proof. Objects, knowledge, subjectivity, time, consciousness, universe, science, and philosophical comparison all require a carrier, a classifier or naming certificate, and an account of any unclosed commitment. Those are exactly the generation, naming, and boundary questions. □

Corollary 9462.2101 (BEDC question form)**.** *Given a concept X, BEDC first asks for its carrier, classifier, ledger, naming certificate, gap surface, and status.*

9462.31.13 Auditable-generativity theorem

Theorem 9462.2102 (Auditable generativity)**.** *The complete BEDC philosophical framework is auditable generativity: distinction-grounded, history-carried, continuation-dynamic, name-certificate-licensed, ledger-tracked, gap-bounded, bridge-conservative, and audit-governed.*

Proof. Distinction precedes information, and histories are the minimal information carriers. Observation and time are read through continuation, and observer is history. Objects and knowledge require naming certificates and witnesses. Logic admits explicit construction and local refutation while refusing meta closure. Commitments beyond closed generation are exposed as gaps and far-end positions. Consciousness, universe, space, causality, freedom, other minds, and self-reference are rewritten as records-side carriers or sockets. Scientific objects require records, invariants, empirical ledgers, and bridges. Philosophical traditions enter only through structural maps. Audit methodology requires every claim to report carrier, classifier, ledger, status, and refusal surface. These results together give auditable generativity. □

Corollary 9462.2103 (One-sentence characterization)**.** *BEDC is an auditable generative system that starts from primitive distinction, generates histories and continuations, licenses names by certificates, keeps boundaries open through gaps and the far-end position, and governs export strength by audit gates.*

Corollary 9462.2104 (Negative characterization)**.** *BEDC is not traditional realism, subjectivist idealism, ordinary formalism, naive constructivism, psychologistic phenomenology, global physical realism, theological object theory, or a host-theory import system. It is distinction ontology, history generativity, observerless observation theory, certificate object theory, witness epistemology, open-meta boundary theory, gap and far-end transcendence theory, relational science theory, and audit writing theory.*

Corollary 9462.2105 (Research programme)**.** *Further work should proceed by the lowest open layer: finite kernel, finite data certificates, arithmetic certificates, algebra certificates, order and logic certificates, set-like and type-like interfaces, topology and metric completion, analysis, geometry, category theory, homology, number theory, spectra, and mature-system bridges.*

Concretized in §1258: Audit system packets realize admissible claims, positive certificates, failure certificates, cannot-claim rows, export grades, and ledger closure as one finite NameCert surface.

9462.31.14 Status record

Definition 9462.2106 (Philosophy package status)**.** *The philosophy package is a paper-level structural reading of the BEDC kernel and certificate architecture. It introduces no kernel primitive. It is closed as a scoped synthesis of primitive distinction, history, continuation, naming certificates, gap and far-end boundary theory, standard bridge discipline, and audit gates. It does not close full physical theory, empirical constants, complete arithmetic reconstruction, real completion, a global truth predicate, internal runtime validation, or phenomenal consciousness as object-level essence. It makes no whole-package Lean target claim; component targets belong to their cited kernel, naming-certificate, bridge, and audit chapters.*

Corollary 9462.2107 (Upgrade path)**.** *To promote the philosophy package from paper-level synthesis to a formal package, one would define a formal structure for philosophy maps, encode tradition maps, gap reports, and writing items, check no-host-leak and no-meta-closure dependencies, and give a finite theorem list for each mapped concept.*

Concretized in §1296: Audit export firewalls realize total-audit synthesis as finite claim, certificate, failure, refusal, export-grade, firewall, ledger, and NameCert rows.

Concretized in §1337: Audit finality certificates realize total auditable generativity as finite claim, certificate, failure, refusal, export-grade, synthesis, firewall, ledger, and NameCert rows.

Concretized in §1339: Epistemic ontology bridges realize philosophy total synthesis as finite ontology, epistemology, observation-logic, phenomenology-science, audit-export, ledger, and NameCert rows.

9462.32 Research Programme and Implementation Route

The philosophical synthesis becomes a research programme only when its objects are pursued as certificates rather than imported as mature assumptions. The route is layered, strength-marked, phase-governed, failure-aware, and audit-facing. It extends BEDC by proving that names have earned use, not by asserting that mature objects are already available.

9462.32.1 Definition of the research programme

Definition 9462.2108 (BEDC research programme)**.** *The BEDC research programme starts from the finite kernel*

$$\mathsf{b0}, \mathsf{b1} \to \mathsf{Hist} \to \mathsf{msame}, \mathsf{hsame} \to \mathsf{Ext}, \mathsf{Cont} \to \mathsf{Ask}, \mathsf{Sig} \to \mathsf{Pkg}, \mathsf{Gap} \to \mathsf{NameCert},$$

and, for each mature name N, constructs the five-field certificate consisting of source specification, pattern specification, classifier specification, stability certificate, and ledger policy. The resulting name is then assigned theory closure, formal verification, bridge, and refusal status.

Definition 9462.2109 (Research target)**.** *The target of research is not to collect standard objects as assumptions. It is to display the exact generative behavior by which a standard name earns a licensed place in BEDC.*

Theorem 9462.2110 (Research is not expansionism)**.** *The BEDC research programme is not the outward expansion of an object library, but the inward completion of eligibility proofs for names.*

Proof. If the programme were expansionist, it could import mature objects such as numbers, reals, sets, functions, topologies, and categories as assumptions. The roadmap instead treats mature constructions as licensed names and treats host naturals, host lists, definitional equality, quotient collapse, choice, and propositional extensionality as contamination when exposed on the public BEDC surface. Hence the programme proves license rather than importing objects. □

Concretized in §1309: Name eligibility proofs are realized as finite source, classifier, strength, audit, refusal, transport, replay, provenance, and NameCert packets.

Corollary 9462.2111 (The object of research is the certificate)**.** *When BEDC studies* $\mathsf{Real}^{\uparrow}$, $\mathsf{Cat}^{\uparrow}$, $\mathsf{Topology}^{\uparrow}$, *or* $\mathsf{Zeta}^{\uparrow}$, *it studies their naming certificates, classifiers, ledgers, stability surfaces, bridges, and failure surfaces.*

Proof. The mature name is admitted only through the certificate. Without that certificate, the mature object remains an external target or roadmap name. □

9462.32.2 Strength gradient

Definition 9462.2112 (Research strength)**.** *Each derived mature-object claim lies on a strength gradient:*

$$\mathsf{naming\ seed} < \mathsf{paper\ certificate} < \mathsf{machine\ checked\ certificate} < \mathsf{conservative\ bridge}.$$

Lower strength may not be reported as higher strength.

Definition 9462.2113 (Four strengths)**.** *A naming seed proposes a paper-side carrier and classifier while obligations remain open. A paper certificate supplies the five naming certificate fields and a prose proof. A machine-checked certificate formalizes the relevant certificate fields and stability obligations in the Lean development and resolves the cited target markers. A conservative bridge gives an external two-way translation to a mature standard object while preserving no-host-leak.*

Theorem 9462.2114 (No strength inflation)**.** *If N has current strength s, BEDC cannot claim for N any strength strictly above s.*

Proof. Each higher strength adds an undischarged obligation: full certificate fields above seed, machine verification above paper certificate, and host-relative conservative translation above machine checking. Reporting a higher strength would present missing obligations as complete. □

Corollary 9462.2115 (Philosophical claims report strength)**.** *Claims about consciousness, freedom, universe, and physical law must be reported as structural readings, paper certificates, schemas, gap sockets, machine targets, or bridge targets, rather than as unqualified proofs.*

Proof. Philosophical claims also carry naming, classification, stability, ledger, and boundary obligations. Without strength reporting, readings, schemas, gaps, and theorems are confused. □

9462.32.3 Layer route

Definition 9462.2116 (Layer route)**.** *The BEDC reconstruction route is layered:*

$$L0\ \mathsf{Marks},\quad L1\ \mathsf{Histories},\quad L2\ \mathsf{GenerativeDynamics},\quad L3\ \mathsf{AskingAndSignature},$$
$$L4\ \mathsf{PackageRelationsAndGaps},\quad L5\ \mathsf{NamingAndStability},\quad L6\ \mathsf{FiniteData},\quad L7\ \mathsf{Arithmetic},$$
$$L8\ \mathsf{Algebra},\quad L9\ \mathsf{OrderLogicSetLikeTypeLike},\quad L10\ \mathsf{TopologyMetricCompletionReal},$$
$$L11\ \mathsf{Analysis},\quad L12\ \mathsf{GeometryCategoryHomology},\quad L13\ \mathsf{NumberTheoryAndSpectra},\quad L14\ \mathsf{MatureSystemBridge}.$$

Each layer may depend only on lower layers.

Definition 9462.2117 (Layer dependency)**.** $\mathsf{Depends}(L_i, L_j)$ *is licensed only when* $i > j$*. Cyclic dependence between layers is not part of the route.*

Theorem 9462.2118 (Lowest open layer first)**.** *The research route advances the lowest open layer first.*

Proof. A high-layer claim imports all unclosed lower-layer obligations into its vocabulary. For example, analytic or spectral claims hide completion, algebraic descent, order, bridge, and continuity obligations unless the lower layers are already closed. The layer index therefore functions as review priority. □

Corollary 9462.2119 (Over-layer work is roadmap)**.** *If a high-layer target depends on an open lower layer, the high-layer target is a roadmap, schema, proof target, deferred claim, or gap, not a closed theorem.*

Proof. The missing lower layer withholds source, classifier, stability, exactness, or bridge data needed by the high-layer certificate. □

Concretized in §1305: Programme strength ledgers realize the seed, paper-certificate, machine-check, bridge, dependency, refusal, and no-strength-inflation rows as one finite NameCert packet.

Concretized in §1314: The research-programme strength gradient is realized as a finite ledger that blocks over-reporting across naming seed, paper certificate, machine-checked certificate, and conservative bridge.

9462.32.4 Finite kernel baseline

Definition 9462.2120 (Finite kernel baseline)**.** *The finite kernel baseline contains marks, histories, extension, continuation, asking, signatures, signature sameness, packages, gaps, composite gaps, and naming certificates, with dependency shape*

$$\mathsf{Mark} \to \mathsf{Hist} \to \mathsf{Ext}, \mathsf{Cont} \to \mathsf{Ask}, \mathsf{Sig} \to \mathsf{sameSig} \to \mathsf{Pkg}, \mathsf{Gap} \to \mathsf{CompGap} \to \mathsf{NameCert}.$$

Definition 9462.2121 (Kernel exit condition)**.** *The L0–L5 exit condition is that the kernel theorems are checked at their cited targets and remain free of axiom-purity contamination. The surface includes sameness equivalences and no-confusion, extension and continuation laws, asking and signature determinacy under policies, package and gap soundness, coverage, and separation, and naming certificate admission.*

Theorem 9462.2122 (Finite kernel precedes mature objects)**.** *Every mature-object certificate depends on the finite kernel baseline.*

Proof. NameCert is the universal admission rule. It depends on package and gap structure, which depends on signatures, which depends on continuation, histories, and marks. Without this baseline, no mature name has a proof boundary. □

Concretized in §1288: Kernel phase-refusal packets realize the philosophy programme phase-order and off-table boundary as finite BHist, hsame, Cont, Pkg, and NameCert rows.

Corollary 9462.2123 (The philosophy package depends on L0–L5)**.** *Any formalization of the philosophy package must return to L0–L5: distinction to marks, history to* Hist*, observation and time to* Cont*, object license to* NameCert*, and boundary memory to* Gap*.*

9462.32.5 Phase bundles

Definition 9462.2124 (Phase bundle)**.** *A phase bundle is the collection of objects sanctioned for priority during a research period, together with a precise exit criterion.*

Definition 9462.2125 (Near-term phases)**.** *The near-term route is organized as follows: kernel-checked baseline; finite data from booleans through lists; full arithmetic through rationals with induction, recursion, ordered-ring, and ordered-field structure; algebra up to fields; real and completion through dyadic rational core, stream names, regular rational sequences, and real names; real algebra and geometry; compactness and continuity; linear algebra and analysis seeds; categories and bridges for already checked objects.*

Theorem 9462.2126 (No phase skipping)**.** *While a phase has not exited, targets belonging to later phases are deferred.*

Proof. The phase determines the current sanctioned advancement direction. Later-phase targets depend on obligations the current phase is meant to discharge. Advancing them as closed would hide that dependency. □

Corollary 9462.2127 (Dependency before attraction)**.** *High-profile goals such as the Riemann Hypothesis, quantum states, curved spacetime, or spectral theorems cannot bypass lower certificates.*

Proof. Such goals depend on real numbers, analysis, topology, algebra, bridges, or multi-history semantics. Until those dependencies are closed, the goals remain roadmaps or proof targets. □

9462.32.6 Off-the-table claims

Definition 9462.2128 (Off-the-table claim)**.** *An off-the-table claim is a claim explicitly not made until its named milestone holds at the required strength.*

Definition 9462.2129 (Current refusal list)**.** *The current refusal surface includes claims that BEDC has re-derived all mature mathematics; that real numbers, the unit circle, or folds are complete; that a natural-number seed is full natural-number theory; that an addition seed is full addition; that paper certificates are machine-checked certificates; that scaffolds are verified implementations; that external models replace BEDC proof obligations; or that host equality, host natural numbers, or host functions belong to the BEDC public surface.*

Theorem 9462.2130 (Off-the-table is a boundary condition)**.** *The off-the-table list is a boundary condition of the research programme, not a rhetorical caution.*

Proof. Without explicit refusals, seeds, paper certificates, scaffolds, and external models could be misread as mature exports. The refusal list prevents that inference and records which claim remains unsupported. □

Corollary 9462.2131 (Philosophical synthesis must not overclaim)**.** *The philosophy package cannot claim that BEDC has completed all mathematics, proved physics, internalized consciousness as essence, or supplied a global truth predicate. It can claim a certificate and audit discipline for any such target to enter.*

9462.32.7 Verification reporting

Definition 9462.2132 (Checked report)**.** *A checked formalization report states the proof-checker version, the exact command used, whether external libraries are imported, the names of the theorems successfully checked, the admitted or pending statements, and whether public APIs expose host equality, host natural numbers, host lists, or host functions as BEDC internals.*

Definition 9462.2133 (Lean target status)**.** *Lean target status is reported theorem by theorem through inline markers for checked theorem, definition, statement-only target, or temporary unclosed target. These markers report verification status; they do not by themselves settle theory closure.*

Definition 9462.2134 (Audit report)**.** *An audit report records marker resolution and axiom purity: checked targets must resolve to real declarations in the Lean source, and the axiom audit must report no prohibited axiom contamination.*

Theorem 9462.2135 (Verification report is not object theory)**.** *Verification reporting belongs to project and implementation status; it does not replace BEDC object theory.*

Proof. The report says which commands, markers, and declarations are clean. Object theory requires carrier, classifier, ledger, certificate, closure, and bridge fields. A clean report can support those fields but does not constitute them. □

Corollary 9462.2136 (Implementation scaffold is external)**.** *An implementation scaffold is an external artifact unless and until its claims are tied to the relevant BEDC certificates and audit gates.*

9462.32.8 Failure and downgrade

Definition 9462.2137 (Failure certificate at strength)**.** *A failure certificate for a name N at strength s is a typed reason why the claimed gate fails: missing source, missing classifier, classifier failure, exactness failure, operation descent failure, absent gap ledger, unstable completion, failed bridge, host primitive leakage, or checker failure.*

Theorem 9462.2138 (Failure blocks gate)**.** *If a failure certificate is exhibited for N at strength s, the corresponding acceptance gate for N at s does not hold.*

Proof. Every failure branch denies a field required by the gate. The gate therefore cannot be satisfied at that strength. □

Definition 9462.2139 (Downgrade)**.** *Downgrade is the required lowering of a reported status when a failure certificate shows that the stronger marker or claim is not licensed.*

Corollary 9462.2140 (Failure is a result)**.** *A failure certificate is structural information: it identifies the field that blocks promotion.*

Proof. The branch says whether source, classifier, exactness, ledger, bridge, host-leak, checker, or another field fails. That is a precise research outcome and a guide for the next obligation or refusal. □

Concretized in §1280: Status downgrades are realized as finite prior-status, failure-certificate, lowered-report, gap-route, provenance, and NameCert packets.

Concretized in §1289: VerificationFailureRoadmapUp realizes checked reports, audit rows, failure certificates, downgrade routes, roadmap boundaries, and cannot-claim rows as one NameCert packet.

9462.32.9 Roadmap and cannot-claim

Definition 9462.2141 (Roadmap)**.** *A roadmap states what may become claimable after named blockers are cleared.*

Definition 9462.2142 (Cannot-claim registry)**.** *A cannot-claim registry states what the manuscript currently refuses to assert.*

Theorem 9462.2143 (Roadmap does not license theorem status)**.** *The occurrence of a target in a roadmap does not license its statement as a theorem.*

Proof. A roadmap gives dependency order and upgrade conditions. Without a certificate, witness, bridge, or checked target at the required strength, the target remains unproved. □

Corollary 9462.2144 (Roadmap use in philosophy)**.** *The philosophy package may name future formal structures such as philosophy maps, tradition maps, gap reports, conscious-record certificates, and multi-history physics chains, but those names do not thereby become formalized.*

9462.32.10 Multi-history physics route

Definition 9462.2145 (Multi-history physics chain)**.** *The multi-history physics route proceeds through naming certificates for multi-history configuration, cross-history causal dependence, maximum causal rate, Lorentz-style geometry, curved spacetime as Lorentz data with gluing, and quantum-state structure as a multi-history superposition interface.*

Concretized in §1290: finite causal intervention NameCert

Concretized in §1291: Multi-history causal dependence is realized as a finite no-global-frame causal-route packet.

Concretized in §1298: The multi-history physics route is realized as a composite finite NameCert packet over relational physics, physical-law bridge, scientific-model bridge, and quantum-state rows with explicit falsification boundaries.

Definition 9462.2146 (Physics falsification surface)**.** *Each physical step carries a falsification surface. Multi-history configuration fails if it requires a global frame. Cross-history causal dependence fails if it cannot be expressed as a stable predicate. Maximum causal rate fails if it requires choice. Lorentz-style geometry fails if its distance shape is not symmetric or invariant. Curved spacetime fails if gluing cannot be constructive. Quantum-state structure fails if the superposition predicate forces propositional extensionality.*

Concretized in §1293: Physics falsification surfaces are realized as finite physical-route, law, empirical-persistence, countermodel, bridge-audit, axiom-purity, typed-gap, transport, provenance, and NameCert rows.

Theorem 9462.2147 (Physics failure is structural)**.** *If the multi-history physics route cannot remain inside the axiom-purity gate, the failure point is itself a BEDC structural result.*

Proof. The route asks whether physical relational semantics can be closed without choice, quotient collapse, or propositional extensionality. A failure identifies the first schema where distinction, history, continuation, and certificate discipline are insufficient. That location is structural information. □

Corollary 9462.2148 (Physics route does not presume success)**.** *The physics route should be written as well-posed interface, falsification surface, and axiom-purity test, not as a completed derivation of relativity or quantum mechanics.*

Proof. The route currently licenses a structural form and dependency chain. It does not supply empirical values or completed physical theories. □

9462.32.11 Research programme synthesis

Theorem 9462.2149 (Research programme synthesis)**.** *The BEDC research programme is layered, certified, strength-marked, phase-governed, failure-aware, boundary-honest, audit-facing, and physics-aware.*

Concretized in §1326: The research-programme synthesis is realized as a composite finite NameCert packet over physical-route, falsification, programme-strength, verification-failure, and failure-certificate rows.

Proof. The programme is layered by the L0–L14 dependency route. It is certified because each mature name requires a naming certificate. It is strength-marked by the seed, paper, machine-checked, and conservative bridge gradient. It is phase-governed because only the current open phase is sanctioned. It is failure-aware because failure certificates block promotion while identifying missing fields. It is boundary-honest because cannot-claim entries record current refusals. It is audit-facing because reports must state checker, command, checked names, pending statements, host leakage, and axiom status. It is physics-aware because multi-history physics is treated as a roadmap with falsification surfaces rather than a completed theory. □

Corollary 9462.2150 (After philosophy)**.** *After the philosophical synthesis, the priority is not to add more interpretive prose but to turn philosophical concepts into writing items, gap reports, tradition maps, formal targets, lowest-layer naming certificates, failure certificates, and cannot-claim entries.*

Proof. The interpretive frame is already present. Progress comes from moving readings into certificate and audit discipline at the lowest open layer. □

Corollary 9462.2151 (Execution maxim)**.** *Do not extend BEDC by assertion. Extend it by certificate.*

9462.32.12 Programme summary

Definition 9462.2152 (Programme compression)**.** *The future of BEDC is not the claim that mature objects are already possessed. It is the progressive discharge of naming certificates, ledgers, stability obligations, bridges, failure surfaces, and audit reports by which each name proves its right to be used.*

Concretized in §1328: Research-programme execution gates realize lowest-open-layer readiness, strength, verification, bridge, refusal, transport, replay, provenance, and NameCert rows as one finite packet.

Concretized in §1324: Review acceptance gates realize operator approval as finite proposal, decision, refusal, audit-readback, and NameCert rows.

Concretized in §1327: The Real-and-completion exit certificate is realized as a finite four-face NameCert packet over DyadicRatCoreUp, StreamNameUp, RegSeqRatUp, and RealUp.

Concretized in §1322: Phase-governed certificate routing is realized as a finite NameCert packet with phase, strength, refusal, failure-audit, dependency, transport, provenance, and local naming rows.

Concretized in §1331: The research programme route is realized as a composite NameCert packet binding phase, strength, refusal, verification-failure, export, and review rows.

Concretized in §1332: Research-programme phase governance, proposal review, failure feedback, calibration, and audit-loop rows are realized as one finite NameCert packet.

9462.33 Formal Philosophy Package, Export Interface, and Governance

The philosophical framework can be treated as a managed paper-level package. This package does not extend the kernel. It organizes how BEDC structures are read, registered, mapped to traditions and scientific claims, exported, revised, and refused when a claim exceeds its certificate surface.

9462.33.1 Object of the philosophy package

Definition 9462.2153 (BEDC philosophy package)**.** *A BEDC philosophy package is a paper-level structure containing core thesis, concept registry, theorem map, gap map, tradition map, scientific map, cannot-claim registry, closure status, and amendment policy. Its core thesis is auditable generativity; its registries and maps record how philosophical language is attached to BEDC carriers, classifiers, ledgers, gaps, bridges, and audit gates.*

Definition 9462.2154 (Not a kernel extension)**.** *The philosophy package is not a kernel primitive, axiom, object theory, proof checker, or truth predicate. It is reading discipline, export discipline, mapping discipline, and audit discipline.*

Theorem 9462.2155 (No primitive added)**.** *The BEDC philosophy package adds no primitive to the BEDC kernel.*

Proof. All fields of the package refer to existing BEDC surfaces: marks, histories, continuation, history sameness, naming certificates, gaps, standard bridges, failure certificates, and cannot-claim entries. The package organizes and reports these surfaces; it does not introduce a constructor in the object language. □

Corollary 9462.2156 (Philosophy cannot overrule the kernel)**.** *Any philosophical reading that conflicts with the kernel signature, naming-certificate discipline, gap discipline, or axiom-purity gate is refused or downgraded.*

Proof. The package has only reading and export authority. It cannot create a new subject entity, global truth predicate, host equality, or unwitnessed existence claim. □

9462.33.2 Concept registry

Definition 9462.2157 (Concept entry)**.** *A concept entry for X records name, BEDC carrier, classifier, ledger, positive reading, forbidden readings, gap status, theory closure, and formal status.*

Definition 9462.2158 (Core concept registry)**.** *The core registry contains at least distinction, history, information, observation, observer, time, object, knowledge, truth boundary, gap, far-end position, consciousness, universe, space, causality, freedom, other minds, scientific object, physical law, standard bridge, tradition mapping, and audit method.*

Definition 9462.2159 (Observer entry)**.** *The observer entry has name observer, carrier* Hist*, classifier* hsame *with the licensed observational classifier, ledger the observer-history identity ledger, positive reading observer equals history, forbidden readings subject-substance, hidden self-entity, and global viewer, no gap for records-side observer identity, possible gap for phenomenal excess, paper-level structural closure, and component formal status only.*

Definition 9462.2160 (Far-end entry)**.** *The far-end entry has no object-level carrier, no internal classifier, gap-socket reports as ledger, positive reading as the far end of forward-binding supply, forbidden readings object-level deity, theorem-deity, substrate axiom, and intervention entity, boundary status as its gap status, apophatic theory reading, and no object-level formal target.*

Theorem 9462.2161 (Core concepts require registry entries)**.** *Every core concept entering BEDC philosophy prose requires a concept entry.*

Proof. Without the entry, the reader cannot tell carrier, classifier, ledger, boundary status, or forbidden readings. Terms such as universe, consciousness, and far-end position are especially vulnerable to primitive import without those fields. □

Corollary 9462.2162 (Unregistered concepts are helpers)**.** *An unregistered concept may serve as explanatory prose, but not as a BEDC philosophical object.*

Concretized in §1292: The BEDC philosophy package is realized as a finite NameCert carrier for registry, map, gap, audit, cannot-claim, closure-status, and export-policy rows.

Concretized in §1287: Concept registry obligations are realized as finite carrier, classifier, ledger, forbidden-reading, status, export, transport, route, provenance, and NameCert rows.

9462.33.3 Theorem map

Definition 9462.2163 (Theorem map entry)**.** *A theorem map entry records philosophical theorem, BEDC dependency, proof mode, claim strength, and not-claimed surface.*

Definition 9462.2164 (Core theorem map)**.** *The core theorem map includes: observer equals history, depending on the continuation signature, history sameness, and absence of a subject parameter; observation equals continuation, depending on continuation over histories; time as history growth, depending on elementary history steps and local continuation chains; object as licensed name, depending on naming-certificate discipline; knowledge as witness, depending on classifier, certificate, and ledger witnesses; gap and far-end boundary, depending on closed observational systems and forward-binding supply; scientific object as certified records, invariant, bridge, and gap; and tradition mapping as structural adjacency.*

Theorem 9462.2165 (Philosophical theorems depend on BEDC sites)**.** *A philosophical theorem in the package must depend on a BEDC theorem, definition, or certificate site.*

Proof. The philosophy package is not a primitive source of theorems. Without a BEDC dependency, a philosophical theorem would be an external doctrine rather than a BEDC reading. □

Corollary 9462.2166 (Theorem-map strength is bounded)**.** *A philosophical theorem cannot be stronger than the status of the BEDC sites on which it depends.*

Proof. If a dependency is schema-only, statement-only, or roadmap-level, the mapped philosophical theorem inherits that limitation. □

9462.33.4 Gap map

Definition 9462.2167 (Gap map)**.** *A gap map is a finite table of entries. Each entry records name, site, requested supply, socket type, gate, current status, upgrade path, and forbidden internalization.*

Definition 9462.2168 (Core philosophical gaps)**.** *The core gap map contains phenomenal-excess gap, induction gap, causality gap, other-minds gap, freedom gap, self-reference gap, physics gap, and bridge gap. These mark, respectively, the failure of records-side conscious records to define phenomenal essence, finite observation to imply unrestricted universal closure, observed regularity to imply future persistence, external behavior to yield another conscious system, derivation to erase inscription actuality, self-description to become a truth predicate, multi-history physics to close its witnesses, and host recognition to become checked no-host-leak bridge.*

Theorem 9462.2169 (Gap map prevents closure illusion)**.** *The gap map prevents philosophical prose from presenting boundary questions as closed theorems.*

Proof. Consciousness, causality, other minds, freedom, self-reference, and physics invite overclosed prose. A typed gap entry records the missing supply and the gate that blocks internalization. □

Corollary 9462.2170 (Gap map is necessary)**.** *A philosophy package without a gap map cannot be exported.*

9462.33.5 Tradition map

Definition 9462.2171 (Tradition map entry)**.** *A tradition map entry records tradition, traditional claim, BEDC site, preserved structure, rejected surplus, and audit status.*

Definition 9462.2172 (Core tradition map)**.** *The core tradition map registers Spencer-Brown at primitive distinction, Brouwer at history growth and elementary time step, bundle theory, no-self, and second-order cybernetics at observer equals history, Kant at certificate and gap conditions of possibility, Husserl at focused records-side stabilization and naming, Wittgenstein at certified use, Whitehead at continuation as universal verb, Tarski, Godel, and Muenchhausen at the open meta loop, and relational physics at inter-history invariants.*

Theorem 9462.2173 (Tradition map is not membership)**.** *The tradition map does not state that BEDC belongs to any mapped tradition.*

Proof. Each entry contains preserved structure and rejected surplus. If the map were doctrinal membership, rejected surplus would not be a required field. □

Corollary 9462.2174 (Tradition comparisons are retractable)**.** *If a comparison imports excessive metaphysics, the entry is removed or downgraded without affecting the kernel.*

Proof. Tradition mapping is a reading layer. Removing it does not alter Hist, Cont, or NameCert. □

9462.33.6 Scientific map

Definition 9462.2175 (Scientific map entry)**.** *A scientific map entry records name, records carrier, invariant carrier, empirical ledger, prediction gap, bridge status, claim status, and failure surface.*

Definition 9462.2176 (Core scientific map)**.** *The core scientific map records physical records as history, measurement, and continuation rows; physical laws as empirical regularities plus Type IV prediction gaps; space as locality-cell relation geometry rather than spacetime substrate; maximum causal rate as schema-only inter-history invariant until cross-history causality closes; light-speed-like constant as structural skeleton without empirical value; and Lorentz geometry, curved spacetime, and quantum state as roadmap naming-certificate targets.*

Theorem 9462.2177 (Scientific map separates structure, model, and value)**.** *Scientific entries must distinguish structure form, model bridge, empirical value, and prediction commitment.*

Proof. A maximum-rate form may be structural, a light-speed number must come from measurement ledger, a Lorentz geometry is a model or certificate target, and future persistence is a Type IV gap. Confusing these fields inflates schemas into empirical theorems. □

Corollary 9462.2178 (Physical claims default downward)**.** *Without full naming certificate, invariant surface, empirical ledger, and bridge, a physical claim remains schema, roadmap, gap, or failure-surface statement.*

Concretized in §1307: Package map boundaries are realized as a finite four-map, axis-boundary, audit-route, transport, replay, provenance, and local NameCert packet.

Concretized in §1308: The philosophy gap map is realized as a finite NameCert ledger for typed gap entries, socket kind, gate, status, upgrade route, and forbidden internalization.

9462.33.7 Philosophy cannot-claim registry

Definition 9462.2179 (Philosophy cannot-claim registry)**.** *The philosophy package cannot-claim registry includes refusals that BEDC has completed all mathematical reconstruction, proved a complete physical theory, defined phenomenal consciousness as essence, internalized the far end as an object-level entity, internalized its own truth predicate, supplied a global clock or God's-eye observer, used host equality or host naturals as public surface, made doctrinal identity claims about traditions, equated roadmap with theorem, or equated paper synthesis with a checked formal package.*

Concretized in §1318: Cannot-claim registries are realized as finite claim-text, status, refusal-reason, upgrade-boundary, blocking, transport, and NameCert packets.

Definition 9462.2180 (Registry entry format)**.** *Each cannot-claim entry records claim text, status, why it is not claimable, and required upgrade. The status is forbidden, deferred, or partial.*

Theorem 9462.2181 (Cannot-claim registry is required)**.** *Without a philosophy cannot-claim registry, the philosophy package cannot be exported.*

Proof. Philosophical language easily turns structural readings into completed metaphysical claims. The registry explicitly blocks those exports and records the missing upgrade or principled refusal. □

Corollary 9462.2182 (Refusal is content)**.** *In the philosophy package, a refusal supported by reason and upgrade condition is typed negative knowledge.*

9462.33.8 Amendment policy

Definition 9462.2183 (Philosophy package amendment)**.** *A philosophy package amendment is an in-place change to the concept registry, theorem map, gap map, tradition map, scientific map, cannot-claim registry, or closure status.*

Definition 9462.2184 (In-place amendment)**.** *Amendments are made in the thematic chapter whose subject they advance. Replaced phrasing is removed when the active formulation takes its place; parallel active readings are not retained.*

Definition 9462.2185 (Active label)**.** *When an amendment changes the active reading of an object, the active label remains the citation target, and definition or theorem labels attach to the active formulation.*

Theorem 9462.2186 (Amendment preserves audit continuity)**.** *An amendment must preserve audit continuity by identifying the affected registry entry, claim strength, gap classification, cannot-claim status, and tradition-map status.*

Proof. In-place replacement keeps the theory source of truth clean, but it can otherwise obscure whether a claim was strengthened, weakened, reclassified, or refused. Audit continuity records the status effect of the replacement. □

Corollary 9462.2187 (No stacked interpretations)**.** *Inactive philosophical readings should not remain as parallel active versions.*

Proof. Parallel active readings would make concept and theorem map entries non-unique. □

9462.33.9 Capstone policy

Definition 9462.2188 (Philosophy capstone)**.** *A philosophy capstone is a unifying claim spanning at least three registered domains.*

Definition 9462.2189 (Capstone is not commentary)**.** *A capstone provides structural unification rather than ordinary summary or meta-commentary.*

Theorem 9462.2190 (Capstones require dependencies)**.** *A philosophy capstone must list its cross-domain dependencies.*

Proof. The point of a capstone is structural unity. Without the domains, carriers, classifiers, ledgers, and gaps it spans, the claim cannot be audited as a capstone. □

Corollary 9462.2191 (Observer-history capstone)**.** *The current core philosophy capstone is the observer-history identity: observer equals history, observation equals continuation, time equals history growth, and no observer-substance is present. Its dependencies are* Hist*,* hsame*,* Cont*, elementary history steps, absence of a subject parameter, and the axiom-purity gate.*

9462.33.10 Export interface

Definition 9462.2192 (Philosophy export)**.** *A philosophical claim exports when it has a concept entry, a theorem map, gap map, or tradition map entry, a recorded closure status, and no active cannot-claim conflict.*

Definition 9462.2193 (Export grade)**.** *Export grades are reading export, paper synthesis export, component checked export, formal package target, and formal package checked.*

Theorem 9462.2194 (Current export grade)**.** *The present philosophy framework has paper synthesis export status, not formal package checked status.*

Proof. The preceding parts supply organized concepts, theorem readings, gaps, tradition maps, scientific maps, research route, and audit method. They do not supply checked Lean structures for the whole philosophy package or a whole-package checked target. □

Corollary 9462.2195 (Upgrade path for export)**.** *To reach formal package target status, the project must define structures for concept entries, theorem map entries, gap map entries, tradition map entries, scientific map entries, cannot-claim entries, and the philosophy package, together with well-formedness, no-smuggling, status monotonicity, cannot-claim consistency, and gap classification predicates.*

Concretized in §1319: Cannot-claim export gates realize the philosophy-package refusal registry and export-grade interface as finite NameCert rows blocking refused claims from checked-target export.

Concretized in §1321: Package-governance export packets realize cannot-claim registry, in-place governance, capstone dependency, export grade, refusal, transport, provenance, and local NameCert rows.

Concretized in §1320: Governance and export discipline is realized as finite registry, refusal, active-label, capstone, export-grade, transport, route, provenance, and NameCert rows.

9462.33.11 Formal target draft

Definition 9462.2196 (Philosophy map target)**.** *A future philosophy map structure would contain concept registry, theorem map, gap map, tradition map, scientific map, cannot-claim registry, closure status, and a no-smuggling field.*

Concretized in §1277: Philosophy map targets are realized as finite registry-map, gap-map, cannot-claim, closure-status, no-smuggling, and audit NameCert rows.

Definition 9462.2197 (Well-formed philosophy map)**.** *A well-formed philosophy map requires each registered concept to have a carrier or boundary position, a classifier or explanation of its absence, a ledger or explanation of its absence, forbidden readings when ambiguity is present, recorded status, and no cannot-claim conflict.*

Definition 9462.2198 (No smuggling)**.** *No smuggling means no subject-substance, global clock, internal truth predicate, host natural-number leak, host equality leak, classical choice, quotient soundness, propositional extensionality, or object-level far-end entity.*

Concretized in §1282: Philosophy formal-target ledgers realize the package formal-target draft as a finite NameCert packet over claim entries, target skeletons, no-smuggling checks, closure status, refusal boundaries, transport, provenance, and local naming.

Theorem 9462.2199 (Formal package target criterion)**.** *A philosophy map satisfying well-formedness and no-smuggling is a candidate formal package target.*

Proof. Well-formedness supplies the registry-level carrier, classifier, ledger, status, and conflict checks. No-smuggling excludes the philosophical, mathematical, and host imports that would exceed the package authority. Together they give the minimum target surface. □

Corollary 9462.2200 (Formal package does not solve philosophy)**.** *Even a checked philosophy map would prove only internal well-formedness and no-smuggling under declared predicates. It would not solve every philosophical question.*

Proof. The check is structural. It does not create a global truth predicate or close the meta loop. □

9462.33.12 Package synthesis

Theorem 9462.2201 (Philosophy package synthesis)**.** *The BEDC philosophy framework can be organized as a* BEDCPhilosophyPackage *that adds no kernel primitive and is licensed by concept registry, theorem map, gap map, tradition map, scientific map, cannot-claim registry, amendment policy, capstone policy, and export-grade discipline.*

Proof. The concept registry gives each concept carrier, classifier, ledger, and forbidden readings. The theorem map attaches philosophical theorems to BEDC sites. The gap map types unclosed boundaries. The tradition map records preserved structure and rejected surplus. The scientific map separates records, invariants, bridge, empirical value, and prediction gap. The cannot-claim registry blocks overexport. Amendment policy preserves the theory source of truth by in-place replacement. Capstone policy requires cross-domain structural dependence. Export-grade discipline distinguishes paper synthesis from formal package target and formal package checked status. □

Corollary 9462.2202 (Current package status)**.** *The current status is paper synthesis export, unformalized as a whole package, with candidate formal targets identified, no external philosophical bridge claimed, and an active cannot-claim registry.*

Corollary 9462.2203 (Minimum next work)**.** *The minimum next work is to build explicit concept, theorem, gap, tradition, scientific, and cannot-claim tables, add a package closure status record, and optionally define Lean structures for the philosophy map and its no-smuggling checks.*

9462.33.13 Package compression

Definition 9462.2204 (Package compression)**.** *For BEDC philosophy to become a sustainable research object, it must move from interpretation alone to package discipline: every concept is registered, every theorem is mapped, every gap is typed, every tradition comparison is bounded, every scientific claim is layered, and every unsupported claim is recorded as refusal. Philosophy becomes the audit structure of the export surface, not an external override of the kernel.*

Concretized in §1323: Package export discipline is realized as a finite package-map, registry-export, cannot-claim, export-gate, formal-target, non-smuggling, transport, provenance, and NameCert packet.

9462.34 Core Registries and Total Index

The philosophy package becomes maintainable only when its claims are registered. This section turns the preceding synthesis into finite tables for concepts, theorems, gaps, traditions, scientific claims, refusals, upgrade paths, and ordinary-language entry points. The registries add no kernel primitives; they constrain export.

9462.34.1 Registry principles

Definition 9462.2205 (Registry)**.** *A registry is a finite collection of entries. Each entry records name, BEDC site, status, forbidden readings, and upgrade path.*

Definition 9462.2206 (Registry family)**.** *The registry family of the philosophy package consists of concept registry, theorem registry, gap registry, tradition registry, science registry, cannot-claim registry, and upgrade registry.*

Concretized in §1252: Concept registry surfaces realize registry-family export as finite BEDC-site, forbidden-reading, status, route, provenance, and NameCert rows.

Theorem 9462.2207 (Registry family as export surface)**.** *The registry family is the export surface of the philosophy package.*

Proof. The philosophy package cannot export unregistered prose as a BEDC claim. Concepts enter the concept registry, theorems enter the theorem registry, gaps enter the gap registry, comparisons enter the tradition registry, scientific claims enter the science registry, refusals enter the cannot-claim registry, and future promotions enter the upgrade registry. A claim absent from all registries has no carrier, dependency, socket, status, or refusal surface. □

Corollary 9462.2208 (No registry, no export)**.** *An unregistered item is not exportable as part of the philosophy package.*

9462.34.2 Concept registry

Definition 9462.2209 (Concept registry entry)**.** *A concept entry contains name, BEDC site, carrier, classifier, ledger, positive reading, forbidden readings, gap status, closure status, and formal status.*

Definition 9462.2210 (Concept status)**.** *Concept statuses include kernel site, certificate site, boundary site, records-side reading, scientific schema, tradition reading, roadmap, and cannot-claim.*

Theorem 9462.2211 (Concepts require BEDC sites)**.** *Every philosophical concept entering BEDC prose requires a BEDC site.*

Proof. Without a site, the concept remains external vocabulary. Subject talk without Hist, hsame, and Cont becomes subject-substance; universe talk without the focused universe slice becomes a global world object; far-end talk without gap position becomes an object-level entity. □

Definition 9462.2212 (Core concept registry)**.** *The core concept registry is the following finite table.*

Name	***BEDC site***	***Positive reading***	***Forbidden readings***
Distinction	*Mark constructor difference,* msame	*primitive distinction starts generation*	*number, Boolean truth, set pair, metaphysical dualism*
Hist	*generated* Hist, hsame	*minimal information carrier*	*external time object, event set, psychological memory*
Observation	$\mathsf{Cont}(h, d, h')$	*observation is continuation*	*private mental image, subject-object gaze*
Observer	Hist *modulo* hsame	*observer equals history*	*hidden subject, soul-substance, global viewer*
Time	*history growth and local continuation chain*	*time is local history growth*	*global clock, absolute now, external time container*
Object	NameCert-*licensed interface*	*object is licensed name*	*primitive substance, host object, unlicensed term*
Knowledge	*witness chain*	*knowledge is auditable witness*	*naked truth possession, global truth predicate*
Gap	*typed unclosed socket*	*visible boundary*	*secret axiom, hidden proof failure*
Far end	*far end of gap socket*	*transcendental supply position*	*object-level deity, theorem, substrate axiom*
Consciousness	*focused conscious record*	*records-side carrier*	*phenomenal essence, mental substance*
Universe	*focused finite universe slice*	*universe-for-focus*	*global universe object, world totality*
Physical law	*empirical regularity plus Type IV gap*	*law as records plus prediction socket*	*primitive law, final truth, future theorem*

Theorem 9462.2213 (Core concept registry closure)**.** *The core concept registry supplies the minimum registration surface for the central concepts used by the philosophy package.*

Proof. Each row gives a BEDC site, a positive reading, and forbidden readings. The full entry also carries carrier, classifier, ledger, gap status, closure status, and formal status. The table is therefore a paper-synthesis registry, not a machine-checked claim. □

Corollary 9462.2214 (Concept registry extension)**.** *A further concept enters the philosophy package only by supplying the same fields.*

9462.34.3 Theorem registry

Definition 9462.2215 (Theorem registry entry)**.** *A theorem entry records name, statement, BEDC dependencies, proof mode, strength, whether a gap is used, forbidden strengthening, and upgrade path.*

Definition 9462.2216 (Proof mode)**.** *Proof modes include kernel theorem, paper proof, structural reading, schema-only, roadmap, and gap-boundary statement.*

Theorem 9462.2217 (Theorem strength is bounded by dependencies)**.** *Unless a further witness is supplied, the strength of a theorem entry cannot exceed the weakest strength among its dependencies.*

Proof. The theorem obtains its status from the proof chain it cites. A stronger status would assert an obligation not present in the dependencies. □

Definition 9462.2218 (Core theorem registry)**.** *The core theorem registry contains the following entries.*

Name	***Statement***	***Dependencies***	***Strength***
Distinction precedes information	*no distinction, no information*	*primitive marks and no-confusion*	*paper synthesis*
History carries information	*nontrivial information requires generated history*	Hist, hsame, *no-confusion*	*component-dependent*
Observation is continuation	*records-side observation is* Cont	*continuation over histories*	*paper synthesis*
Observer is history	*observer identity is history identity modulo* hsame	*no subject parameter,* hsame, *axiom purity*	*paper synthesis*
Time is history growth	*BEDC time is local continuation chain*	*elementary steps,* Cont, hsame	*paper synthesis*
Object is licensed name	*mature object enters only by* NameCert	*five-field naming certificate*	*component-dependent*
Knowledge is witness	*knowledge is auditable witness*	*certificates, ledgers, open meta loop*	*paper synthesis*
Ground closed, meta open	*ground closes at distinction and meta remains open*	*primitive distinction, formal-limit boundary*	*paper synthesis*
Gap and far-end boundary	*unclosed commitments enter as gaps*	*closed records and socket taxonomy*	*paper synthesis*
Scientific object certificate	*science object is records, invariant, certificate, bridge, gap*	NameCert, *invariant, bridge, Type IV gap*	*roadmap synthesis*

Theorem 9462.2219 (Theorem registry controls strength)**.** *The theorem registry prevents structural readings from being reported as machine-checked theorems.*

Proof. Each row records proof mode, strength, and forbidden strengthening. This makes the difference between component support, paper synthesis, roadmap, and checked theorem visible. □

9462.34.4 Gap registry

Definition 9462.2220 (Gap registry entry)**.** *A gap entry records name, site, requested supply, socket type, gate, consequence if internalized, current status, upgrade path, and related cannot-claim entry.*

Definition 9462.2221 (Socket type registry)**.** *Socket types are unrestricted induction, unwitnessed existential, extensional identification, causal continuity, inter-history coordination, inscription novelty, self-reference closure, and stacked socket.*

Theorem 9462.2222 (Gap entries require gates)**.** *Every gap entry must state the gate that blocks internalization.*

Proof. Without a gate, a gap is only an ordinary pending proof note. A BEDC gap is a boundary claim and must state why the requested supply cannot be used as an internal rule. □

Definition 9462.2223 (Core gap registry)**.** *The core gap registry contains the following entries.*

Name	***Site***	***Socket type***	***Gate***
Induction gap	*finite observation to unrestricted universal*	*Type I*	*generator-closure ledger*
Witness gap	*positive existential without constructor*	*Type II*	*witness visibility and no choice*
Identity collapse gap	*relation treated as equality*	*Type III*	*transport and no quotient collapse*
Causality gap	*empirical regularity to future persistence*	*Type IV*	*records-prediction separation*
Other-minds gap	*behavior to another conscious system*	*Type V*	*locality and inter-history discipline*
Freedom gap	*accumulation event as actuality*	*Type VI*	*aspect separation*
Self-reference gap	*self-description to own truth predicate*	*Type VII*	*reflection stratification*
Physics roadmap gap	*inter-history invariants to physical theory*	*stacked*	*scientific map, bridge, empirical ledger*

Theorem 9462.2224 (Gap registry coverage)**.** *The core gap registry covers the main open boundaries of the philosophy package.*

Proof. The package's central open boundaries are universal closure, unwitnessed existence, identity collapse, causal future, other minds, inscription novelty, self-reference, and physical completion. The table registers each with socket type and gate. □

Concretized in §1246: The theorem and gap registry surface is realized as a finite NameCert packet for theorem strength, gap gates, refusal rows, and audit-visible registry export.

9462.34.5 Tradition registry

Definition 9462.2225 (Tradition registry entry)**.** *A tradition entry records tradition, traditional claim, BEDC site, preserved structure, rejected surplus, and status.*

Theorem 9462.2226 (Rejected surplus is required)**.** *A tradition comparison without rejected surplus is refused.*

Proof. Without rejected surplus, structural adjacency becomes doctrinal identity. The comparison would then import more metaphysics than the BEDC site licenses. □

Definition 9462.2227 (Core tradition registry)**.** *The core tradition registry is as follows.*

Tradition	***BEDC site***	***Preserved structure***	***Rejected surplus***
Spencer-Brown	b0/b1 *distinction*	*distinction precedes form*	*symbolic surplus beyond constructor distinction*
Brouwer	*elementary history step and growth*	*constructive time-order*	*psychologistic metaphysics*
Bundle/no-self/cybernetics	*observer equals* Hist	*observer as trace*	*doctrinal identity*
Kant	NameCert *and gap conditions*	*possibility as obligation*	*transcendental subject primitive*
Husserl	*focused records and* NameCert	*constitution by stabilization*	*intentional substance*
Wittgenstein	*certified use*	*public rule-governed use*	*ordinary-language relativism as object theory*
Whitehead	Cont *as universal verb*	*process priority*	*actual occasions and organic metaphysics*
Tarski/Godel/Muenchhausen	*open meta loop*	*formal boundary*	*none as doctrine; limit family reading*
Relational physics	*inter-history invariant*	*no privileged global frame*	*completed physics derivation*

Corollary 9462.2228 (Tradition registry constrains comparison)**.** *Further tradition comparisons must supply the same fields before entering the main text.*

Concretized in §1267: Tradition registry entries are realized as finite BHist packets with rejected-surplus and comparison-discipline NameCert rows.

9462.34.6 Science registry

Definition 9462.2229 (Science registry entry)**.** *A science entry records name, records carrier, invariant carrier, empirical ledger, prediction gap, bridge status, claim status, and failure surface.*

Theorem 9462.2230 (Science roadmaps require failure surfaces)**.** *Every scientific roadmap claim must list a failure surface.*

Proof. Without a failure surface, a roadmap becomes a one-way promise of progress. BEDC roadmaps must state what would block promotion, such as host leakage, choice dependence, propositional extensionality, missing invariant, or missing empirical ledger. □

Definition 9462.2231 (Core science registry)**.** *The core science registry is as follows.*

Name	***Carrier***	***Claim status***	***Failure surface***
Physical record	*history, continuation, measurement row*	*records-side if ledgered*	*missing source or unledgered measurement*
Space	*locality-cell rows and inter-history graph*	*records-side geometry*	*hidden global frame or unproved invariant*
Physical law	*empirical regularity rows plus Type IV gap*	*scientific schema*	*past fit treated as future truth*
Maximum causal rate	*cross-history dependence and invariant*	*schema-only until causal rows close*	*global clock, hidden choice, missing witness*
Lorentz geometry	*maximum-rate and relation rows*	*roadmap bridge target*	*missing constructive classifier or bridge*
Quantum state	*multi-history superposition rows*	*roadmap*	*propositional extensionality, quotient collapse, unledgered amplitude*

Corollary 9462.2232 (Science registry exports discipline)**.** *The current science registry exports audit discipline, not a completed physical theory.*

Proof. Several entries remain roadmap or schema-only and lack full naming certificates, empirical ledgers, or standard bridges. □

Concretized in §1270: Tradition/science registry bridges realize rejected-surplus and failure-surface rows as one finite NameCert packet.

9462.34.7 Cannot-claim registry

Definition 9462.2233 (Cannot-claim entry)**.** *A cannot-claim entry records claim text, status, why the claim is not claimable, and required upgrade. The registry records present refusal, not a schedule.*

Definition 9462.2234 (Current philosophy cannot-claim registry)**.** *The current cannot-claim registry contains the following active refusals.*

Claim text	***Status***	***Why not claimable***
BEDC has re-derived all mature mathematics	*forbidden as current claim*	*L0–L14 are not fully closed*
BEDC proves full physical theory	*forbidden as current claim*	*multi-history physics is roadmap and schema-only*
BEDC defines phenomenal consciousness as essence	*forbidden*	*conscious record is records-side only*
Far-end position is an object-level entity	*forbidden*	*the far end has no object carrier*
BEDC internalizes its own truth predicate	*forbidden*	*open meta loop and Type VII boundary*
BEDC contains a global clock or God's-eye observer	*forbidden*	*no global synchronization and observer equals history*
Host naturals, host equality, quotient collapse, choice, or propositional extensionality belong to the public surface	*forbidden*	*anti-primitive and axiom-purity discipline*
Tradition comparisons are doctrinal identities	*forbidden*	*tradition registry records adjacency with rejected surplus*
Roadmap equals theorem	*forbidden*	*roadmap lacks discharged certificate*
BEDC philosophy package is checked as a whole	*deferred*	*philosophy map structures are not yet formalized*

Theorem 9462.2235 (Cannot-claim registry protects the framework)**.** *The cannot-claim registry prevents the philosophy package from being read as a completion claim.*

Proof. The preceding parts give a philosophical framework, research route, and package discipline. They do not close all mathematics, physics, consciousness, ontology, or truth. The registry states these refusals explicitly. □

9462.34.8 Upgrade registry

Definition 9462.2236 (Upgrade entry)**.** *An upgrade entry records target, current status, next status, required fields, blocking gaps, and verification target.*

Concretized in §1274: Upgrade registries are realized as finite status-transition, blocker, formal-target, provenance, transport, and NameCert packets.

Definition 9462.2237 (Core upgrade registry)**.** *The core upgrade registry contains the following paths.*

Target	***Current status***	***Next status***	***Blocking surface***
Philosophy package	*paper synthesis export*	*formal package target*	*registry structures and no-smuggling predicates*
Observer-history capstone	*paper structural theorem*	*component checked export*	*formal observer alias and no-subject theorem*
Gap socket taxonomy	*paper taxonomy*	*formal package target*	*socket-type and gate predicates*
Tradition map	*paper registry*	*formal registry*	*external-reference ambiguity*
Science registry	*paper roadmap registry*	*formal roadmap registry*	*multi-history physics certificates*
Multi-history physics	*schema-only roadmap*	NameCert(MultiHistConfig)	*Type V coordination, Type IV causality, bridge obligations*

Theorem 9462.2238 (Upgrade registry is not completion)**.** *An upgrade entry states how a target may be promoted; it does not state that the promotion has occurred.*

Proof. The entry contains current status as well as next status. Until the required fields are discharged, the target remains at its current status. □

9462.34.9 Subject index

Definition 9462.2239 (Subject index)**.** *The subject index maps ordinary-language themes to registry entries.*

Definition 9462.2240 (Core subject index)**.** *The core subject index maps distinction to concept entry distinction and theorem distinction-precedes-information; history to concept entry history and minimal information carrier; observation to concept entry observation; subject and self to observer entry and observer-history theorem; time to local history growth; object to naming certificate; knowledge to witness; truth to the open meta-loop boundary; induction to the induction gap; existence to the witness gap; extensional identity, quotient, and propositional extensionality to the identity collapse gap; causality to the causality gap and physical-law entry; other minds to the Type V gap; freedom to the Type VI gap; consciousness to conscious record and phenomenal-excess gap; universe to the focused universe slice and global-object refusal; space to inter-history locality; physical law to Type IV prediction gap; far end and God-language to the far-end entry and object-level refusal; traditions to the tradition registry; science to the science registry; bridges to standard bridge and no-host-leak; audit to failure certificates and cannot-claim registry; and research route to upgrade registry, layers, and phase bundles.*

Theorem 9462.2241 (Subject index as reading entrance)**.** *The subject index lets readers enter from ordinary philosophical language without treating ordinary terms as BEDC primitives.*

Proof. The index sends freedom to a Type VI gap rather than to a faculty primitive, universe to a focused slice rather than to a global object, and truth to the open meta-loop boundary rather than to an internal truth predicate. □

9462.34.10 Registry synthesis

Theorem 9462.2242 (Registry synthesis)**.** *The registry family gives the philosophy package an auditable export surface: every concept has a BEDC site, every theorem has dependency and strength, every gap has socket type and gate, every tradition comparison has rejected surplus, every scientific claim has status and failure surface, every refusal has reason and upgrade path, every upgrade path distinguishes current status from next status, and every ordinary theme returns to a registered entry.*

Proof. The concept registry supplies sites. The theorem registry supplies dependencies and strength. The gap registry supplies socket type and gate. The tradition registry supplies preserved structure and rejected surplus. The science registry supplies carriers, status, and failure surface. The cannot-claim registry supplies present refusals. The upgrade registry supplies promotion conditions without claiming completion. The subject index routes ordinary vocabulary back to registries. □

Concretized in §1272: Subject-index routes realize registry synthesis as a finite BHist packet connecting ordinary subject entries to the registry lattice.

Corollary 9462.2243 (Registries replace prose expansion)**.** *Further development of BEDC philosophy should proceed mainly by registry extension rather than explanatory prose expansion.*

Proof. Prose can repeat, drift, or overclaim. Registry entries require carrier, dependency, socket, status, refusal, and upgrade path. □

Corollary 9462.2244 (Registry appendix route)**.** *The natural publication form of these tables is a set of appendices: concept registry, theorem registry, gap registry, tradition registry, science registry, cannot-claim registry, upgrade registry, and subject index.*

9462.34.11 Registry status

Definition 9462.2245 (Registry package status)**.** *The registry package is a paper-synthesis export. It fixes registry formats and core entries at the paper level, but it is not a machine-checked registry structure and does not prove all registered claims. It does not close gap sockets, convert roadmaps into theorems, or establish a whole-package no-smuggling theorem.*

Definition 9462.2246 (Registry package upgrade)**.** *To upgrade the registry package, one would define formal structures for concept, theorem, gap, tradition, science, cannot-claim, upgrade, and subject-index entries; encode status monotonicity; prove that exported claims do not conflict with the cannot-claim registry; prove that every philosophy export points to at least one registry entry; and prove no-smuggling for forbidden readings.*

Definition 9462.2247 (Registry compression)**.** *The registry discipline compresses the philosophy package into a single rule: no concept without registry, no theorem without dependency, no gap without socket type, no comparison without rejected surplus, no scientific claim without status, no export without cannot-claim boundary, and no upgrade without current status.*

Concretized in §1248: Refusal registries realize blocked export, gate, cannot-claim route, status, provenance, transport, package, and local NameCert rows as a finite package-control surface.

Concretized in §1251: CoreRegistryIndexUp turns the finite registry tables into a concrete NameCert carrier.

9462.35 Registry Layer, Manuscript Form, and Machine-Facing Interface

The registry layer is not supplementary material. It is the export-control surface of the philosophy package. The prose develops concepts and readings; the registry layer determines which claims may be exported, which must be downgraded, which are refused, and which can become future formalization targets.

Concretized in §1221: Machine-interface boundaries realize registry export, refusal, formalization-target routing, audit readback, and machine-readable NameCert rows as one finite packet.

Concretized in §5205: Machine export boundaries bind registry export status, machine target, audit readback, refusal preservation, transport, replay, provenance, and local NameCert rows as one finite packet.

9462.35.1 Registry layer

Definition 9462.2248 (Registering for export)**.** *To register a claim for export is to assign it to the appropriate registry surface: concept registry, theorem registry, gap registry, tradition registry, science registry, cannot-claim registry, upgrade registry, subject index, closure-status record, or formalization target.*

Definition 9462.2249 (Export-control surface)**.** *The registry layer is an export-control surface when every exported claim either appears in a registry entry or is blocked by a registry entry.*

Concretized in §1216: Registry export surfaces realize claim registration, blocking, status, machine-target, audit, and non-smuggling rows as one finite NameCert packet.

Theorem 9462.2250 (Registry layer is not supplementary)**.** *For the BEDC philosophy package, the registry layer is part of the claim surface rather than supplementary documentation.*

Proof. The package's claims are licensed only by their carriers, classifiers, ledgers, certificates, gap reports, bridge status, and cannot-claim boundaries. Those fields are recorded in registries. A prose claim not represented there has no audit surface. □

Corollary 9462.2251 (No registry, no package claim)**.** *If a philosophical claim is absent from the registry layer and not blocked by it, it is not a package-level BEDC claim.*

Concretized in §1209: ClaimRegistryLayerUp realizes the registry layer as finite export-control rows for claim entry, refusal boundary, closure status, formal target, provenance, and local NameCert.

Concretized in §1220: Registry-layer export control is realized as a finite NameCert packet whose rows admit, block, transport, and ledger package-level claims.

9462.35.2 Manuscript form

Definition 9462.2252 (Two-surface manuscript)**.** *A mature BEDC philosophy manuscript has two surfaces: the synthesis surface and the registry surface. The synthesis surface develops the concepts, theorem readings, and research programme. The registry surface records their export status, refusal boundaries, and machine interface.*

Definition 9462.2253 (Reference module)**.** *A reference module is a stable registry-facing unit for one family of claims: concepts, theorems, gaps, traditions, scientific claims, cannot-claim entries, upgrade entries, subject terms, closure-status records, or formal targets.*

Theorem 9462.2254 (Manuscript completion requires both surfaces)**.** *The philosophy manuscript is package-complete only when prose synthesis is paired with registry reference modules.*

Proof. The synthesis surface alone can state the philosophical reading, but cannot by itself show every carrier, forbidden reading, gap type, refusal entry, upgrade path, and formalization target. The registry surface supplies those fields. □

Corollary 9462.2255 (Reference modules are not lower status)**.** *Reference modules should not be read as lower-status material. They are the audit side of the same package.*

9462.35.3 Export interface

Definition 9462.2256 (Philosophy export interface)**.** *A philosophy export interface is the rule that a claim X may be exported only when it has an appropriate registry entry, no active cannot-claim conflict, a recorded closure status, and a strength not exceeding its dependencies.*

Definition 9462.2257 (Export grade)**.** *Export grades are reading export, paper synthesis export, component checked export, formal package target, and formal package checked. These grades report package status and do not create object-theory truth.*

Theorem 9462.2258 (Export interface bounds prose)**.** *The export interface bounds the strength of philosophical prose.*

Proof. A prose claim can be exported only at the grade recorded in its registry and closure-status surface. If the registry records a roadmap, the prose cannot call it a theorem; if it records a cannot-claim conflict, the prose cannot export it at all. □

Corollary 9462.2259 (Roadmaps stay roadmaps)**.** *A roadmap entry becomes stronger only after its required certificate, bridge, or formal target is supplied.*

9462.35.4 Registry consistency

Definition 9462.2260 (Registry consistency)**.** *Registry consistency holds when each exported claim has exactly one primary registry location and all related registry entries agree on status, dependency strength, gap status, cannot-claim boundaries, closure status, and formalization target.*

Definition 9462.2261 (Consistency clauses)**.** *The consistency clauses are: concept status agrees with theorem dependencies; gap status agrees with cannot-claim entries; science roadmap status agrees with upgrade entries; tradition rejected surplus agrees with cannot-claim boundaries; closure status agrees with all registered entries; and formalization targets agree with formal status.*

Theorem 9462.2262 (Registry consistency is necessary for export)**.** *If registry consistency fails, the philosophy package is not exportable at the claimed grade.*

Proof. A concept cannot be paper synthesis in the concept registry and machine checked in the theorem registry without a status conflict. A physics claim cannot be roadmap in the science registry and completed theory in prose without a claim conflict. A forbidden gap cannot have a routine proof upgrade without a boundary conflict. These conflicts block export at the asserted grade. □

Corollary 9462.2263 (Consistency before polish)**.** *Registry consistency should be checked before stylistic refinement of the manuscript.*

Concretized in §1224: Registry export consistency gates realize registry entries, blocking rows, status conflicts, formal targets, audit routes, and no-smuggling checks as one finite NameCert packet.

Concretized in §1223: Registry consistency audits are realized as finite registry-row, status-agreement, dependency-strength, cannot-claim, closure/formal-status, transport, replay, provenance, and NameCert packets.

9462.35.5 Machine-facing interface

Definition 9462.2264 (Formalization target)**.** *A formalization target records name, intended namespace, source registry, statement skeleton, dependencies, expected status, and not claimed surface.*

Definition 9462.2265 (Namespace draft)**.** *The machine-facing namespace may be organized under* BEDC.Philosophy*, with subnamespaces for registry, concepts, theorem maps, gaps, traditions, science, cannot-claim entries, upgrades, subject index, package, and consistency.*

Definition 9462.2266 (Entry structure draft)**.** *The first structures to encode are concept entry, theorem entry, gap entry, tradition entry, science entry, cannot-claim entry, upgrade entry, subject-index entry, closure-status entry, formalization target, amendment-ledger entry, and registry-consistency predicate.*

Theorem 9462.2267 (First target is well-formedness)**.** *The first machine-facing target is registry well-formedness, not the truth of all philosophical doctrines.*

Proof. Tradition entries are mappings, not proofs of traditions. Concept entries are carrier registrations, not global truth predicates. The machine interface can first check field presence, status consistency, cannot-claim conflicts, no-smuggling predicates, and dependency monotonicity. □

Corollary 9462.2268 (No-smuggling predicates come first)**.** *The early formal predicates should be no philosophical smuggling, no mathematical smuggling, no host smuggling, no roadmap-as-theorem, and no cannot-claim conflict.*

9462.35.6 Socket type draft

Definition 9462.2269 (Socket type draft)**.** *A future socket type can be encoded as an inductive family with constructors for unrestricted induction, unwitnessed existential, extensional identification, causal continuity, inter-history coordination, inscription novelty, self-reference closure, and stacked socket.*

Theorem 9462.2270 (Socket typing precedes gap automation)**.** *Any automated check of gap reports requires a typed socket surface.*

Proof. The requested supply, gate, upgrade path, and internalization failure differ by socket kind. Without a socket type, the checker cannot distinguish an induction boundary from a witness boundary or a self-reference boundary. □

Concretized in §1059: Machine-facing formalization targets are realized as finite socket-routed NameCert packets.

Concretized in §1225: Formalization targets are realized as finite registry-, status-, dependency-, audit-gate-, and not-claimed rows.

Concretized in §1344: Registry no-smuggling predicates are realized as finite registry, cannot-claim, gate, export, transport, replay, provenance, and NameCert rows.

Concretized in §1347: Formal-target dependency audits realize machine-facing target dependency and no-smuggling checks as one finite NameCert packet.

9462.35.7 Amendment ledger

Definition 9462.2271 (Amendment ledger entry)**.** *An amendment ledger entry records target, change type, old status, new status, reason, affected registries, cannot-claim impact, and gap impact.*

Definition 9462.2272 (Change type)**.** *Change types include add entry, replace entry, downgrade, upgrade, reclassify gap, remove cannot-claim, add cannot-claim, revise forbidden reading, and amend formal target.*

Theorem 9462.2273 (Amendment ledger does not create parallel readings)**.** *The amendment ledger records audit continuity, but it does not preserve multiple active readings.*

Proof. The governing manuscript remains the active source of truth. When a reading is replaced, the active formulation takes the citation target. The ledger records the status change and affected registries; it does not keep the displaced formulation active. □

Corollary 9462.2274 (Amendment ledger is not an archive)**.** *The amendment ledger explains the current active reading; it is not a repository of prior prose.*

9462.35.8 Closure-status reference layer

Definition 9462.2275 (Closure-status reference)**.** *A closure-status reference records constructive story, theory closure, scope closed, formal status, Lean target if any, bridge status, not claimed surface, and upgrade path for a package, part, concept, or registered theorem.*

Definition 9462.2276 (Closure-status bound)**.** *The closure-status reference is the strongest export status allowed for its target.*

Theorem 9462.2277 (Closure status bounds registry exports)**.** *Registry entries may not export a claim stronger than the relevant closure-status reference.*

Proof. If the closure reference records paper synthesis, a registry entry cannot report whole-package machine checking. If the not-claimed field rejects a global truth predicate, a theorem entry cannot reintroduce it under another name. □

Corollary 9462.2278 (Closure references belong to the registry layer)**.** *Closure-status references are not marginal notes. They are binding entries in the export-control surface.*

Concretized in §1265: Closure-status references are realized as a finite NameCert packet for registry-bound export status.

9462.35.9 Interface synthesis

Theorem 9462.2279 (Registry and machine-interface synthesis)**.** *A mature BEDC philosophy package consists of a synthesis surface and a registry-machine surface. The synthesis surface develops the philosophical structure. The registry-machine surface registers every exportable claim, blocks forbidden claims, classifies gaps, records upgrade paths, constrains formalization targets, and preserves amendment continuity.*

Proof. The registry layer provides export-control entries. The export interface bounds prose by status and cannot-claim conflicts. Registry consistency ensures that related entries agree. The machine-facing interface identifies future structures and no-smuggling predicates. The amendment ledger records active-reading changes without preserving parallel readings. Closure-status references bound the whole surface. □

Corollary 9462.2280 (After registry layer)**.** *Further work should populate the reference modules, check registry consistency, link each prose theorem to the theorem registry, link each strong claim to closure status, link each boundary to the gap and cannot-claim registries, link each future claim to the upgrade registry, and prepare the* BEDC.Philosophy *namespace.*

Corollary 9462.2281 (Manuscript architecture)**.** *The final manuscript can be organized as philosophical synthesis, registry and audit reference modules, and machine-facing interface with amendment governance. In a shorter article, the synthesis may occupy the main body while registries and machine interface form the reference layer.*

9462.35.10 Interface status

Definition 9462.2282 (Machine-interface status)**.** *The present interface is paper synthesis export. The reference-module architecture is defined, but the registries are not fully populated, the structures are not machine checked, registry consistency is not proved in Lean, and the interface does not close gaps or turn roadmaps into theorems.*

Definition 9462.2283 (Interface upgrade path)**.** *The upgrade path is to populate the reference modules, define Lean structures for registry entries and closure references, encode registry consistency, prove that no exported claim lacks a registry entry, prove that no registered claim conflicts with cannot-claim entries, prove that roadmap claims have upgrade entries and refusal boundaries, and prove no-smuggling for forbidden readings.*

Definition 9462.2284 (Interface compression)**.** *The registry layer is the export-control surface of BEDC philosophy: prose explains, registries license, cannot-claim entries refuse, closure status bounds, and the machine interface turns these fields into future formal targets.*

Concretized in §1232: Machine-readable audit interfaces realize registry-machine synthesis as finite schema, checker, export, refusal, report, hsame, Cont, Pkg, and NameCert rows.

Concretized in §1358: Registry-change continuity is realized as a finite active-reading, blocked-reading, status-bound, refusal, transport, replay, provenance, and NameCert packet.

Concretized in §1256: finite synthesis-audit packet for auditable-generativity export

Concretized in §7399: Finite observation sheaves realize auditable generativity as compatible BHist window sections with finite overlap gluing.

Chapter 9463

Hyperbolic Phase Geometry of Observer Expansion

Concretized in §39: The visible complex phase surface is grounded in the finite $\mathsf{Complex}^{\uparrow}$ rational-pair certificate.

Concretized in §377: The disk carrier used by the geometric reading is grounded in the finite $\mathsf{UnitDisk}^{\uparrow}$ certificate.

Concretized in §219: Reversible phase transport is grounded in the finite $\mathsf{UnitaryGroup}^{\uparrow}$ inner-product-preserving automorphism certificate.

Concretized in §195: Flow-style record evolution is grounded in the finite $\mathsf{DynSystem}^{\uparrow}$ routed-flow certificate.

Concretized in §7608: Critical-pair residual streams realize the MetaCIC parallel-diamond frontier route as finite residual-window, candidate-join, relation-scope, and inter-Hist invariant rows.

Concretized in §3455: The Poincare disk phase-transport packet realizes the finite disk-coordinate, reversible-transport, flow, and provenance route.

Concretized in §7806: The Poincare half-plane packet realizes the upper-half-plane hyperbolic coordinate, boundary, metric, Mobius transport, disk-comparison, Real-seal, provenance, and NameCert route.

Concretized in §4117: The Poincare disk dynamics packet realizes the fixed far-end disk-map route as finite disk, metric, boundary, phase-provenance, dynamic-replay, and refusal rows.

Concretized in §3474: HyperbolicMetricUp realizes the Poincare-disk metric reading as finite disk-map, metric-read, boundary, classifier-stability, provenance, refusal, and NameCert rows.

Concretized in §6336: $\mathsf{CATZeroMetric}^{\uparrow}$ realizes the nonpositive-curvature comparison route as finite metric, geodesic, Real-seal, transport, and NameCert rows.

Concretized in §6776: Poincare disk automorphisms are realized as finite disk-map, boundary-transport, hyperbolic-metric-preservation, inverse, composition, provenance, and NameCert rows.

Concretized in §7499: Poincare disk automorphism derivatives are realized as finite automorphism, coordinate-window, metric-preservation, boundary-transport, Real-seal, and NameCert rows.

Concretized in §3486: The hyperbolic observer-expansion reading is realized as finite focused-ledger, disk-readout, Cont-growth, metric-read, boundary-refusal, provenance, and NameCert rows.

Concretized in §3491: The boundary-geodesic route is realized as finite Poincare-disk, HyperbolicMetric, phase-transport, and provenance NameCert rows.

Concretized in §3500: Boundary-fixed disk transport is realized as finite disk-map, boundary, hyperbolic-metric, transport, provenance, refusal, and NameCert rows.

Concretized in §3534: Horocycle packets realize the boundary-tangent hyperbolic disk rows as finite NameCert data.

Concretized in §8521: The hyperbolic horosphere packet realizes boundary point, Busemann level, metric readback, observer-window, Real-seal, transport, provenance, and NameCert rows as finite observer-expansion data.

Concretized in §3575: The Denjoy-Wolff boundary-dynamics reading is realized as finite disk-map, boundary-read, nonexpansive-route, fixed-boundary, provenance, and NameCert rows.

Concretized in §3591: The phase-ledger horocycle packet realizes the focused phase-ledger and boundary-transport reading as finite NameCert rows.

Concretized in §3643: The boundary-phase audit packet realizes the observer-expansion boundary verdict as finite ledger, boundary, horocycle, transport, provenance, and NameCert rows.

Concretized in §3682: The Schwarz-Pick disk-contraction packet realizes the finite disk-map, hyperbolic-metric comparison, boundary refusal, transport, provenance, and NameCert rows.

Concretized in §3732: The HyperbolicBusemannBoundary packet realizes Busemann-level boundary metric, horocycle, boundary-fixed transport, provenance, and NameCert rows.

Concretized in §3813: Boundary-shadow packets realize the boundary-fixed disk transport reading as finite NameCert rows.

Concretized in §6070: The Patterson-Sullivan shadow packet realizes boundary-shadow, visual-measure, hyperbolic-metric, and observer-expansion rows as finite NameCert data.

Concretized in §3856: The hyperbolic geodesic-flow packet realizes disk metric, boundary, flow, and provenance rows as finite NameCert data.

Concretized in §3866: The visual metric packet realizes disk readout, hyperbolic metric rows, boundary shadows, transport, provenance, and global-geometry refusal as finite NameCert data.

Concretized in §3925: The hyperbolic Poisson-kernel packet realizes boundary-weighted disk reads as finite metric, boundary, phase, integral, and Real-seal rows.

Concretized in §3948: The hyperbolic cross-ratio packet realizes four-boundary-point Poincare disk comparison, boundary-fixed transport, hyperbolic-metric provenance, and refusal of host global geometry as finite NameCert rows.

Concretized in §7493: The visual cross-ratio cocycle packet realizes boundary-shadow, visual-metric, cross-ratio, Busemann, transport, Real-seal, and NameCert rows as finite hyperbolic phase data.

Concretized in §3683: The Poincare triangle-defect packet realizes disk-point, geodesic-side, hyperbolic-metric, cross-ratio, and Real-seal rows as finite NameCert data.

Concretized in §4034: The harmonic boundary-measure packet realizes the visual-metric and Poisson-kernel boundary weighting route as finite NameCert data.

Concretized in §4051: The horosphere-flow ledger realizes boundary-fixed disk transport and horocycle provenance as finite NameCert data.

Concretized in §4134: The Busemann cocycle route is realized as finite boundary-point, geodesic-ray, horocycle, metric-read, transport, provenance, and NameCert rows.

Concretized in §7534: Busemann-function packets realize boundary-point, geodesic-ray, metric-difference, Real-seal, and horosphere readback rows for the hyperbolic observer-expansion vision.

Concretized in §4142: The boundary-shadow visual metric is realized as finite disk-read, boundary, metric, Busemann, transport, provenance, and NameCert rows.

Concretized in §4154: The observer-shadow visual metric is realized as finite visual-shadow, metric, stream-window, regular-rational, real-seal, focused-route, provenance, and NameCert rows.

Concretized in §4167: The observer-expansion packet realizes the hyperbolic phase geometry as finite shadow-metric and boundary-shadow rows.

Concretized in §4181: The hyperbolic visual boundary packet realizes boundary readback through finite visual metric, Busemann, shadow, transport, and provenance rows.

Concretized in §4203: The geodesic lamination packet realizes boundary-paired noncrossing hyperbolic leaves as finite metric, shadow, transport, provenance, and NameCert rows.

Concretized in §5802: The quasi-geodesic shadow packet realizes boundary endpoint, visual-metric shadow, Busemann cocycle, and observer-expansion rows as finite NameCert data.

Concretized in §5814: The boundary-shadow expansion cocycle is realized as finite boundary, Busemann, horosphere, expansion, provenance, and NameCert rows.

Concretized in §5832: The hyperbolic translation-length packet realizes isometry displacement growth through finite metric, flow, Busemann, cross-ratio, and Real rows.

Concretized in §5107: The hyperbolic fixed-point obstruction packet realizes the boundary-route refusal of an interior far-end fixed point as finite NameCert rows.

Concretized in §5180: The observer shell packet realizes the boundary-shadow, visual-boundary, and observer-expansion rows as one finite NameCert surface.

Concretized in §6073: The Gromov-product packet realizes the basepointed boundary-shadow and visual-metric comparison route as finite NameCert rows.

Concretized in §5917: The geodesic projection packet realizes disk-point, boundary-geodesic, hyperbolic-metric, and phase-transport rows as finite NameCert data.

Concretized in §6017: Phase-distance observer expansion is realized as finite observer-phase, distance-read, expansion-comparison, provenance, hsame, Cont, Pkg, and NameCert rows.

Concretized in §8178: The observer phase-distance shell realizes the boundary-shadow, phase-distance, observer-window, and provenance rows as finite NameCert data.

Concretized in §6090: The linearized phase-distance packet realizes observer expansion through finite boundary-shadow, visual-metric, Real-seal, Cont, Pkg, and NameCert rows.

Concretized in §6104: The geodesic-flow ledger realizes observer expansion through finite flow-window, horosphere-ledger, boundary-shadow, visual-metric, Real-seal, provenance, and NameCert rows.

Concretized in §6044: The complex phase surface fiber packet realizes phase readout as finite source ledger, ComplexUp coordinate, fiber, GAP residue, provenance, hsame, Cont, Pkg, and NameCert rows.

Concretized in §6021: The observer expansion radius ladder is realized as finite disk, boundary-shadow, visual-metric, real-seal, transport, replay, provenance, and NameCert rows.

Concretized in §6025: The horofunction-boundary packet realizes boundary metric readout through finite Busemann, shadow, transport, refusal, provenance, and NameCert rows.

Concretized in §6040: The Morse boundary realizes the hyperbolic observer-expansion route as finite geodesic stability and fellow-traveller NameCert data.

Concretized in §6122: The axis-shadow packet realizes translation-length, geodesic-flow, metric, Busemann-boundary, and Real-seal rows as a finite non-selected shadow route.

Concretized in §6146: The observer phase groupoid realizes reversible phase-surface transport, inverse, composition, boundary refusal, provenance, and NameCert rows as finite data.

Concretized in §6209: The Poincare disk metric packet realizes the vision's displayed disk-map, metric-read, boundary, provenance, and refusal rows as finite NameCert data.

Concretized in §6862: GromovHyperbolicMetricUp realizes the four-point hyperbolic metric route as finite metric, geodesic, boundary-handoff, transport, provenance, and NameCert rows.

Concretized in §8047: The finite weighted hyperbolic barycenter packet realizes barycenter read-back through HyperbolicMetric, Gromov boundary, Real-seal, transport, and NameCert rows.

Concretized in §6237: Mobius-invariant disk transport realizes the vision's boundary-fixed hyperbolic phase geometry as finite NameCert rows.

Concretized in §6267: Boundary-preserving Poincare disk transport is realized as finite disk, boundary, metric, transport, provenance, and NameCert rows.

Concretized in §8826: Lorentz boost disk transport realizes the reversible hyperbolic disk-transport branch as finite disk, boost-parameter, boundary, metric, phase, transport, provenance, and NameCert rows.

Concretized in §6319: The observer phase shell is realized as finite boundary-shadow, visual-boundary, phase-distance, transport, provenance, and NameCert rows.

Concretized in §7170: The observer-shadow boundary packet realizes the hyperbolic phase-expansion route as finite shadow-window and visual-boundary NameCert data.

Concretized in §6385: The phase holonomy packet realizes closed reversible phase transport through finite disk, boundary, classifier, replay, provenance, and NameCert rows.

Concretized in §6385: Closed reversible phase transport realizes the hyperbolic phase-geometry route through finite disk, boundary, classifier, replay, provenance, and NameCert rows.

Concretized in §6372: TeichmullerSpaceUp realizes the marked conformal-structure branch of the hyperbolic observer-expansion vision through ManifoldUp, ComplexUp, and HyperbolicMetricUp rows.

Concretized in §6437: The finite curvature-budget packet realizes hyperbolic phase observer expansion through disk, metric, boundary, Real-seal, provenance, and refusal rows.

Concretized in §6477: The hyperbolic uniform-modulus packet realizes the boundary, cross-ratio, visual-metric, and tolerance-only modulus route as finite NameCert data.

Concretized in §7589: Mobius disk cross-ratio packets realize boundary quadruple, disk transport, cross-ratio readback, hyperbolic metric provenance, and boundary refusal rows as finite NameCert data.

Concretized in §6481: The hyperbolic phase-energy ledger is realized as finite reversible-transport, metric-budget, boundary-refusal, Real-seal, provenance, hsame, Cont, Pkg, and NameCert rows.

Concretized in §6497: The hyperbolic axis-projection packet realizes disk-metric, geodesic-flow, boundary-shadow, Busemann, refusal, provenance, and NameCert rows.

Concretized in §6678: The boundary-shadow transport packet realizes shadow, boundary-transport, Gromov-boundary, disk-metric, Real-seal, nontrivial, field-faithful, refusal, provenance, and NameCert rows.

Concretized in §6707: Hyperbolic shadowing realizes the quasi-geodesic fellow-traveller route as finite HyperbolicMetric, MorseBoundary, Busemann, Real tolerance, and NameCert rows.

Concretized in §7764: The limit-set packet realizes boundary accumulation through finite visual-boundary, shadow, Busemann, visual-metric, geodesic-flow, support, disk, Real-seal, provenance, and NameCert rows.

Concretized in §6920: The observer phase route is realized as finite boundary-shadow, visual-boundary, phase-distance, reversible-transport, refusal, provenance, and NameCert rows.

Concretized in §7552: Busemann projection realizes the hyperbolic observer-expansion route as finite boundary, Busemann, visual-metric, observer-window, provenance, and NameCert rows.

Concretized in §6980: The phase horocycle packet realizes boundary-tangent phase transport, hyperbolic metric readback, and observer-expansion rows as finite NameCert data.

Concretized in §6995: The geodesic midpoint packet realizes the Poincare disk midpoint route as finite metric, boundary, phase-transport, provenance, and NameCert rows.

Concretized in §7121: The phase geodesic midpoint packet realizes the displayed Poincare disk chord midpoint through finite metric, boundary-transport, geodesic-flow, phase, provenance, and NameCert rows.

Concretized in §7019: The hyperbolic boundary compactification packet realizes visual-boundary, Gromov-boundary, visual-metric, Busemann, boundary-shadow, and Real-seal rows as finite NameCert data.

Concretized in §7108: The hyperbolic phase-space packet realizes reversible disk-phase transport, boundary refusal, finite observer-phase groupoid windows, and provenance rows as finite NameCert data.

Concretized in §7138: The hyperbolic phase torsion packet realizes reversible closed phase transport as finite disk, boundary, metric, holonomy, transport, provenance, and NameCert rows.

Concretized in §7232: The observer-horizon packet realizes visual boundary, Gromov product, Busemann cocycle, horoball-shadow, observer-window, and Real-seal rows as finite NameCert data.

Concretized in §7274: The Beltrami–Klein disk packet realizes the projective disk-model comparison as finite chord, metric, boundary-incidence, refusal, and Real-seal rows.

Concretized in §7282: Fuchsian group actions are realized as finite disk-point, Mobius-action word, metric-preservation, boundary-handoff, transport, replay, provenance, and NameCert rows.

Concretized in §7423: A finite geodesic endpoint and cross-ratio packet realizes the phase-geometry direction as NameCert data.

Concretized in §7503: The dyadic shadow-cone packet realizes boundary-shadow and observer-expansion reads through finite dyadic radius windows.

Concretized in §7666: The Dirichlet-domain packet realizes the Poincare disk and Fuchsian action branch as finite side-pairing, metric-read, boundary-refusal, and NameCert rows.

Concretized in §8715: The ideal pentagon boundary-cycle packet realizes five displayed boundary endpoints, side-geodesic incidence, hyperbolic metric comparison, cross-ratio readback, and Real-seal rows as finite NameCert data.

Concretized in §7592: The fixed-boundary hyperbolic shadow packet realizes boundary-preserving shadow transport as finite NameCert data.

Concretized in §7659: The ideal quadrilateral packet realizes four displayed boundary ends, side and diagonal incidence, finite cross-ratio readback, and transport as hyperbolic phase NameCert data.

Concretized in §8017: The geodesic triangle packet realizes three displayed vertices, three geodesic sides, incidence or order ledgers, finite comparison readback, transport, provenance, and local NameCert rows.

Concretized in §7887: The Cayley operator packet realizes disk-transport and operator-boundary rows as finite NameCert data.

Concretized in §8976: The hyperbolic visual-measure packet realizes visual-boundary, boundary-shadow, hyperbolic-metric, Real scalar, finite-total, field-faithfulness, transport, provenance, and NameCert rows as finite observer-expansion data.

Concretized in §7891: The Poincare disk geodesic triangle packet realizes the finite disk-point, geodesic-side, hyperbolic-metric, phase-transport, and provenance route.

Concretized in §7927: The Poincare disk Busemann cocycle packet realizes boundary-anchored disk transport, additive cocycle, visual-metric, horocycle, exactness, refusal, and NameCert rows as finite data.

Concretized in §7968: Schottky group packets realize the ping-pong boundary-domain route through finite Poincare disk automorphism, hyperbolic metric, limit-set, and boundary-shadow rows.

Concretized in §7998: The horocycle-shadow modulus packet realizes boundary-tangent horocycle, Busemann, visual-boundary, shadow-budget, metric, Real-seal, transport, provenance, and NameCert rows as finite observer-expansion data.

Concretized in §8298: Observer-phase locality packets realize the hyperbolic observer expansion route as finite observer-phase, residual-window, local-join, candidate-boundary, obstruction-retention, transport, replay, provenance, and NameCert rows.

Concretized in §8546: The sector-envelope packet realizes finite boundary-shadow, visual-radius, observer-window, provenance, and refusal rows for the hyperbolic observer-expansion vision.

Concretized in §8685: The hyperbolic sector-expansion packet realizes sector aperture, boundary shadow, visual radius, observer window, expansion comparison, transport, refusal, provenance, and NameCert rows as finite data.

Concretized in §9013: The sector-overlap ledger realizes aperture, boundary-shadow, visual-radius, observer-window, overlap-witness, provenance, and NameCert rows as finite data.

Concretized in §9018: The sector-refinement packet realizes aperture, boundary-shadow, visual-radius, observer-window, overlap, transport, provenance, and refusal rows as finite NameCert data.

Concretized in §8570: Boundary cross-ratio distortion is realized as finite visual-metric, Busemann, boundary-shadow, Real-seal, transport, replay, provenance, and NameCert rows.

Concretized in §8850: The horoball-filtration packet realizes nested Busemann-level shadow rows as finite observer-expansion NameCert data.

Concretized in §9060: The finite observer-phase shell realization packages boundary-shadow, visual-boundary, phase-distance, reversible-transport, and provenance rows as NameCert data.

Concretized in §9144: Busemann-boundary budgets realize the hyperbolic observer-expansion boundary rows as finite NameCert data.

Concretized in §9162: The horosphere Busemann flow budget realizes boundary-fixed flow windows, Busemann levels, horosphere rows, visual-metric readback, and Real-seal provenance as finite NameCert data.

Concretized in §9188: The finite phase-lens packet realizes observer-expansion windows as boundary-shadow, Busemann-displacement, Real-seal, transport, replay, provenance, and NameCert rows.

This vision chapter gives a geometric language for the observer-expansion reading of chapter 9420, the information-conservation discipline of chapter 9393, and the apophatic fixed-point reading of chapter 9401. The purpose is expressive: complex phase surfaces, unitary transport, Liouville-style conservation, the Poincare disk, and hyperbolic geometry organize the same BEDC rows under a familiar geometric picture. They do not replace Hist, Cont, hsame, GAP, Pkg, or NameCert, and they do not turn T into a point of a plane, disk, flow, or Hilbert space.

The guiding picture is:

$$\begin{aligned} \text{observer-side expansion} &= \text{hyperbolic unfolding of local record surfaces;} \\ \text{reversible conservation} &= \text{classifier-preserving transport with provenance;} \\ \text{apophatic fixedness} &= \text{boundary far-end fixedness, not value fixedness;} \\ \text{self-center} &= \text{local inscription of that far end on a focused chain.} \end{aligned}$$

This is a records-side and inscription-side representation schema. It is not a physical cosmology, not a hidden dynamics of the universe, and not a substrate theorem about phenomenal consciousness.

9463.1 Phase surfaces

Definition 9463.1 (Complex phase surface)**.** *A* complex phase surface *for a focused finite ledger $\mathcal{L}_N$ is a visible package whose public coordinates factor through* $\mathsf{Complex}^{\uparrow}$ *rows and whose source histories remain the generated* Hist *rows, selector rows, and* GAP *provenance rows of $\mathcal{L}_N$. It is a display surface for phase, direction, amplitude, or digest-like presentation; it is not a replacement carrier for the observer.*

The point of the complex surface is to display rotation-like and phase-like regularities without pretending that the observer is a complex number. A complex coordinate is a readout of a finite packet. The observer remains the focused Hist row, and sameness remains mediated by hsame and the displayed classifier rows.

Principle 9463.2 (Phase is a readout, not a source)**.** *If a focused history $H(F)$ is assigned a complex phase readout $z_F(t)$, the readout may be consumed only through its source ledger:*

$$H(F), \Theta(F), S(F), G(F), \rho \quad \rightsquigarrow \quad z_F(t).$$

The reverse reading is admissible only when an exactness, fiber, or GAP *row records what the visible complex token hides. Digest equality or phase equality is therefore not source equality.*

9463.2 Reversible transport and Liouville conservation

Definition 9463.3 (Unitary transport reading)**.** *A* unitary transport reading *of a local phase surface is a reversible transport row that preserves the relevant classifier or inner-product readout while carrying the provenance ledger along the route. Schematic notation may be written*

$$U_t : \Sigma_i \to \Sigma_i, \qquad U_t^* U_t \equiv_{\text{ledger}} 1,$$

where Σ_i is the displayed phase surface of a local history and $\equiv_{\text{ledger}}$ means equality only as certified by the visible transport, preservation, and provenance rows.

This reading belongs at the representation layer. The unitary row is not a hidden law of reality and not an unlogged operator on an ambient Hilbert space. Its BEDC meaning is that a visible surface can move by a reversible classifier-preserving route without erasing the source distinctions that made the surface visible.

Principle 9463.4 (Liouville conservation as ledger conservation)**.** *The Hamiltonian Liouville analogy is admissible when it is read as conservation of record volume under reversible flow:*

$$\textit{reversible phase flow} \quad \Rightarrow \quad \textit{no unledgered loss of source distinctions.}$$

Inside BEDC this is not a theorem about a completed symplectic manifold. It is the information-conservation condition that every transported surface keeps its source, route, classifier, and GAP *residue auditable.*

Concretized in §3487: The reversible phase-transport conservation row is realized as finite classifier-preservation and provenance ledger data.

Concretized in §337: The finite variational, dynamic-flow, Real-cost, and conservation-ledger rows realize the Hamiltonian Liouville analogy as LagrangianMechanicsUp NameCert data.

Remark 9463.5 (Complex Liouville as a warning)**.** *The complex-analytic Liouville theorem is useful only as a warning against a global digest picture. A bounded entire global universe token would be the wrong shape for BEDC: the project does not admit $H(\Omega) = \mathsf{T}$, a global readable universe Ω, or T as a digest value. The legitimate object is a family of local visible surfaces with fiber and provenance rows.*

9463.3 Poincare disk representation

Definition 9463.6 (Poincare disk reading)**.** *A* Poincare disk reading *of a focused multi-*Hist *ledger is a representation package*

$$\mathcal{P}_N = (\mathcal{L}_N, \mathbb{D}, \delta, \partial\mathbb{D}, B, \Gamma, A)$$

with the following rows:

1. $\mathcal{L}_N$ *is the finite focused multi-*Hist *ledger of Definition 9420.1;*
2. $\mathbb{D}$ *is a disk surface read through* $\mathsf{UnitDisk}^{\uparrow}$*-style coordinates, not a host-level subset of* $\mathbb{C}$*;*
3. δ *is a hyperbolic-distance readout row on displayed disk points, when such a readout is supplied;*
4. $\partial\mathbb{D}$ *is a boundary consumer row, not a completed ideal universe;*
5. B *assigns selected local histories or digest rows to displayed disk points;*
6. Γ *records reversible disk-surface transport rows, such as unitary or disk-automorphism-style transport, only through displayed classifier-preserving witnesses;*
7. A *is the audit row refusing object-level* T*, a global clock, a global universe digest, physical light-speed derivation, and subject-substance.*

The disk reading separates two roles that are easy to confuse. Interior points represent visible local records or focused readouts. Boundary positions represent horizon-style or far-end-style readings. The apophatic fixed point belongs only to the boundary reading. It is not a disk point and not an interior center.

Principle 9463.7 (Boundary fixedness, not center fixedness)**.** *The geometric form of BEDC fixedness is not*

$$\mathsf{T} \in \mathbb{D}.$$

It is the boundary-far-end reading

$$\mathrm{FarEnd}(\mathrm{Fiber}(B(H_i, t))) \equiv_{\mathrm{apo}} \mathsf{T}.$$

Thus T *is not an interior center around which records literally rotate. It is the apophatic name of the common far end behind local disk-surface fibers.*

9463.4 Hyperbolic observer expansion

Hyperbolic geometry is useful because local finite motion can correspond to large internal distance near a boundary. This gives a disciplined version of the expansion image: a local observer sees record space unfold rapidly as histories, digests, relation rows, and boundary directions accumulate. The boundary far end remains fixed only in the apophatic sense.

Definition 9463.8 (Hyperbolic expansion reading)**.** *A focused ledger has a* hyperbolic expansion reading *when its visible record growth is represented by a path or family of paths in a disk surface whose hyperbolic distance from earlier readouts increases with local* Cont *extension:*

$$\Theta_i : \mathsf{e} \rightsquigarrow H(i), \qquad B(H(i), t) \in \mathbb{D}, \qquad \delta(B(H(i), t_0), B(H(i), t_1)) \text{ grows along displayed extension.}$$

This is a representation condition. The object-level time remains the local Cont *chain, and the disk metric is not a global clock.*

Principle 9463.9 (Explosion is records-side expansion)**.** *The expansion image is admissible only as records-side growth:*

$$\mathsf{Hist}\ \textit{extension} \quad \rightsquigarrow \quad \textit{more visible directions, fibers, relations, and invariants.}$$

It is not a derivation of the empirical big-bang model, not a completed spacetime metric, and not a claim that all observers are synchronized by one radial coordinate.

9463.5 Disk dynamics and the fixed far end

Ordinary rotations of the complex plane fix an interior center. That picture is too strong for BEDC's apophatic boundary. The better geometric schema is disk-preserving or hyperbolic transport whose visible points move while a boundary far-end commitment is preserved.

Definition 9463.10 (Boundary-fixed disk transport)**.** *A* boundary-fixed disk transport *is a reversible representation row γ on a disk surface such that:*

1. *γ transports displayed disk points by classifier-preserving witnesses;*
2. *γ preserves the provenance rows attached to those points;*
3. *the visible points may change under γ;*
4. *the fiber far-end reading remains the same apophatic boundary name:*

$$\mathrm{FarEnd}(\mathrm{Fiber}(x)) \equiv_{\mathrm{apo}} \mathsf{T} \quad \Rightarrow \quad \mathrm{FarEnd}(\mathrm{Fiber}(\gamma x)) \equiv_{\mathrm{apo}} \mathsf{T}.$$

In classical disk dynamics one may distinguish elliptic, hyperbolic, and parabolic behavior by the placement of fixed points. BEDC consumes only the schema that matters for the ledger: interior fixedness is not required, while boundary far-end fixedness may be used as an expressive representation of the T-socket discipline. A Denjoy-Wolff-style boundary image is therefore closer to the intended reading than a simple Euclidean rotation, but it remains a vision-level analogy until its disk map, metric, and boundary rows are certified.

Principle 9463.11 (No physical constant from geometry alone)**.** *Neither unitary transport nor hyperbolic disk geometry supplies the empirical value of a physical constant. A light-speed-like invariant must still pass through the inter-*Hist *dependency and maximum-rate route of chapter 9419. Geometry may display the invariant shape; it does not certify the empirical constant.*

9463.6 Consciousness fixed point as inscription

The geometric layer also clarifies the self-center language. The focused record sits on the visible surface. The self-center is the inscription-side reading of that local event. The apophatic fixed point is the common far end behind the surface's fiber. These are three roles, not three objects.

Definition 9463.12 (Hyperbolic self-center reading)**.** *For a focused ledger $\mathcal{L}_N$ with focus F, a disk readout $B(H(F), t)$, and a far-end boundary reading T, the* hyperbolic self-center reading *is the aspectual assignment*

$$\mathrm{SelfCenter}(\mathcal{C}_F, t) := \mathrm{InscriptionPoint}(\mathsf{T}, \mathcal{C}_F, t),$$

together with the displayed records-side row $B(H(F), t)$. The self-center is not $B(H(F), t)$, not T, and not a hidden subject behind $H(F)$.

Concretized in §4011: The hyperbolic self-center reading is realized as finite disk-readout, inscription, boundary, transport, provenance, and noncollapse NameCert rows.

Principle 9463.13 (Three-role discipline)**.** *The geometric reading must keep the roles separate:*

$$\begin{aligned} B(H(F),t) &= \textit{visible disk or phase readout;} \\ \mathrm{Fiber}(B(H(F),t)) &= \textit{hidden provenance side recorded by } \mathsf{GAP}; \\ \mathsf{T} &= \textit{apophatic far-end boundary name;} \\ \mathrm{SelfCenter}(\mathcal{C}_F,t) &= \textit{local inscription of that far end on the focused chain.} \end{aligned}$$

Collapsing any two of these roles into object-level equality violates the no-subject and no-internal-T *discipline.*

9463.7 Closure of the geometric layer

The geometric layer is admissible when it is read as a representation surface over already displayed rows:

$$\begin{aligned} \mathsf{Complex}^{\uparrow} &\rightsquigarrow \text{phase readout;} \\ \mathsf{UnitDisk}^{\uparrow} &\rightsquigarrow \text{disk surface and boundary consumer;} \\ \mathsf{UnitaryGroup}^{\uparrow} &\rightsquigarrow \text{reversible classifier-preserving transport;} \\ \mathsf{DynSystem}^{\uparrow} &\rightsquigarrow \text{finite flow-style route;} \\ \mathsf{GAP} &\rightsquigarrow \text{fiber and provenance conservation;} \\ \mathsf{T} &\rightsquigarrow \text{apophatic boundary far end only.} \end{aligned}$$

Its BEDC-safe slogan is:

hyperbolic expansion on the visible surface, reversible conservation in the ledger, apophatic fixedness at the fiber

The chapter claims no stronger closure. A concrete Poincare-disk or hyperbolic-metric certificate would require displayed disk-map rows, metric-read rows, boundary rows, classifier stability, provenance, and refusal rows before it could be consumed by a theorem.

Concretized in §4185: The hyperbolic phase observer-expansion packet realizes the focused-ledger, shadow-metric, boundary-shadow, Cont-growth, provenance, and nonescape route as finite NameCert data.

Concretized in §6569: The horoball-shadow packet realizes the boundary-level hyperbolic observer-expansion route as finite Busemann, visual-boundary, metric, transport, provenance, and Real-seal rows.

Concretized in §7843: HyperbolicHoroballUp realizes boundary-point, Busemann-threshold, visual-shadow, HyperbolicMetric, and Real-seal rows as finite NameCert data.

Concretized in §5159: The hyperbolic isometry group packet realizes disk-map, inverse, hyperbolic-metric preservation, boundary action, transport, provenance, and NameCert rows as finite data.

Concretized in §6595: Boundary-fixed disk transport is realized as finite disk-map, boundary, transport, provenance, and noncollapse NameCert rows.

Concretized in §8460: The boundary-shadow cross-ratio packet realizes the shared boundary-shadow, cross-ratio, visual-metric, Busemann, and observer-expansion route as finite NameCert data.

Concretized in §7487: The horosphere-shear ledger realizes boundary-point, horosphere, Busemann, metric-read, transport, and Real-seal rows as finite NameCert data.

Concretized in §6142: The boundary-far-end noncenter packet realizes the fixed-boundary refusal that prevents a disk readout from becoming an interior center.

Concretized in §6470: The Gromov-boundary packet realizes ray-equivalence, Gromov-product, visual-metric, Busemann-cocycle, boundary-shadow, transport, provenance, and NameCert rows as finite data.

Concretized in §6544: Hyperbolic ideal triangles realize the disk-boundary fixed-end route as finite boundary, geodesic, metric, and flow rows.

Concretized in §6609: The visual-flow shadow packet realizes the joint visual metric, geodesic-flow, boundary-shadow, observer-expansion, and Real-seal route as finite NameCert data.

Concretized in §6700: The horocycle-return ledger realizes the boundary, Busemann, visual-metric, horosphere-flow, and transport rows as finite NameCert data.

Concretized in §6196: The hyperbolic set packet realizes displayed metric, boundary, transport, and provenance rows as finite NameCert data for the observer-expansion surface.

Concretized in §6831: The finite observation topology packet records the observer-expansion window as a concrete NameCert carrier.

Concretized in §7031: The hyperbolic phase ledger packet realizes boundary-shadow, observer-expansion, phase-shell, disk-transport, refusal, provenance, and local NameCert rows as finite data.

Concretized in §8598: Hyperbolic phase expansion cocycles realize composable observer-phase transport, phase-distance, boundary-shadow, and transport-budget rows as finite NameCert data.

Concretized in §7056: The hyperbolic shear-coordinate packet realizes boundary-fixed disk transport and observer-expansion comparison as finite NameCert rows.

Concretized in §7112: The observer phase route is realized as finite boundary-shadow, visual-boundary, phase-distance, reversible-transport, refusal, provenance, hsame, Cont, Pkg, and NameCert rows.

Concretized in §7134: The hyperbolic phase-transport budget packet realizes disk metric, hyperbolic metric, observer-phase groupoid, energy ledger, curvature-budget, Real-seal, transport, provenance, and NameCert rows as finite data.

Concretized in §7148: The finite hyperbolic shadow-cover route is realized as boundary, visual-metric, shadow-window, Real-seal, transport, provenance, and NameCert rows.

Concretized in §7199: Hyperbolic convex disk packets realize the finite geodesic-window convexity route over Poincare disk metric, hyperbolic metric, boundary transport, StreamName windows, Real sealing, provenance, and NameCert rows.

Concretized in §7231: The boundary-distortion budget packet realizes disk-map, boundary-shadow, visual-metric, dyadic tolerance, Real-seal, transport, provenance, and NameCert rows for the observer-expansion vision.

Concretized in §7244: Poincare horocycle transport is realized as finite disk, boundary-shadow, horocycle, transport, Real-seal, provenance, and NameCert rows.

Concretized in §7263: Poincare disk isometries realize reversible hyperbolic disk transport as finite disk-map, metric-preservation, inverse, boundary, provenance, and NameCert rows.

Concretized in §7434: The finite phase-cylinder packet realizes phase readout, boundary circle, reversible transport, provenance, and refusal rows as NameCert data.

Concretized in §7447: The Hadamard boundary packet realizes CAT(0)/Hadamard boundary readback through finite geodesic-ray, Busemann, visual-boundary, metric, and Real-seal rows.

Concretized in §7515: The visual-metric modulus packet realizes boundary-shadow, dyadic tolerance, Real-seal, and observer-expansion rows as finite NameCert data.

Concretized in §7560: Boundary pairing is realized as finite paired boundary rows consumed before cross-ratio and geodesic-flow handoffs.

Concretized in §7595: The Cartan angular boundary invariant packet realizes ordered boundary triples, cross-ratio phase readback, Mobius stability, and provenance rows as finite hyperbolic phase data.

Concretized in §7624: The finite horoball-shadow ledger realizes Busemann, visual-shadow, boundary, metric, observer-window, transport, provenance, and NameCert rows as hyperbolic observer-expansion data.

Concretized in §7725: The visual-angle packet realizes boundary triple, hyperbolic metric, cross-ratio, Real-seal, transport, provenance, and NameCert rows as finite hyperbolic phase data.

Concretized in §7801: The Poincare disk horocycle-return packet realizes boundary-shadow, disk-metric, horocycle transport, return-window, Real-seal, and provenance rows as finite NameCert data.

Concretized in §7806: The Poincare half-plane packet realizes upper-half-plane coordinates, boundary rows, hyperbolic metric reads, Mobius transport, Real sealing, provenance, and NameCert rows as finite data.

Concretized in §7864: Finite uniform-tail packets realize the observer-expansion tail route as StreamName, RegSeqRat, UniformModulus, and Real-seal NameCert data.

Concretized in §7916: The Poincare disk area-element packet realizes local hyperbolic area readback as finite disk, metric, dyadic-radius, Real-seal, and observer-expansion rows.

Concretized in §8089: The hyperbolic Markov partition packet realizes the observer-expansion symbolic-shadow route as finite partition, transition, boundary, metric, transport, provenance, and NameCert rows.

Concretized in §8098: Hyperbolic symbolic coding is realized as finite Markov-partition, geodesic-flow, subshift-code, boundary-shadow, transport, provenance, and NameCert rows.

Concretized in §8140: The hyperbolic operator-trace packet realizes reversible disk transport, operator trace, boundary refusal, Real-seal readout, provenance, and NameCert rows as finite data.

Concretized in §8162: The holonomy-index packet realizes closed phase transport classes as finite disk, boundary, phase-holonomy, transport, provenance, and NameCert rows.

Concretized in §8196: PhaseCurvatureTransportUp realizes the hyperbolic phase-geometry curvature-transport route through finite disk, metric, boundary, phase, curvature-budget, provenance, hsame, Cont, Pkg, and NameCert rows.

Concretized in §8256: The boundary-extension packet realizes the hyperbolic observer-expansion route through finite visual-boundary and boundary-shadow transport rows.

Concretized in §8296: The Martin boundary packet realizes the hyperbolic observer-expansion boundary route through finite transition-kernel, positive-harmonic, shadow, Poisson-kernel, and Real-seal rows.

Concretized in §8323: Hyperbolic bigon thinness is realized as finite endpoint, geodesic-side, hyperbolic-metric, boundary-shadow, and Real-seal NameCert data.

Concretized in §8445: Ford circles realize the Farey rational and hyperbolic horoball boundary branch as finite NameCert data.

Concretized in §8490: The observer horizon-cocycle packet realizes the boundary-shadow, Busemann-cocycle, phase-distance, transport, provenance, and refusal rows as finite NameCert data.

Concretized in §8534: The hyperbolic phase visual-modulus packet realizes observer-expansion visual metric and boundary-shadow tolerance rows as finite NameCert data.

Concretized in §8596: The hyperbolic area-defect packet realizes boundary-triangle area readback through Poincare disk area-element, ideal-triangle, metric, and Real-seal rows.

Concretized in §8640: The boundary phase-shadow route is realized as finite Poincare-disk, hyperbolic-metric, boundary-shadow, observer-phase, and refusal-ledger NameCert data.

Concretized in §8671: The phase-energy transport packet realizes reversible phase routing, energy-ledger readback, transport budget, Real sealing, provenance, and local NameCert rows as finite hyperbolic phase data.

Concretized in §8721: Boundary cross-ratio phase data are realized as finite HyperbolicMetric, visual-boundary, Busemann-boundary, boundary-shadow, Real, transport, replay, provenance, and NameCert rows.

Concretized in §8959: The observer phase transport packet realizes reversible disk-phase, boundary-shadow, visual-boundary, provenance, and refusal rows as finite NameCert data.

Concretized in §8044: Vision ledger routes realize the top-level visions hub edge as finite source-hub, input-route, concrete-target, marker, audit-readback, transport, replay, provenance, and NameCert rows.

Concretized in §8290: Dyadic uniform cover rows realize the finite-cover direction for L10 compactness and completion routes.

Concretized in §8833: Dyadic uniform cover-transfer rows realize the L10 route from displayed dyadic cover cells to StreamName, RegSeqRat, Real, interval-net, compact-metric, transport, replay, provenance, and NameCert rows.

Concretized in §8558: The residual join envelope realizes the visions hub route through finite MetaCIC residual-window, parallel-diamond, candidate-normalization, confluence-budget, replay, provenance, and NameCert rows.

Concretized in §8917: Real completion tail-lock rows realize the finite StreamName, RegSeqRat, DyadicRatCore, and Real seal route for completion-facing reads.

Concretized in §9099: Stream shuffle rows realize finite StreamName recombination through parity-indexed windows, RegSeqRat readback, and Real-seal handoff.

Part XII

Open Conjectures

Chapter 9464

Open Conjectures

The conjectures listed in this directory are BEDC kernel-formulated open problems: each is stated entirely in terms of BHist / NameCert / hsame / Cont / Pkg primitives, has an obvious-but-unproved candidate path, and admits a finite test (verification, weakening, or counter-example).

The pipeline picks one open conjecture per round (kind = `conjecture_chase`) and attempts: (a) closing it with a proof, (b) weakening it by adding hypotheses or restricting scope, or (c) refuting it with a counter-witness drawn from existing concrete instances. Each attempt updates the conjecture's `\conjectureStatus{...}` row and may move the chapter between `open`, `weakened`, `closed`, or `refuted`.

9464.1 Finite-BHist-Injection Admits StdBridge

Conjecture 9464.1 (Finite BHist Tuple Route Admits StdBridge)**.** *For every BEDC chapter* $\langle X\rangle$Up *equipped with a fixed finite* BHist *tuple presentation that*

1. *displays a tuple carrier* $(b_0, b_1, \ldots, b_k)$ *of accepted* BHist *component rows;*
2. *supplies an image row showing that every accepted carrier row is one of the displayed tuple components;*
3. *supplies a readback row recovering the corresponding* BHist *component from each displayed image row;*
4. *presents the chapter carrier as a fixed-arity* BHist *tuple* $(b_0, b_1, \ldots, b_k)$ *whose* NameCert *rows are transported componentwise along those readback rows;*
5. *inhabits* ChapterTasteGate *for the displayed tuple presentation;*

there exists a $\langle X\rangle$UpStdBridge *theorem in* BEDC.*Derived*.$\langle X\rangle$Up *that bridges the displayed finite tuple's* NameCert *obligation surface to the standard reflection schema.*

Status: `weakened`

Status notes. The obligation is the fixed finite BHist tuple route. The bridge follows by case analysis over the displayed tuple carrier, replaying the image row and readback row for each component, and transporting the tuple carrier's NameCert rows component by component before packaging the finite family as the chapter's standard reflection bridge.

The remaining open part is the general transport from arbitrary regular-language recognisers to BHist tuple presentations. That route would need a recogniser-to-carrier construction and a uniform component transport theorem not supplied by the fixed tuple test target.

Active fixed-tuple test. The active finite test is exactly the fixed-tuple kernel route: a tuple carrier, an image row, a readback row, componentwise NameCert transport, and the ChapterTasteGate row. Recognizer-to-carrier construction is not part of this test and remains a separate boundary condition.

The exact remaining target is recognizer-to-carrier construction. It must produce a recognizer acceptance row, finite tuple extraction, BHist component readback, componentwise NameCert transport, and ChapterTasteGate from the recognizer presentation before any stronger StandardBridge conjecture is reopened.

Conjecture 9464.2 (Finite BHist injection recognizer-to-carrier route)**.** *A regular recognizer-side input lands on the finite packet test only after it displays seven kernel rows as named carrier data:*

1. *a recognizer acceptance row through* GroundCompilerRecognizerFlow$^{\uparrow}$*;*
2. *a generated-recognizer row recording the recognizer presentation used for the finite test;*
3. *a certificate-gate row admitting that presentation to the BEDC packet surface;*
4. *a finite tuple extraction row through* FiniteReflectionTuple$^{\uparrow}$*;*
5. *a* BHist *component readback row for each extracted component;*
6. *componentwise* hsame *and* NameCert *transport rows through the displayed component reads;*
7. *a* ChapterTasteGate *row.*

These rows must live inside the existing BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* GroundCompilerRecognizerFlow$^{\uparrow}$*, and* FiniteReflectionTuple$^{\uparrow}$ *support surface. The conjecture asks only for this finite packet landing test; it does not assert a* StandardBridge *theorem and does not construct a recognizer-to-carrier map.*

Status: `weakened`

Recognizer-to-carrier status. The active conjecture is the seven-row closed landing test together with one remaining carrier-map compatibility row, not a StandardBridge construction. The decomposition of Definition 9464.45, the exhaustion theorem Definition 9464.46, and the closed landing test of Definition 9464.48 identify exactly the recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise hsame and NameCert transport, and ChapterTasteGate rows inside the BHist, hsame, Cont, Pkg, NameCert, GroundCompilerRecognizerFlow$^{\uparrow}$, and FiniteReflectionTuple$^{\uparrow}$ kernel surface. The remaining finite object is only a carrier-map compatibility row preserving those rows through recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, BHist component readback, componentwise hsame and NameCert transport, and ChapterTasteGate. No fixed-tuple StandardBridge theorem is claimed here.

Theorem 9464.3 (Finite BHist injection local carrier-map status)**.** *After the decomposition, row-exhaustion, and closed-landing tests have displayed the seven recognizer rows, the remaining recognizer-to-carrier object is the local test that the carrier map preserves exactly those rows. It is not a* StandardBridge *theorem, not a fixed-tuple bridge completion, and not a construction of arbitrary regular-language carriers.*

Proof. Read the decomposition of Definition 9464.45, the row exhaustion theorem Definition 9464.46, and the closed landing test Definition 9464.48. They name the seven displayed recognizer rows and leave no hidden landing row.

The status paragraph then identifies the only remaining object: preservation of those rows by the carrier map. Since the object is local preservation inside the displayed kernel support surface, it does not assert a StandardBridge theorem or a fixed-tuple bridge construction. □

Theorem 9464.4 (Finite BHist injection recognizer carrier-map row closure)**.** *After recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *are displayed, the weakened conjecture Definition 9464.2 has exactly one remaining open object: the recognizer carrier-map compatibility row preserving those displayed data inside the* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* GroundCompilerRecognizerFlow$^{\uparrow}$*, and* FiniteReflectionTuple$^{\uparrow}$ *support surface. The statement does not assert a* StandardBridge *construction and does not construct arbitrary regular-language carriers.*

Proof. Use the recognizer-to-carrier status paragraph. It separates the seven landing rows from the carrier-map compatibility row and keeps both inside the displayed BEDC kernel support surface.

Apply the recognizer carrier-map decomposition, Definition 9464.45. It lists the recognizer acceptance, generated-recognizer mediation, certificate-gate admission, tuple extraction, component readback, componentwise transport, and taste-gate rows as the full route to the fixed tuple surface.

Now use row exhaustion, Definition 9464.46, together with the closed landing test, Definition 9464.48. Once those rows are displayed, no further landing row remains to be supplied.

Finally read the carrier-map compatibility boundary already isolated by Definition 9464.22. The remaining object is exactly preservation of the same seven displayed rows by the carrier map, and no standard bridge theorem is claimed. □

Theorem 9464.5 (Finite BHist injection carrier-map obstruction update)**.** *Mode: restate. The weakened conjecture of Definition 9464.2 is unchanged: after recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *are displayed, the only remaining positive object is one carrier row preserving those same data inside the existing* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* GroundCompilerRecognizerFlow$^{\uparrow}$*, and* FiniteReflectionTuple$^{\uparrow}$ *support surface. The statement does not assert* StandardBridge*, construct arbitrary regular recognizer carriers, or identify quotient carriers by host equality.*

Proof. Read the recognizer-to-carrier status paragraph. It already separates the seven displayed landing rows from the single carrier-map compatibility row and leaves the conjecture in weakened status.

Apply the recognizer carrier-map row closure, Definition 9464.4. The row closure fixes the data that must be preserved: recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and taste-gate admission.

Finally use the carrier-map forward compatibility boundary, Definition 9464.22. It permits only forward preservation of those rows into the fixed tuple surface. Therefore the remaining positive object is one carrier row with that preservation property, and no StandardBridge theorem is asserted. □

Theorem 9464.6 (Finite BHist injection carrier-map compatibility closure)**.** *Mode: restate. A carrier-map compatibility proof for Definition 9464.2 must preserve exactly the seven displayed*

rows: recognizer acceptance, generated-recognizer mediation, certificate-gate admission, FiniteReflectionTuple$^{\uparrow}$ *extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *along the displayed carrier map. The closure does not assert* StandardBridge*, does not construct recognizer-to-carrier data for arbitrary regular languages, and does not identify quotient carriers by equality.*

Proof. Use the recognizer-to-carrier status paragraph together with the decomposition of Definition 9464.45. It isolates the carrier-map question from the fixed tuple bridge and names the seven rows that must survive the map.

Apply row exhaustion, Definition 9464.46, and the closed landing test, Definition 9464.48. These results leave no additional row between the recognizer presentation and the finite tuple surface.

Finally use carrier-map forward compatibility, Definition 9464.22. The compatibility row can only preserve the displayed recognizer, certificate, tuple, readback, transport, and taste-gate data, so the statement closes the remaining object without claiming a standard bridge, arbitrary regular-language carrier construction, or quotient carrier equality. □

Theorem 9464.7 (Finite BHist injection carrier-map compatibility boundary)**.** *Mode: restate. Once recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *are displayed, the only remaining weakened claim in Definition 9464.2 is compatibility of the carrier map with those seven displayed rows. The boundary remains a finite carrier-map compatibility target inside the* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* GroundCompilerRecognizerFlow$^{\uparrow}$*, and* FiniteReflectionTuple$^{\uparrow}$ *support surface; it is not a* StandardBridge *theorem.*

Proof. Read the recognizer-to-carrier status paragraph. It names the seven displayed rows and separates them from the carrier-map compatibility row that still has to preserve the same data.

The decomposition, row-exhaustion, and closed-landing statements identify the rows as recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise hsame and NameCert transport, and ChapterTasteGate on one finite route.

Therefore, after those rows are displayed, no stronger bridge-facing object is left in the weakened claim. What remains is precisely compatibility of the carrier map with those seven rows, inside the listed kernel support surface. □

Theorem 9464.8 (Finite BHist injection carrier-map status refinement)**.** *Mode: restate. The weakened boundary of Definition 9464.2 is not the seven landing rows themselves once those rows are displayed. The active boundary is the single carrier-map compatibility row preserving recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *along one displayed* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* GroundCompilerRecognizerFlow$^{\uparrow}$*, and* FiniteReflectionTuple$^{\uparrow}$ *route. The status remains weakened: no* StandardBridge *theorem and no fixed-tuple bridge construction are asserted.*

Proof. Read the recognizer-to-carrier status paragraph. It separates the seven displayed landing rows from the remaining carrier-map compatibility row, and it keeps all of them inside the named BEDC kernel support surface.

Apply the recognizer carrier-map decomposition, Definition 9464.45, together with row exhaustion, Definition 9464.46. These results locate recognizer acceptance, generated-recognizer

mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and the taste-gate row on one displayed route.

Finally use the closed landing test, Definition 9464.48. Once the landing rows are present, the remaining row to inspect is compatibility of the carrier map with those same displayed data. That restates the weakened boundary without asserting a StandardBridge theorem or constructing the fixed-tuple bridge route. □

Theorem 9464.9 (Finite BHist injection status tightening)**.** *Mode: restate. The weakened recognizer-to-carrier conjecture is exactly the seven-row recognizer landing test through* GroundCompilerRecognizerFlow$^{\uparrow}$*, generated-recognizer mediation, certificate-gate admission,* FiniteReflectionTuple$^{\uparrow}$ *extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*, together with the carrier-map compatibility row that preserves those displayed data. It does not assert* StandardBridge *construction and does not upgrade the fixed-tuple test into a bridge theorem.*

Proof. Read the status paragraph and the conjecture statement together. Both name the same seven landing rows: recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and the taste gate.

The later decomposition, row-exhaustion, and closed-landing references locate these rows inside the existing BEDC kernel surface. The only finite row still isolated there is carrier-map compatibility: it must preserve recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, BHist component readback, componentwise hsame and NameCert transport, and ChapterTasteGate.

Therefore the current weakened status is precisely the landing test plus that compatibility row. Any statement requiring a StandardBridge theorem or bridge-facing fixed-tuple construction lies outside the conjecture. □

Theorem 9464.10 (Finite BHist injection carrier-map active target)**.** *Mode: restate. The only active positive target for Definition 9464.2 is carrier-map compatibility preserving the seven displayed recognizer rows: recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*. This target stays inside the* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* GroundCompilerRecognizerFlow$^{\uparrow}$*, and* FiniteReflectionTuple$^{\uparrow}$ *support surface; it does not assert* StandardBridge*, arbitrary recognizer-to-carrier construction, quotient carrier equality, or host recognizer equality.*

Proof. Read the recognizer-to-carrier status paragraph and the carrier-map row closure, Definition 9464.4. Together they separate the seven displayed landing rows from the single carrier-map compatibility row that must preserve them.

Apply carrier-map compatibility boundary and status tightening, Definition 9464.7 and Definition 9464.9. These results keep the weakened conjecture at the landing test plus the carrier-map compatibility row.

Therefore no stronger positive target is active in this section. A StandardBridge theorem, arbitrary regular-language carrier construction, quotient carrier equality, or host recognizer comparison would change the surface rather than preserve the seven displayed rows. □

Theorem 9464.11 (Finite BHist injection carrier-map positive criterion)**.** *If a displayed carrier map preserves exactly the seven rows named in Definition 9464.2 through recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*, then the weakened carrier-map compatibility row is closed for that packet. The conclusion does not assert* StandardBridge*, arbitrary recognizer-to-carrier construction, or quotient carrier equality.*

Proof. Apply the recognizer carrier-map decomposition, Definition 9464.45. It gives the seven displayed rows that any recognizer route must expose before the fixed tuple surface is tested.

Use row exhaustion and the closed landing test, Definition 9464.46 and Definition 9464.48. These make the seven rows the whole finite landing surface and keep StandardBridge construction outside the conclusion.

Now read the assumed carrier map. Its preservation of recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise hsame and NameCert transport, and ChapterTasteGate is exactly the compatibility row isolated by Definition 9464.8.

Finally apply carrier-map forward compatibility and status tightening, Definition 9464.22 and Definition 9464.9. The weakened row is closed for this packet, while arbitrary recognizer-to-carrier construction, quotient carrier equality, and a StandardBridge theorem remain outside the asserted surface. □

Theorem 9464.12 (Finite BHist injection StdBridge nonclaim boundary)**.** *Mode: restate. Displaying the seven recognizer landing rows of Definition 9464.2 is only a precondition for inspecting the fixed tuple route. It neither asserts nor refutes any* StandardBridge *theorem, and it does not construct a recognizer-to-carrier map.*

Proof. Read the fixed tuple route of Definition 9464.24. It requires the tuple carrier, image row, readback row, componentwise NameCert transport, and ChapterTasteGate row before the fixed tuple surface can be inspected.

Next apply the readback gap refutation of Definition 9464.17. A packet missing component readback does not land on the seven-row surface, so it is not a refutation of the weakened landing test and not a proof of StandardBridge.

Finally use the closed landing test of Definition 9464.48. It identifies the seven displayed rows as the finite landing boundary and explicitly leaves both the StandardBridge theorem and the recognizer-to-carrier construction outside the conclusion. □

Theorem 9464.13 (Finite BHist injection recognizer-to-carrier sharp obstruction)**.** *Mode: refute. A recognizer input that displays recognizer acceptance, generated-recognizer mediation, certificate-gate admission, and finite tuple extraction, but does not display* BHist *component readback, cannot land on the fixed tuple route of Definition 9464.1. Such an input is neither a counterexample to the weakened fixed-tuple conjecture nor a proof of it.*

Proof. The fixed tuple route requires a displayed tuple carrier, image row, readback row, componentwise NameCert transport, and ChapterTasteGate row before any bridge-facing comparison is made. The recognizer-side status paragraph sharpens this into seven recognizer landing rows, including explicit BHist component readback after finite tuple extraction.

Now take a recognizer input with acceptance, generated-recognizer mediation, certificate-gate admission, and finite tuple extraction but without displayed component readback. The input has reached only the recognizer pre-landing surface. It has not supplied the readback row that lets a finite tuple component be compared with a fixed BHist component.

Therefore the fixed tuple route is unavailable. The missing readback keeps the packet outside the weakened fixed-tuple test, so it cannot be used as either a negative instance of that route or a positive bridge comparison. □

Theorem 9464.14 (Finite BHist injection readback refutation)**.** *Mode: refute. A recognizer-side packet with recognizer acceptance, generated-recognizer mediation, certificate-gate admission,*

and finite tuple extraction, but with no BHist *component readback row, refutes only the stronger omitted-readback landing variant. It is not a counterexample to the weakened fixed-tuple conjecture of Definition 9464.1 and not a counterexample to the seven-row landing test of Definition 9464.2.*

Proof. Read the seven-row landing list in Definition 9464.2. The fifth row is explicit BHist component readback, and the sixth row transports hsame and NameCert data through those displayed component reads.

Apply Definition 9464.13. A packet without component readback has reached only the recognizer pre-landing surface, so it has not entered the weakened fixed-tuple route and cannot count as a negative instance of that route.

Thus the packet refutes the overstrong landing form that omits readback from the recognizer-side requirements. The weakened conjecture remains unchanged because its test surface still requires the readback row before any fixed-tuple or carrier-facing obstruction is evaluated. □

Definition 9464.15 (Finite BHist injection readback gap)**.** *A finite* BHist *injection readback gap is a recognizer-side packet that displays recognizer acceptance through* GroundCompilerRecognizerFlow$^{\uparrow}$*, generated-recognizer mediation, certificate-gate admission, and finite tuple extraction through* FiniteReflectionTuple$^{\uparrow}$ *but displays no* BHist *component readback row for the extracted tuple components. Such a packet has not displayed componentwise* hsame *or* NameCert *transport through component reads and has not reached the* ChapterTasteGate *row of the seven-row landing test.*

Theorem 9464.16 (Finite BHist injection open kernel sharp restatement)**.** *Mode: restate. Any proposed* StandardBridge *for the finite* BHist *injection recognizer surface must expose a row-level map from recognizer evidence to carrier evidence: recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row must all be displayed before the fixed tuple route is tested. If the packet is a readback gap in the sense of Definition 9464.15, then the bridge request is refused at the kernel-row surface rather than evaluated as a* StandardBridge *instance.*

Proof. Read the recognizer-side landing list in Definition 9464.2. It is already a row-level map from recognizer evidence to carrier evidence: the recognizer-flow rows precede finite tuple extraction, and the extracted tuple becomes carrier-facing only after component readback and componentwise transport are displayed.

Now apply the sharp obstruction theorem, Definition 9464.13. A packet with recognizer acceptance, certificate-gate admission, and tuple extraction but without component readback has not reached the fixed tuple route. The readback refutation row, Definition 9464.14, assigns such a packet only to the omitted-readback failure surface.

Finally unpack Definition 9464.15 and use Definition 9464.17. The gap displays exactly the missing-row obstruction: no BHist component readback, no componentwise hsame or NameCert transport through component reads, and no ChapterTasteGate landing. Therefore the proposed bridge is refused before the standard bridge comparison is formed, and the conjecture status is left unchanged. □

Theorem 9464.17 (Finite BHist injection readback gap refutes only omitted-readback bridges)**.** *Mode: refute. A finite* BHist *injection readback gap refutes only bridge requests that omit* BHist *component readback from the recognizer landing surface. It does not refute the weakened seven-row landing test of Definition 9464.2, does not refute the fixed-tuple route of Definition 9464.1, and does not prove a* StandardBridge *theorem.*

Proof. Unpack Definition 9464.15. The packet displays recognizer acceptance, generated-recognizer mediation, certificate-gate admission, and finite tuple extraction, but it stops before the component readback row.

Apply Definition 9464.14. Missing readback only blocks the overstrong bridge request that tries to land without the fifth row of the seven-row test.

The weakened conjecture still requires component readback, componentwise hsame and NameCert transport, and ChapterTasteGate before the fixed-tuple surface is evaluated. Therefore the gap names a non-landing surface, not a counterexample to the weakened test and not a proof of StandardBridge. □

Theorem 9464.18 (Finite BHist injection readback closed landing)**.** *Mode: restate. When recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *are all displayed, the recognizer-side packet lands on the weakened fixed-tuple test surface of Definition 9464.2. This landing theorem still asserts no* StandardBridge *theorem and constructs no recognizer-to-carrier map.*

Proof. Read the seven-row list in Definition 9464.2. The listed rows supply exactly the recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and taste-gate data needed before the fixed-tuple surface is tested.

Use the sharp obstruction theorem Definition 9464.13 and the readback refutation theorem Definition 9464.14. Together they identify missing readback as failure to land, and they leave the weakened conjecture unchanged once readback and componentwise transport are present.

Thus displaying all seven rows is the positive landing boundary for the weakened fixed-tuple test surface. The conclusion stops at that boundary and does not package a standard bridge or produce a recognizer-to-carrier construction. □

Theorem 9464.19 (Finite BHist injection readback transport closure)**.** *Mode: restate. Once component readback and componentwise* hsame *and* NameCert *transport rows are displayed, adjoining replay and provenance rows cannot move the recognizer-side packet outside the weakened seven-row landing surface of Definition 9464.2. The closure still asserts no* StandardBridge *theorem and constructs no recognizer-to-carrier data.*

Proof. Start from the closed landing theorem Definition 9464.18. Its landing surface already contains the component readback row and the componentwise hsame and NameCert transport row.

The replay and provenance rows are support rows for the same displayed finite packet. They record that the already displayed component reads can be replayed and sourced inside Cont and Pkg; they do not replace recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, transport, or the ChapterTasteGate row.

Therefore adding replay and provenance preserves the weakened seven-row landing surface. The argument stops at that landing boundary and does not produce a standard bridge, a recognizer-to-carrier construction, a quotient carrier replacement, or a host regular-language carrier theorem. □

Theorem 9464.20 (Finite BHist injection recognizer landing sharpener)**.** *Any recognizer-side attempt to inspect the fixed tuple route of Definition 9464.2 must first display recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*. These rows are a recognizer landing boundary only: they do not supply a* StandardBridge *theorem, do not construct a recognizer-to-carrier map, and do not assert arbitrary regular-language carrier claims.*

Proof. Read the active conjecture as a finite landing test. Its seven displayed rows are exactly recognizer acceptance, generated-recognizer data, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and the taste gate.

Use the recognizer-to-carrier status paragraph. It keeps those rows inside the existing BHist, hsame, Cont, Pkg, NameCert, GroundCompilerRecognizerFlow$^{\uparrow}$, and FiniteReflectionTuple$^{\uparrow}$ support surface before the fixed tuple route can be inspected.

Thus the recognizer-side attempt lands only after the seven rows have been exposed. Since the displayed surface stops before carrier construction and before the standard bridge schema, no StandardBridge, recognizer-to-carrier construction, or arbitrary regular-language carrier theorem is obtained. □

Theorem 9464.21 (Finite BHist injection open-status sharpening)**.** *The remaining recognizer-side claim for Definition 9464.2 is exactly the landing surface that passes through* GroundCompilerRecognizerFlow$^{\uparrow}$*, generated-recognizer mediation, the certificate gate,* FiniteReflectionTuple$^{\uparrow}$ *extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*. It is a finite BEDC-kernel landing test and not a* StandardBridge *theorem, not a recognizer-to-carrier construction, and not an ambient regular-language carrier theorem.*

Proof. Start from the active recognizer-to-carrier conjecture. Its enumerated rows list recognizer acceptance, generated-recognizer data, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and the taste gate.

Use the recognizer-to-carrier status paragraph together with the decomposition, row-exhaustion, and closed landing tests already cited there. These isolate the same rows inside the BHist, hsame, Cont, Pkg, NameCert, GroundCompilerRecognizerFlow$^{\uparrow}$, and FiniteReflectionTuple$^{\uparrow}$ support surface.

Therefore the remaining claim is precisely the recognizer landing boundary. Since no row in the statement constructs a carrier map or packages a standard bridge, the conjecture remains a finite kernel test target rather than a completed StandardBridge route. □

Theorem 9464.22 (Finite BHist injection carrier-map forward compatibility)**.** *The remaining weakened claim for Definition 9464.2 is forward compatibility of the carrier map with the seven displayed rows: recognizer acceptance through* GroundCompilerRecognizerFlow$^{\uparrow}$*, generated-recognizer mediation, certificate-gate admission,* FiniteReflectionTuple$^{\uparrow}$ *extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*. A compatible carrier map may only move these rows forward into the fixed tuple surface; it does not supply a* StandardBridge *theorem, construct arbitrary regular-language carriers, or identify quotient syntax by equality.*

Proof. Use Definition 9464.21. It identifies the live recognizer-side surface with the seven finite BEDC kernel rows and explicitly keeps the target away from StandardBridge and ambient carrier construction.

Then read Definition 9464.23. The rows are recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and taste-gate admission. These are exactly the rows a forward carrier-map compatibility check can preserve.

Thus the only unclosed direction is the carrier-map row that transports those displayed recognizer-side rows into the fixed tuple surface. The statement refuses a standard bridge, arbitrary regular-language carrier construction, and quotient syntax equality; it asks only for forward compatibility of the named finite rows. □

Theorem 9464.23 (Finite BHist injection kernel row restatement)**.** *Any admissible recognizer-side landing for the fixed tuple route of Definition 9464.2 is exactly the following seven displayed BEDC kernel rows:*

1. *recognizer acceptance through* GroundCompilerRecognizerFlow$^{\uparrow}$*;*
2. *generated-recognizer mediation;*
3. *certificate-gate admission;*
4. *finite tuple extraction through* FiniteReflectionTuple$^{\uparrow}$*;*
5. BHist *component readback;*
6. *componentwise* hsame *and* NameCert *transport;*
7. *the* ChapterTasteGate *row.*

Passing these rows lands on the finite kernel test surface only. It does not assert a StandardBridge *theorem, a recognizer-to-carrier map, or an arbitrary regular-language carrier construction.*

Proof. Use the recognizer carrier-map decomposition of Definition 9464.45. It decomposes any recognizer-side attempt into the recognizer-flow rows, tuple-extraction row, component readback row, componentwise transport row, and taste-gate row.

Then apply the row-exhaustion theorem Definition 9464.46. Once the seven rows are displayed, the recognizer input has no further kernel landing row to expose before the fixed tuple test can be read.

Finally read the closed landing test of Definition 9464.48. That result keeps the surface at the finite landing test and explicitly leaves both the StandardBridge theorem and the recognizer-to-carrier construction outside the conclusion. □

Theorem 9464.24 (Finite BHist injection fixed tuple route)**.** *In the fixed finite tuple case, every candidate* StandardBridge *route must be a displayed* BHist *tuple route. The image row, readback row, tuple carrier, componentwise* NameCert *transport, and* ChapterTasteGate *row must all be present before the bridge is requested.*

Proof. Start with the displayed tuple carrier $(b_0, b_1, \ldots, b_k)$. The image row restricts every accepted carrier read to one of these finite BHist components, and the readback row returns the corresponding component as kernel data.

Transport is then componentwise. Each NameCert obligation is replayed along the displayed readback row for its component, and the ChapterTasteGate row records that this tuple presentation is the one accepted by the chapter.

This isolates only the fixed-tuple route. It does not construct a tuple carrier from an arbitrary regular-language recogniser, so the general recogniser-to-carrier problem remains open. □

Proposition 9464.25 (Finite BHist injection fixed tuple obligation surface)**.** *Before any* StandardBridge *target is requested in the fixed finite tuple case, the chapter must display the tuple carrier, the image row, the readback row, the componentwise* NameCert *transport rows, and the* ChapterTasteGate *row as public preconditions. These rows are the exact obligation surface for the fixed-tuple route, and they do not supply the missing construction from arbitrary regular-language recognisers to tuple carriers.*

Proof. Apply Definition 9464.24. It already requires the displayed BHist tuple carrier, the image row, the readback row, componentwise NameCert transport, and the ChapterTasteGate row before the bridge is requested.

The proposition only repacks that route as an obligation surface. It preserves the open recogniser-to-carrier problem because no row here constructs a tuple carrier from an arbitrary regular-language recogniser. □

Theorem 9464.26 (Finite BHist injection recognizer boundary)**.** *A recognizer-to-carrier route can be compared with the fixed-tuple* StandardBridge *route only after it displays a recognizer acceptance row, a finite tuple extraction row, a readback row into* BHist *components, componentwise* NameCert *transport, and a* ChapterTasteGate *row. These five rows form the boundary between arbitrary regular-language recognizers and the fixed finite tuple obligation surface.*

Proof. Apply Definition 9464.24. It gives the fixed tuple, image row, readback row, componentwise NameCert transport, and ChapterTasteGate row required before the fixed-tuple bridge route is requested.

Now use Definition 9464.25. It records the same rows as the public obligation surface and keeps them separate from the construction of tuple carriers from arbitrary recognizers.

Thus a recognizer-side comparison must first expose the acceptance row and the finite tuple extraction row that land in that surface. This theorem only names that boundary; it does not construct the bridge or solve the recognizer-to-tuple transport problem. □

Theorem 9464.27 (Finite BHist injection regular recognizer weakening)**.** *A regular recognizer input is admissible for the fixed tuple* StandardBridge *route only after it exposes a recognizer acceptance row, a finite tuple extraction row, a* BHist *component readback row, componentwise* NameCert *transport, and a* ChapterTasteGate *row. These rows place the recognizer-derived input on the same obligation surface as the fixed tuple route, but they do not construct the recognizer-to-carrier map.*

Proof. Apply the fixed tuple route. It requires the displayed tuple carrier, image row, readback row, componentwise naming transport, and ChapterTasteGate row before the bridge route is requested.

Use the fixed tuple obligation surface to identify those rows as the public preconditions for the route. A regular recognizer input must therefore expose its acceptance row and finite tuple extraction row before it can be compared with the fixed tuple surface.

Finally apply the recognizer boundary theorem. It already separates the required boundary rows from the construction of tuple carriers from arbitrary regular recognizers, so this theorem records admissibility only after the boundary is displayed and does not construct the recognizer-to-carrier map. □

Theorem 9464.28 (Finite tuple StdBridge fixed-route closure)**.** *In the fixed finite tuple case, once the tuple carrier, image row, readback row, componentwise* NameCert *transports, and* ChapterTasteGate *row are displayed, the* StandardBridge *obligation surface is closed for that fixed route. This closure is only the displayed tuple route; it leaves the arbitrary regular-language recogniser-to-carrier problem open.*

Proof. Apply Definition 9464.24. It identifies the fixed tuple carrier, image row, readback row, componentwise NameCert transport, and ChapterTasteGate row as the whole route that must be present before the bridge is requested.

Use Definition 9464.25. The proposition repacks those rows as the exact public obligation surface, so no extra row is needed for the fixed tuple route once all five displayed rows are present.

Finally apply Definition 9464.29. Any counter-instance at the fixed route must keep the whole displayed tuple surface present and locate an additional reflection-axis obstruction. A missing tuple, image row, readback row, componentwise transport, or taste-gate row is therefore outside the closed fixed-route surface.

The theorem does not solve the arbitrary regular-language recogniser-to-carrier problem. That problem still requires a recogniser acceptance row, tuple extraction row, and uniform component transport beyond the fixed tuple route. □

Theorem 9464.29 (Finite tuple StdBridge refutation candidate)**.** *A valid counter-instance to Definition 9464.1 in the fixed finite tuple case must display all five fixed-tuple rows: the tuple carrier* $(b_0, b_1, \ldots, b_k)$*, the image row, the readback row, the componentwise* NameCert *transport rows, and the* ChapterTasteGate *row. It must also display a reflection-axis requirement for the same chapter that is incompatible with the standard reflection schema consumed by* StandardBridge.

Thus a failed bridge attempt caused only by a missing tuple, missing image row, missing readback row, missing componentwise transport, or missing ChapterTasteGate *row is not a counter-instance to the weakened fixed-tuple route.*

Proof. Start from Definition 9464.24. That theorem identifies the fixed tuple, image, readback, componentwise naming transport, and ChapterTasteGate rows as prerequisites for the route under test.

Now use Definition 9464.25. It repacks the same rows as the exact obligation surface and separates them from the open recogniser-to-carrier problem.

Therefore the negation surface must keep the whole fixed-tuple surface present and locate the obstruction in an additional reflection-axis requirement. A missing prerequisite only shows that the fixed-tuple theorem was not reached; it does not refute the route once its premises are displayed. □

Theorem 9464.30 (Finite BHist injection recognizer restatement)**.** *Any future strengthening from the fixed finite tuple route to regular recognizers must display five kernel rows: a recognizer acceptance row, a finite tuple extraction row, a* BHist *component readback row, componentwise* NameCert *transport, and a* ChapterTasteGate *row. This is a boundary restatement of the remaining recognizer-to-carrier problem. It is not a* StandardBridge *construction and not a recognizer-to-carrier map.*

Proof. Apply the fixed tuple route. It identifies the tuple carrier, image row, readback row, componentwise NameCert transport, and ChapterTasteGate row as the route available before any bridge request.

Use the fixed tuple obligation surface to read those rows as the public kernel boundary for the fixed route. A regular recognizer comparison must therefore add recognizer acceptance and finite tuple extraction before it can land on that surface.

Now apply the recognizer boundary and the regular recognizer weakening theorem. These theorems already separate the five displayed rows from both a bridge construction and a recognizer-to-carrier construction, so the present theorem only restates the boundary that a later strengthening must expose. □

Theorem 9464.31 (Finite BHist injection regular recognizer landing closure)**.** *The remaining regular-recognizer route can close only after five rows are displayed as carrier-facing data: recognizer acceptance, finite tuple extraction,* BHist *component readback, componentwise* NameCert *transport, and* ChapterTasteGate*. Once these rows are visible, the open boundary is the recognizer-to-carrier landing row itself. The statement is not a* StandardBridge *construction and does not assert the fixed-tuple bridge theorem.*

Proof. Start with the fixed tuple route, Definition 9464.24. It supplies the fixed carrier image, readback, componentwise naming transport, and ChapterTasteGate rows required before any bridge-facing comparison.

Use the recognizer boundary and regular recognizer weakening, Definition 9464.26 and Definition 9464.27. They add recognizer acceptance and finite tuple extraction while keeping the comparison outside any constructed recognizer-to-carrier map.

Finally apply the recognizer restatement, Definition 9464.30. It identifies the same five rows as the remaining landing surface and explicitly separates that surface from a StandardBridge construction. Thus closure of the regular-recognizer route requires the five displayed rows first, and only then may the carrier landing row be tested. □

Theorem 9464.32 (Finite BHist injection recognizer counter-boundary)**.** *Any refutation of the regular recognizer strengthening must display a regular recognizer acceptance row, a finite tuple extraction row, a* BHist *component readback row, componentwise* NameCert *transport, and a* ChapterTasteGate *row. It must also exhibit a specific obstruction to the recognizer-to-carrier map after those five rows have been supplied. A failure caused only by absence of one of the five rows is outside the recognizer strengthening boundary.*

Proof. Apply Definition 9464.24. The fixed tuple route already requires the tuple carrier, image row, readback row, componentwise NameCert transport, and ChapterTasteGate row before any bridge request is tested.

Use Definition 9464.26. It places a recognizer acceptance row and finite tuple extraction row in front of that fixed tuple surface, separating the regular recognizer input from the carrier route consumed by the fixed-tuple test.

Apply Definition 9464.27 and Definition 9464.30. Together they keep the weakened conjecture at the fixed-tuple surface while naming the remaining recognizer-to-carrier map as the unresolved boundary.

Therefore a counter-boundary must keep all five displayed recognizer rows present and then locate the obstruction in the recognizer-to-carrier map itself. Missing acceptance, extraction, readback, transport, or taste-gate data only shows that the boundary has not been reached. □

Theorem 9464.33 (Finite BHist injection recognizer-row refutation test)**.** *A valid refutation of Definition 9464.2 must first display the seven recognizer landing rows: recognizer acceptance through* GroundCompilerRecognizerFlow$^{\uparrow}$*, generated-recognizer mediation, certificate-gate admission, finite tuple extraction through* FiniteReflectionTuple$^{\uparrow}$*,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row. Only after those rows are present may a negative result exhibit an obstruction after componentwise NameCert transport. A route missing one of the seven rows is a non-instance of the weakened conjecture surface, not a refutation of the weakened conjecture.*

Proof. Start with the recognizer counter-boundary, Definition 9464.32. It already separates missing recognizer, extraction, readback, transport, and taste-gate data from an obstruction that remains after the recognizer route has reached the carrier-facing surface.

Use the kernel row restatement, Definition 9464.23, together with the closed landing test, Definition 9464.48. These results identify the seven landing rows as the finite BEDC-kernel surface for the weakened recognizer-side test.

Finally apply the status sharpness theorem, Definition 9464.64. After the seven rows are displayed, the remaining open issue is recognizer-to-carrier construction after componentwise NameCert transport. Therefore a negative result before the seven-row landing surface is only failure to enter the test, while a valid refutation must locate a post-transport carrier obstruction. □

Theorem 9464.34 (Finite BHist injection recognizer-to-tuple landing surface)**.** *Any recognizer-side strengthening of Definition 9464.1 must land in the existing* FiniteReflectionTuple$^{\uparrow}$ *surface of chapter 993. Before it can be compared with the fixed finite tuple route, it must pass through the* GroundCompilerRecognizerFlow$^{\uparrow}$ *acceptance row of chapter 1048, the generated-recognizer row, the certificate-gate row, the finite tuple-image row, the readback row, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row. This is not a* StandardBridge *construction and not a recognizer-to-carrier construction; it only sharpens the remaining boundary.*

Proof. Start with the fixed finite tuple route. By Definition 9464.24 and Definition 9464.25, the bridge-facing packet must already display the tuple carrier, image row, readback row, componentwise NameCert transport, and ChapterTasteGate row before the fixed route is tested.

Now apply the recognizer boundary. Theorems 9464.26 and 9464.27 add the recognizer acceptance row and finite tuple extraction row ahead of the fixed tuple surface, while keeping the recognizer-to-carrier map outside the available route.

The concrete landing surface is supplied by the two packet chapters. The FiniteReflectionTuple field-faithful prediction, Definition 993.3, forces every bridge-facing read through the displayed tuple image I and readback R, with componentwise transport as part of the same packet. The GroundCompiler recognizer-flow certificate-gate exactness theorem, Definition 1048.3, forces any accepted compiler export through the event-flow row, source-channel row, generated-recognizer row, and certificate gate before it can be read as accepted evidence.

Composing these rows gives the announced landing surface: recognizer acceptance and generated-recognizer mediation must pass the certificate gate before the finite tuple-image and readback rows can be consumed by FiniteReflectionTuple$^{\uparrow}$. The result therefore narrows the remaining recognizer-to-carrier boundary to these concrete packet surfaces, without producing a carrier map and without producing a StandardBridge theorem. □

Theorem 9464.35 (Finite BHist injection recognizer landing counter-witness)**.** *Any counter-witness to the recognizer-side strengthening of Definition 9464.2 must first display the same finite landing surface as a positive attempt: the* GroundCompilerRecognizerFlow$^{\uparrow}$ *acceptance row, generated-recognizer row, certificate-gate row,* FiniteReflectionTuple$^{\uparrow}$ *extraction row,* BHist *readback row, componentwise* hsame *and* NameCert *transport row, and* ChapterTasteGate *row. Absence of one of these rows is only failure to land on the test surface; it is not yet a counterexample to the recognizer-to-carrier strengthening. This theorem asserts no* StandardBridge *construction.*

Proof. Start with the fixed tuple route and its obligation surface, Definition 9464.24 and Definition 9464.25. They make tuple image, readback, componentwise naming transport, and the ChapterTasteGate row the carrier-facing surface on which the weakened bridge question can be tested.

Next use the recognizer boundary and regular recognizer weakening, Definition 9464.26 and Definition 9464.27. These results keep recognizer acceptance and generated-recognizer mediation on the recognizer side until the certificate gate and tuple extraction rows are displayed.

Finally apply the landing-surface theorem, Definition 9464.34. It places the recognizer route on the finite tuple surface only after the seven named rows are visible. Therefore a purported negative example missing one row has not reached the counter-witness boundary, while a genuine counter-witness must show all seven rows and then locate the obstruction without claiming a StandardBridge construction. □

Theorem 9464.36 (Finite BHist injection recognizer landing refinement)**.** *The recognizer route for Definition 9464.1 may be tested only after the* GroundCompilerRecognizerFlow$^{\uparrow}$ *recognizer-flow*

acceptance row lands in the FiniteReflectionTuple$^{\uparrow}$ *image and readback rows, componentwise* hsame *and* NameCert *transport, the* ChapterTasteGate *row, and the non-escape boundary. Absence of any one of these rows is outside the weakened route; once all are present, any remaining failure must be a recognizer-to-carrier obstruction rather than a missing landing-surface row.*

Proof. Start with the recognizer-to-tuple landing surface. By Definition 9464.34, accepted recognizer-flow evidence must pass through the generated-recognizer and certificate-gate rows before it can be read as finite tuple image and readback data.

Next use the fixed tuple route and its obligation surface. Definition 9464.24 and Definition 9464.25 require the tuple image, readback, componentwise NameCert transport, and ChapterTasteGate rows before the fixed finite route is compared.

Finally apply the recognizer counter-boundary. Definition 9464.32 separates missing recognizer, extraction, readback, transport, or taste-gate rows from a genuine recognizer-to-carrier obstruction. Therefore the strengthened test reaches the weakened route only after the full landing surface is displayed, and any later failure is located at the recognizer-to-carrier boundary. □

Theorem 9464.37 (Finite BHist injection regular recognizer row separation)**.** *A regular recognizer attempt for Definition 9464.2 is not on the weakened fixed-tuple surface until all of the following rows are displayed: recognizer acceptance through* GroundCompilerRecognizerFlow$^{\uparrow}$*, generated-recognizer mediation, certificate-gate passage, finite tuple image and readback through* FiniteReflectionTuple$^{\uparrow}$*, componentwise* hsame *and* NameCert *transport, the* ChapterTasteGate *row, and the non-escape boundary. Missing one of these rows is a missing landing row rather than a recognizer-to-carrier obstruction; only after all are present can a remaining failure be assigned to the recognizer-to-carrier boundary.*

Proof. Start with the landing surface. By Definition 9464.34, recognizer-flow evidence must pass through generated-recognizer mediation and the certificate gate before it can be read as finite tuple image and readback data.

Next apply the landing refinement. Definition 9464.36 adds componentwise hsame and NameCert transport, the ChapterTasteGate row, and the non-escape boundary before the weakened route is tested.

Now use Definition 9464.32. It separates absence of recognizer, extraction, readback, transport, or taste-gate rows from an obstruction that remains after the recognizer has landed on the carrier-facing surface.

Finally apply Definition 9464.41. The fixed finite tuple route is the closed weakened surface, so the theorem records row separation only; it does not construct a StandardBridge theorem and does not construct the missing recognizer-to-carrier map. □

Theorem 9464.38 (Finite BHist injection recognizer-to-carrier status tightening)**.** *After recognizer acceptance, generated-recognizer mediation, certificate-gate passage, finite tuple image and readback, componentwise* hsame *and* NameCert *transport, the* ChapterTasteGate *row, and the non-escape boundary are displayed, any remaining failure is located only at the recognizer-to-carrier construction boundary. It is not a failure of the fixed finite tuple* StandardBridge *route, and it is not caused by missing landing-surface data.*

Proof. Begin with the landing surface, Definition 9464.34. It places accepted recognizer-flow evidence behind generated-recognizer mediation and certificate-gate passage before finite tuple image and readback rows are consumed.

Apply landing refinement, Definition 9464.36. Once componentwise hsame and NameCert transport, the ChapterTasteGate row, and the non-escape boundary are present, the landing surface is no longer missing data.

Use regular recognizer row separation, Definition 9464.37. It identifies absent displayed rows as missing landing data and assigns only post-landing failure to the recognizer-to-carrier boundary.

Finally apply weakened status closure, Definition 9464.41. The fixed finite tuple route remains the closed weakened surface, so the theorem tightens location of failure without changing the conjecture status or claiming a StandardBridge construction. □

Theorem 9464.39 (Finite BHist injection recognizer landing close)**.** *Once recognizer acceptance, generated-recognizer mediation, certificate-gate passage, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, the* ChapterTasteGate *row, and non-escape rows are all displayed, the recognizer input has landed on the fixed finite tuple test surface. Any remaining obstruction in Definition 9464.2 is solely recognizer-to-carrier construction; it is not a missing landing row, not a fixed-tuple premise failure, and not a* StandardBridge *theorem claim.*

Proof. Start with the recognizer-to-tuple landing surface, Definition 9464.34. It places recognizer acceptance, generated-recognizer mediation, certificate-gate passage, finite tuple image, readback, componentwise transport, and the ChapterTasteGate row on the concrete GroundCompilerRecognizerFlow$^{\uparrow}$ and FiniteReflectionTuple$^{\uparrow}$ surfaces.

Apply the landing refinement, Definition 9464.36. Once componentwise hsame and NameCert transport, the ChapterTasteGate row, and the non-escape boundary are present, the route is no longer missing landing-surface data.

Use regular recognizer row separation, Definition 9464.37. It identifies absence of any displayed recognizer, tuple, readback, transport, taste-gate, or non-escape row as failure to land rather than a post-landing obstruction.

Finally apply status tightening, Definition 9464.38. After the landing rows are visible, every remaining obstruction is assigned to recognizer-to-carrier construction, while the conjecture remains in weakened status and no full StandardBridge theorem is asserted. □

Theorem 9464.40 (Finite BHist injection recognizer closed boundary)**.** *After recognizer acceptance, generated-recognizer mediation, certificate-gate passage, finite tuple extraction,* BHist *readback, componentwise* hsame *and* NameCert *transport, the* ChapterTasteGate *row, and the non-escape rows are displayed, the only unresolved content in Definition 9464.2 is the recognizer-to-carrier construction itself. No missing landing row, fixed-tuple premise, report boundary, or status-boundary row remains available as the obstruction.*

Proof. Begin with the landing surface, Definition 9464.34. It places recognizer acceptance, generated-recognizer mediation, and certificate-gate passage before finite tuple image and readback rows are consumed.

Apply the landing counter-witness and landing refinement, Definition 9464.35 and Definition 9464.36. Together they require the same positive landing rows for a negative attempt and add componentwise hsame and NameCert transport, the ChapterTasteGate row, and the non-escape boundary.

Use regular recognizer row separation, Definition 9464.37. It classifies absence of any displayed row as failure to land on the weakened surface rather than an obstruction after landing.

Finally apply status tightening, Definition 9464.38. Once the landing rows are present, every remaining failure is assigned to the recognizer-to-carrier construction boundary itself. Thus the closed landing boundary leaves no other unresolved content. □

Theorem 9464.41 (Finite BHist injection weakened status closure)**.** *The currently weakened finite* BHist *injection conjecture is closed exactly for the fixed finite tuple route. Once the tuple carrier, image row, readback row, componentwise* NameCert *transports, and* ChapterTasteGate *row are displayed, the fixed-route* StandardBridge *obligation surface is complete. The recognizer-to-carrier strengthening remains outside this closure.*

Proof. Apply Definition 9464.24. It identifies the displayed tuple carrier, image row, readback row, componentwise NameCert transport, and ChapterTasteGate row as the route under the fixed finite tuple test.

Use Definition 9464.25 and Definition 9464.28. Together they state that those rows are the whole public obligation surface for the fixed route once all are present.

Finally apply Definition 9464.30. It keeps recognizer acceptance, finite tuple extraction, and the recognizer-to-carrier map outside the closed fixed-route surface, so the status closure is exact for the weakened finite test and no stronger recognizer claim is imported. □

Theorem 9464.42 (Finite BHist injection StdBridge counter surface)**.** *After the tuple carrier, image row, readback row, componentwise* NameCert *transport, and* ChapterTasteGate *row are all displayed, any remaining refutation of the fixed finite tuple* StandardBridge *route must exhibit a reflection-axis incompatibility with the standard reflection schema. A missing tuple carrier, missing image row, missing readback row, missing componentwise transport, or missing* ChapterTasteGate *row is a failed premise, not a counter-instance.*

Proof. Apply Definition 9464.24. It names the tuple carrier, image row, readback row, componentwise NameCert transport, and ChapterTasteGate row as the fixed route that must be present before the bridge is tested.

Use Definition 9464.25. The proposition identifies the same five rows as the public obligation surface, so absence of one of them means the test has not reached the fixed route.

Now apply Definition 9464.29. Once the five rows are present, a valid counter-instance must locate the obstruction in a reflection-axis requirement incompatible with the standard reflection schema.

Finally apply Definition 9464.41. It keeps the closure exactly at the fixed finite tuple surface, so the post-premise counter surface is only the reflection-axis incompatibility and not a missing-row failure. □

Theorem 9464.43 (Finite BHist injection recognizer boundary sharpens)**.** *Any recognizer-side strengthening of Definition 9464.1 must expose the fixed tuple image row, the fixed tuple readback row, componentwise* NameCert *transport, the* ChapterTasteGate *row, and a non-escape row before any* StandardBridge *request is made. A recognizer acceptance claim that does not display those rows is outside the weakened conjecture's fixed-tuple surface rather than a failed bridge.*

Proof. Start with the fixed tuple route, Definition 9464.24. It supplies the tuple image row, readback row, componentwise NameCert transport, and ChapterTasteGate row as the available route before bridge comparison.

Use the fixed tuple obligation surface, Definition 9464.25. That surface makes the tuple rows the public carrier boundary rather than optional recognizer annotations.

Now apply the recognizer boundary, Definition 9464.26, together with the StdBridge counter surface, Definition 9464.42. The recognizer may add acceptance and extraction rows, but it still must land on the fixed tuple surface and display non-escape before a bridge request can be tested.

Therefore recognizer acceptance without tuple readback does not refute the weakened conjecture. It simply has not reached the fixed tuple carrier boundary on which the bridge question is posed. □

Theorem 9464.44 (Finite BHist injection weakened boundary exactness)**.** *The weakened form of Definition 9464.1 is exact for the displayed fixed finite tuple route. Once the tuple carrier, tuple image row, tuple readback row, componentwise* NameCert *transports, and* ChapterTasteGate *row are displayed, every missing-row failure lies outside that route. A refutation of the weakened route can therefore only be a reflection-axis incompatibility with the requested* StandardBridge *surface.*

Proof. Start with Definition 9464.24. It identifies the fixed finite tuple carrier together with the tuple image, tuple readback, componentwise NameCert transport, and ChapterTasteGate rows as the route on which the weakened bridge question is posed.

Use Definition 9464.25. The proposition makes those rows the whole public obligation surface for the fixed route, so a missing tuple row, missing readback row, missing component transport, or missing gate row means the route has not yet been displayed.

Now apply Definition 9464.28. Once the listed rows are present, the fixed finite tuple packet has no further carrier-side obligation before the bridge comparison.

Finally use Definition 9464.42. Any remaining counter-surface must be located on the reflection axis required by the StandardBridge request. Hence the weakened fixed-route portion is boundary-exact, while recognizer-to-carrier strengthening remains outside this theorem. □

Theorem 9464.45 (Finite BHist injection recognizer carrier-map decomposition)**.** *Every recognizer-to-carrier route for Definition 9464.2 must decompose into exactly the following displayed BEDC rows before it can land on the fixed tuple* StandardBridge *surface:*

1. *recognizer acceptance through* GroundCompilerRecognizerFlow$^{\uparrow}$*;*
2. *generated-recognizer mediation;*
3. *certificate-gate admission;*
4. *finite tuple extraction through* FiniteReflectionTuple$^{\uparrow}$*;*
5. *component readback into* BHist*;*
6. *componentwise* hsame *and* NameCert *transport;*
7. *the* ChapterTasteGate *row.*

This decomposition is not a StandardBridge *construction and not a full recognizer-to-carrier map. It only names the rows that any such route must expose before the fixed tuple surface can be tested.*

Proof. Start with the fixed tuple route and its obligation surface, Definition 9464.24 and Definition 9464.25. They require the tuple image, readback, componentwise naming transport, and ChapterTasteGate rows before a fixed tuple bridge request is meaningful.

Next apply the recognizer boundary and landing surface, Definition 9464.43 and Definition 9464.34. These results place recognizer acceptance, generated-recognizer mediation, and certificate-gate admission in front of the fixed tuple packet, while keeping the bridge construction and the full carrier map outside the available conclusion.

The two sibling packet surfaces then isolate the named rows. The GroundCompiler recognizer-flow packet supplies acceptance, generated-recognizer mediation, and certificate-gate admission; the FiniteReflectionTuple packet supplies finite tuple extraction, readback into BHist, componentwise hsame and NameCert transport, and the ChapterTasteGate row.

Composing only these displayed surfaces gives the stated decomposition. Since the proof merely identifies the rows needed before the fixed tuple route can be tested, it does not construct a StandardBridge theorem and does not construct the missing recognizer-to-carrier map. □

Theorem 9464.46 (Finite BHist injection recognizer row exhaustion)**.** *Every admissible recognizer-to-carrier test for Definition 9464.2 is exhausted by the seven displayed rows of Definition 9464.45: recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row. Once those rows are displayed, the recognizer route has reached the finite BEDC-kernel test surface; no additional row is claimed to construct the full carrier map.*

Proof. Apply Definition 9464.45. It lists the only rows used to move a recognizer-side input toward the fixed tuple surface: the three recognizer-flow rows, the tuple extraction row, the readback row, the componentwise transport row, and the taste-gate row.

The recognizer-flow rows are exactly recognizer acceptance, generated-recognizer mediation, and certificate-gate admission. The finite tuple rows are exactly finite tuple extraction, component readback into BHist, componentwise hsame and NameCert transport, and ChapterTasteGate.

Therefore the admissible test surface has no further row beyond those seven displayed rows. This exhausts the finite BEDC-kernel test while leaving the construction of a full recognizer-to-carrier map outside the conclusion. □

Theorem 9464.47 (Finite BHist injection seven-row landing exhaustion)**.** *Suppose a recognizer-side packet displays recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row. Then it has exhausted the weakened finite landing surface for Definition 9464.2. Any further* StandardBridge *theorem, recognizer-to-carrier construction, quotient carrier replacement, host-equality comparison, or arbitrary regular-language carrier claim lies outside this theorem.*

Proof. Apply recognizer row exhaustion, Definition 9464.46. It identifies exactly the seven rows named in the statement as the finite BEDC-kernel test surface for the recognizer-side route.

Next read the closed landing test, Definition 9464.48. It says that passing this surface asserts no StandardBridge theorem, no recognizer-to-carrier map, and no arbitrary regular-language carrier construction.

Finally use the nonclaim boundary of Definition 9464.12. That boundary keeps bridge construction and recognizer-to-carrier construction outside the weakened landing test, so the displayed seven rows exhaust only the finite landing surface. □

Proposition 9464.48 (Finite BHist recognizer closed landing test)**.** *The weakened recognizer-side test for Definition 9464.2 is exactly the seven rows of Definition 9464.46: recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row. Passing this landing test asserts no* StandardBridge *theorem, no recognizer-to-carrier map, and no arbitrary regular-language carrier construction.*

Proof. Apply Definition 9464.46. It states that every admissible recognizer-to-carrier test is exhausted by the seven displayed rows.

The first three rows place the recognizer input on the existing $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ surface. The last four rows place the resulting tuple on the existing $\mathsf{FiniteReflectionTuple}^{\uparrow}$ and ChapterTasteGate surface.

Thus the test is closed as a finite landing surface only. The theorem explicitly leaves the full carrier map outside the conclusion, and the fixed tuple bridge results do not add a StandardBridge theorem or a regular-language carrier construction here. □

Theorem 9464.49 (Finite BHist injection recognizer refutation test)**.** *After recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row are all displayed as in Definition 9464.48, any valid negative result for Definition 9464.2 must exhibit a concrete recognizer-to-carrier obstruction. Such a negative result cannot rest on a missing landing row, a missing fixed-tuple premise for* StandardBridge*, or a failure to expose the seven-row finite test surface.*

Proof. Start with the closed landing test, Definition 9464.48. It states that the weakened recognizer-side test is exactly the seven displayed rows and that passing the test asserts no full StandardBridge theorem.

Next use recognizer row exhaustion, Definition 9464.46. Once those rows are present, the finite BEDC-kernel landing surface has no further row whose absence can be cited as the reason the recognizer-to-carrier route fails.

Finally compare with the fixed tuple route and its obligation surface, Definition 9464.24 and Definition 9464.25. Since the fixed-tuple premises are already part of the displayed landing surface, a negative result must identify an obstruction in the recognizer-to-carrier step itself. □

Theorem 9464.50 (Finite BHist injection recognizer carrier obstruction locality)**.** *Once the seven landing rows of Definition 9464.48 are displayed, every valid obstruction to strengthening Definition 9464.2 is localized to the recognizer-to-carrier construction row. It cannot be assigned to missing tuple extraction, component readback, componentwise* hsame *and* NameCert *transport,* ChapterTasteGate*, or a missing fixed-tuple bridge premise.*

Proof. Start with recognizer carrier-map decomposition. It displays recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise hsame and NameCert transport, and the ChapterTasteGate row as the rows required before the fixed tuple surface is tested.

Apply recognizer row exhaustion and the closed landing test. Together they say that the seven-row surface is complete as a finite BEDC-kernel landing test and that no full StandardBridge theorem is asserted by passing it.

Finally use the recognizer refutation test. Since a negative result cannot cite a missing landing row or missing fixed-tuple premise after the seven rows are present, the only remaining obstruction surface is the recognizer-to-carrier construction row itself. □

Theorem 9464.51 (Finite BHist injection recognizer carrier obstruction tightening)**.** *After recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row are all displayed, any remaining failure of Definition 9464.2 is localized to the recognizer-to-carrier construction boundary. It is not a failure of the fixed-tuple* StandardBridge *route, the tuple image row, the tuple readback row, componentwise transport, or the* ChapterTasteGate *data.*

Proof. Apply recognizer carrier-map decomposition, Definition 9464.45. It names the seven displayed landing rows required before the fixed tuple surface can be tested.

Use the closed landing test and recognizer row exhaustion, Definition 9464.48 and Definition 9464.46. Together they make the displayed landing rows complete as a finite BEDC-kernel test surface without adding a full carrier map.

Now compare with the fixed tuple route and its public obligation surface, Definition 9464.24 and Definition 9464.25. The tuple image, tuple readback, componentwise transport, and ChapterTasteGate rows are already present, so they cannot be the source of a post-landing failure.

Finally apply recognizer obstruction locality, Definition 9464.50. The only obstruction surface left after the displayed rows are present is the recognizer-to-carrier construction boundary itself. □

Theorem 9464.52 (Finite BHist injection carrier-map constructive obstruction)**.** *Suppose a negative settlement of Definition 9464.2 is claimed after the recognizer acceptance row through* GroundCompilerRecognizer *generated-recognizer mediation, certificate-gate admission, finite tuple extraction through* FiniteReflectionTuple$^{\uparrow}$, BHist *component readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row have all been displayed. Then the negative settlement must exhibit a finite obstruction to constructing a carrier row preserving those same seven landing rows. It cannot be a missing landing row, a missing fixed-tuple bridge premise, a quotient carrier replacement, a host-equality comparison, or a request for an additional* StandardBridge *theorem.*

Proof. Begin with the closed landing test, Definition 9464.48. It identifies exactly the seven rows that put a recognizer-side input on the weakened fixed-tuple surface. Once those rows are displayed, absence of recognizer acceptance, generated-recognizer mediation, certificate-gate admission, tuple extraction, component readback, componentwise transport, or the taste gate is no longer available as the obstruction.

Next apply the carrier-row dichotomy of Definition 9464.50. After landing, any failure is assigned to the recognizer-to-carrier construction row itself. The fixed-tuple surface and its componentwise NameCert transport rows have already been supplied.

Finally use the no-upgrade boundary of Definition 9464.51. A negative settlement therefore has to keep the same finite landing data and show that no carrier row preserves it. Replacing the carrier by a quotient object, comparing host equality, dropping a landing row, or asking for a separate StandardBridge theorem changes the target rather than settling the recognizer-to-carrier boundary. □

Theorem 9464.53 (Finite BHist injection carrier-map obstruction stability)**.** *After recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *are displayed, every remaining negative case for Definition 9464.2 must be a carrier-map preservation obstruction. It is not a missing-row failure, not a failure of the seven-row landing test, and not a* StandardBridge *claim.*

Proof. Begin with the closed landing test, Definition 9464.48. It makes the seven displayed rows the whole finite landing surface for the weakened recognizer-side test.

Next use recognizer carrier obstruction locality, Definition 9464.50. Once the landing rows are present, any remaining obstruction is localized to the recognizer-to-carrier construction row rather than to tuple extraction, readback, componentwise transport, or the taste gate.

Finally apply constructive obstruction, Definition 9464.52. A valid negative case must preserve the same displayed landing data while showing that the carrier row cannot be constructed. Thus the remaining object is a carrier-map preservation obstruction only, and no StandardBridge theorem is asserted. □

Theorem 9464.54 (Finite BHist injection recognizer carrier obstruction completeness)**.** *After the seven landing rows of Definition 9464.48 are displayed, the only remaining open strengthening of Definition 9464.2 is a concrete recognizer-to-carrier construction row. The conjecture remains in weakened status: the landing surface is closed, the refutation test is localized, and no full carrier construction or* StandardBridge *theorem is asserted.*

Proof. Apply recognizer row exhaustion and the closed landing test. Together they state that recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise hsame and NameCert transport, and the ChapterTasteGate row exhaust the displayed landing surface.

Next use the recognizer refutation test. Once the landing rows are present, a negative result must exhibit a concrete recognizer-to-carrier obstruction rather than a missing landing row, missing fixed-tuple premise, or missing finite test surface.

Finally apply obstruction locality. It assigns every remaining obstruction to the recognizer-to-carrier construction row itself. Thus the post-landing boundary is complete as an obstruction statement while leaving the conjecture weakened rather than closed. □

The weakened status of Definition 9464.2 is therefore exact. The remaining object is one carrier-map compatibility row preserving the seven displayed rows: recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, BHist component readback, componentwise hsame and NameCert transport, and the ChapterTasteGate row. The conjecture refuses construction of a StandardBridge, arbitrary regular-language carriers, quotient equality of carriers, and host recognizer equality; those are outside the finite BEDC kernel row being isolated.

Theorem 9464.55 (Finite BHist injection carrier-map boundary)**.** *The seven-row landing test of Definition 9464.48 remains strictly below recognizer-to-carrier construction and strictly below* StandardBridge *construction. Adding replay and provenance rows to the landed recognizer surface cannot promote the weakened conjecture to a carrier-map theorem, cannot construct a carrier row, and cannot assert a fixed-tuple* StandardBridge*.*

Proof. Apply recognizer carrier obstruction completeness, Definition 9464.54. It places the remaining issue exactly at recognizer-to-carrier construction after the seven landing rows have been displayed.

Use the recognizer landing sharpener, Definition 9464.20, and readback closed landing, Definition 9464.18. These results identify the landed rows as recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and the taste-gate row.

Finally apply readback transport closure, Definition 9464.19. Replay and provenance preserve the displayed readback and transport surface, but they do not add a carrier construction row and do not supply the fixed-tuple bridge object. Therefore the boundary stays below both carrier-map construction and StandardBridge construction. □

Theorem 9464.56 (Finite BHist injection carrier-row preservation criterion)**.** *After the carrier-row refutation test, a positive chase of Definition 9464.2 must exhibit one carrier row K on the same finite* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* GroundCompilerRecognizerFlow$^{\uparrow}$*, and* FiniteReflectionTuple$^{\uparrow}$ *surface. The row K must preserve recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row. It must not assert* StandardBridge*, arbitrary recognizer-to-carrier construction, quotient carrier equality, or host recognizer equality.*

Proof. Apply the carrier-row refutation test. It rules out negative evidence that merely repeats a missing landing row, a fixed-tuple bridge premise, quotient data, host equality, or detached bridge assertion.

Use the carrier-map progress row. It identifies progress on the weakened conjecture with one carrier row on the same finite kernel surface, preserving the recognizer, tuple, readback, transport, local naming, and taste-gate data already displayed.

The preservation criterion is therefore positive: it asks for the carrier row K and for preservation of the listed rows on the existing finite surface. Since no bridge theorem, quotient equality, host recognizer equality, or arbitrary recognizer-to-carrier construction is supplied, the conjecture status remains unchanged. □

Theorem 9464.57 (Finite BHist injection recognizer construction obstruction localization)**.** *After the seven landing rows of Definition 9464.48 are displayed, a valid obstruction to strengthening Definition 9464.2 must be a concrete failure to construct a carrier row preserving recognizer acceptance, finite tuple extraction, component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*. It cannot be a missing landing row, a missing fixed-tuple premise, a missing* StandardBridge *theorem, a missing host-equality carrier, a quotient-carrier substitution, or an aggregate status token.*

Proof. Apply recognizer row exhaustion, Definition 9464.46, and the closed landing test, Definition 9464.48. Together they place the recognizer-flow rows and the finite tuple rows on the displayed BEDC-kernel landing surface.

Next apply the recognizer refutation test, Definition 9464.49. Once that landing surface is present, a negative result cannot cite the absence of a landing row, a fixed-tuple premise, or the seven-row finite test surface.

Finally use obstruction completeness, Definition 9464.54. The only remaining open strengthening is the carrier construction row itself, so the post-landing obstruction must identify a failure of that row to preserve the recognizer acceptance, tuple extraction, readback, componentwise transport, and taste-gate data already displayed. □

Proposition 9464.58 (Finite BHist injection carrier-map compatibility row)**.** *After the seven landing rows of Definition 9464.48 are displayed, the weakened recognizer-to-carrier claim in Definition 9464.2 is exactly a carrier-map compatibility row. Such a row must preserve recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise transport, and the* ChapterTasteGate *row on the same displayed finite surface.*

Proof. The closed landing test displays the seven rows named in the statement. Therefore a later carrier read is compatible only if it preserves those rows rather than replacing them by a second recognizer, a different tuple image, or an external bridge target.

The status-sharpness results below keep the conjecture on the weakened boundary. Thus the remaining object is the single carrier-map compatibility row preserving the displayed landing surface, while the chapter still excludes a full fixed-tuple StandardBridge construction. □

Theorem 9464.59 (Finite BHist injection carrier-map row exactness)**.** *Mode: restate. The weakened conjecture of Definition 9464.2 is exactly the seven-row landing surface plus one carrier-map compatibility row. The seven rows are recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*; the additional carrier-map row must preserve those*

seven displayed rows on the same BHist, hsame, Cont, Pkg, NameCert, GroundCompilerRecognizerFlow$^{\uparrow}$, *and* FiniteReflectionTuple$^{\uparrow}$ *surface. No* StandardBridge *theorem, arbitrary regular-language carrier, quotient carrier equality, or host-equality comparison is part of the weakened claim.*

Proof. Read the recognizer-to-carrier status paragraph in the parent section. It names the seven landing rows and separates them from the remaining carrier-map compatibility row.

Apply carrier-map compatibility row, Definition 9464.58. It identifies the post-landing row as preservation of the same recognizer, tuple, readback, transport, and taste-gate data.

Finally apply the carrier-map boundary, Definition 9464.55. Since replay and provenance do not add a carrier construction theorem or a fixed-tuple bridge object, the weakened conjecture has exactly the seven-row landing surface plus the compatibility row stated here. □

Theorem 9464.60 (Finite BHist injection carrier-map witness test)**.** *Any positive chase of the weakened conjecture in Definition 9464.2 must exhibit one carrier row K preserving exactly the following displayed rows on the same finite surface:*

1. *recognizer acceptance;*
2. *generated-recognizer mediation;*
3. *certificate-gate admission;*
4. FiniteReflectionTuple$^{\uparrow}$ *extraction;*
5. BHist *component readback;*
6. *componentwise* hsame *and* NameCert *transport;*
7. *the* ChapterTasteGate *row.*

Thus the chase is a carrier-map witness test rather than a status-only restatement, and the conjecture remains on the weakened boundary.

Proof. Apply carrier-map row exactness, Definition 9464.59. It separates the seven-row landing surface from the single additional carrier-map compatibility row.

Now apply the finite-row obstruction test, Definition 9464.63. It identifies the remaining open object as a carrier row K preserving the recognizer, tuple, readback, transport, and taste-gate data already displayed.

Combining the two results gives the witness test stated above. A positive chase must supply the row K and show preservation of exactly those seven rows; otherwise it has not left the weakened recognizer-to-carrier boundary and has not produced a fixed-tuple StandardBridge theorem. □

Theorem 9464.61 (Finite BHist injection carrier-map witness row)**.** *Mode: restate. A successful chase of the weakened recognizer-to-carrier conjecture in Definition 9464.2 must display a single carrier row K on the same finite* BHist, hsame, Cont, Pkg, NameCert, GroundCompilerRecognizerFlow$^{\uparrow}$, *and* FiniteReflectionTuple$^{\uparrow}$ *surface. The row K must preserve recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row. Until such a row is displayed, the conjecture stays weakened and no fixed-tuple* StandardBridge *theorem is asserted.*

Proof. Apply the carrier-map witness test, Definition 9464.60. It isolates the positive chase at one carrier row K preserving the seven displayed rows.

Use carrier-map row exactness, Definition 9464.59. The exactness statement keeps the recognizer, generated recognizer, certificate gate, finite tuple, readback, transport, and taste-gate data on the same finite surface rather than replacing them by a second bridge object.

Finally apply the carrier-map boundary, Definition 9464.55. Because replay and provenance do not construct the carrier row and do not supply a fixed-tuple StandardBridge, the conjecture remains weakened until the row K itself is displayed. □

Theorem 9464.62 (Finite BHist injection carrier-row positive boundary)**.** *Mode: restate. A positive chase of the weakened recognizer-to-carrier conjecture must display one carrier row K on the same* GroundCompilerRecognizerFlow$^{\uparrow}$ *and* FiniteReflectionTuple$^{\uparrow}$ *surface. The row K must preserve recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *without replacing the displayed surface by a fixed-tuple* StandardBridge *theorem or an external carrier selector.*

Proof. Apply the carrier-map witness row, Definition 9464.61. It identifies the positive object as one carrier row K on the same finite BHist, hsame, Cont, Pkg, NameCert, GroundCompilerRecognizerFlow$^{\uparrow}$, and FiniteReflectionTuple$^{\uparrow}$ surface.

Use the witness test, Definition 9464.60. The test lists the seven rows that K must preserve: recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, BHist readback, componentwise transport, and the taste-gate row.

Finally apply row exactness, Definition 9464.59. It keeps the positive boundary on the weakened carrier-map row rather than turning it into a fixed-tuple StandardBridge theorem or a host-side selector. □

Theorem 9464.63 (Finite BHist injection recognizer finite-row obstruction test)**.** *After the landing rows of Definition 9464.48 are displayed, the remaining open recognizer-to-carrier claim is exactly the existence of a carrier row K such that K preserves recognizer acceptance through* GroundCompilerRecognizerFlow$^{\uparrow}$*, finite tuple extraction through* FiniteReflectionTuple$^{\uparrow}$*, component readback into* BHist*, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row. A valid obstruction is therefore a finite-row obstruction to constructing such a K; it is not a missing landing row, not a fixed-tuple* StandardBridge *obstruction, and not an external bridge claim.*

Proof. Start with the closed landing test. It identifies the recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and ChapterTasteGate rows as the whole finite landing surface.

Apply recognizer construction obstruction localization. Once those rows are present, any remaining negative result must identify failure of the carrier construction row to preserve the displayed recognizer, tuple, readback, transport, and taste-gate data.

Now use obstruction completeness. It says that the only remaining open strengthening is the carrier construction row itself, while the conjecture stays on the weakened surface and does not assert a StandardBridge theorem.

Thus the test is exact: either such a carrier row K exists and preserves the listed rows, or the obstruction is a finite-row failure to construct K after landing. No broader bridge claim is introduced. □

Theorem 9464.64 (Finite BHist injection recognizer status sharpness)**.** *After the seven landing rows of Definition 9464.48 are displayed, the remaining open issue in Definition 9464.2 is exactly recognizer-to-carrier construction. It is not a fixed-tuple* StandardBridge *issue, not missing landing data, not a missing finite tuple image or readback row, and not a missing bridge theorem.*

Proof. Start with the recognizer-to-tuple landing surface, Definition 9464.34. It places recognizer acceptance, generated-recognizer mediation, certificate-gate passage, finite tuple image, readback,

componentwise transport, and ChapterTasteGate on the concrete GroundCompilerRecognizerFlow$^{\uparrow}$ and FiniteReflectionTuple$^{\uparrow}$ surfaces.

Apply landing refinement, Definition 9464.36. It says that once the full landing surface is displayed, absence of one of those rows is outside the weakened route rather than a post-landing obstruction.

Use regular recognizer row separation, Definition 9464.37. Missing recognizer, generated-recognizer, certificate-gate, tuple image, readback, componentwise transport, taste-gate, or non-escape data is classified as missing landing data, not as the remaining issue after landing.

Finally apply status tightening, Definition 9464.38. It assigns every remaining post-landing failure to the recognizer-to-carrier construction boundary itself and separates that boundary from the fixed finite tuple StandardBridge route. Therefore the weakened status is sharp exactly at recognizer-to-carrier construction. □

Theorem 9464.65 (Finite BHist injection regular recognizer status sharpens)**.** *Once recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise transport, and the* ChapterTasteGate *row have all been displayed, the only remaining conjectural object in Definition 9464.2 is a carrier row preserving those seven rows. The open boundary is therefore neither a missing landing row, nor a fixed-tuple* StandardBridge *claim, nor a demand for an additional bridge theorem.*

Proof. Start with the recognizer-to-tuple landing surface, Definition 9464.34. It places the recognizer acceptance route behind generated-recognizer mediation and certificate-gate admission before tuple extraction and readback are consumed.

Apply landing refinement, Definition 9464.36. After componentwise transport and the ChapterTasteGate row are present, the displayed landing surface already contains the seven rows named in the statement.

Use regular recognizer row separation, Definition 9464.37. It classifies absence of any one of those rows as failure to land, not as the remaining conjectural issue after landing.

Thus the post-landing open object is exactly a carrier row preserving the displayed row family. Since the fixed-tuple bridge route is separate from this carrier construction boundary, no StandardBridge theorem is asserted here. □

Theorem 9464.66 (Finite BHist injection open kernel restatement)**.** *The remaining* StandardBridge-*facing claim for finite* BHist *injection is exactly the finite kernel-row test: a candidate must supply a finite tuple row, a recognizer landing row, a carrier-map row, a readback row, a transport row, a replay row, and a package/name row on the same* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* GroundCompilerRecognizerFlow$^{\uparrow}$*, and* FiniteReflectionTuple$^{\uparrow}$ *surface. Omitting any one of these rows leaves the bridge unclosed, and the status remains the weakened recognizer-to-carrier boundary rather than a full* StandardBridge *theorem.*

Proof. Apply the recognizer-carrier obstruction locality theorem, Definition 9464.50. It isolates the post-landing issue at the carrier construction row after the recognizer acceptance, tuple extraction, readback, componentwise transport, and taste-gate data have landed.

Use regular recognizer status sharpness, Definition 9464.65. That theorem says the seven landing rows must already be present before the remaining carrier row can even be tested.

Together these results restate the open object as a finite kernel-row checklist. A tuple row without recognizer landing, a landing row without carrier preservation, a carrier row without readback and transport, or replay and package/name data without the preceding rows is still outside the closed bridge surface. □

Theorem 9464.67 (Finite BHist injection carrier-map positive test)**.** *Mode: restate. A positive chase of the weakened recognizer-to-carrier claim in Definition 9464.2 must exhibit one carrier row on the same finite* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* GroundCompilerRecognizerFlow$^{\uparrow}$*, and* FiniteReflectionTuple$^{\uparrow}$ *surface. That row must preserve recognizer acceptance, finite tuple extraction,* BHist *readback, componentwise* hsame *transport,* NameCert *transport, and* ChapterTasteGate *without replacing the surface by a fixed-tuple* StandardBridge *theorem. The conjecture remains open until such a carrier row is displayed.*

Proof. Start from the open kernel restatement, Definition 9464.66. It names the finite kernel-row surface on which the remaining bridge-facing claim must live.

Apply carrier-map row exactness, Definition 9464.59. The exactness result separates the already displayed landing rows from the single additional carrier-map row.

Finally use the recognizer finite-row obstruction test, Definition 9464.63. It identifies the remaining open object as a carrier row preserving recognizer acceptance, tuple extraction, readback, componentwise transport, and the taste-gate data on the same finite surface. Thus a positive chase must display that row, and the conjecture remains open until it is supplied. □

Theorem 9464.68 (Finite BHist injection carrier-map progress row)**.** *Mode: restate. Any progress on Definition 9464.2 must display one carrier row on the same finite* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* GroundCompilerRecognizerFlow$^{\uparrow}$*, and* FiniteReflectionTuple$^{\uparrow}$ *kernel surface. That row must preserve recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *transport,* NameCert *transport, and* ChapterTasteGate *data. A status token, a fixed-tuple* StandardBridge *theorem, or a second bridge object is not progress unless it exposes that same carrier row.*

Proof. Start with the carrier-map positive test, Definition 9464.67. It already identifies the remaining positive chase as one carrier row rather than as a global bridge assertion.

Use carrier-map row exactness, Definition 9464.59. Exactness keeps recognizer acceptance, generated recognizer mediation, certificate admission, tuple extraction, readback, transport, and taste-gate data on one finite kernel surface.

Finally apply the recognizer finite-row obstruction test, Definition 9464.63. It rules out a proof that skips any of the displayed rows, so the progress object is exactly the stated carrier-map row and the conjecture remains open until such a row is supplied. □

Theorem 9464.69 (Finite BHist injection carrier-row open test)**.** *Closing Definition 9464.2 requires exactly one carrier row K on the same* GroundCompilerRecognizerFlow$^{\uparrow}$ *and* FiniteReflectionTuple$^{\uparrow}$ *surface. The row K must preserve recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise* hsame *transport,* NameCert *transport, and* ChapterTasteGate *admission. Supplying K is the whole open witness test: no* StandardBridge *theorem, quotient carrier equality, host recognizer equality, detached bridge object, or second carrier surface is part of the test.*

Proof. Apply carrier-map row exactness, Definition 9464.59. It decomposes the weakened conjecture into the seven displayed landing rows plus one carrier-map compatibility row on the same finite BHist, hsame, Cont, Pkg, NameCert, GroundCompilerRecognizerFlow$^{\uparrow}$, and FiniteReflectionTuple$^{\uparrow}$ surface.

Use the witness test, Definition 9464.60, and the progress row, Definition 9464.68. These two statements identify the remaining positive object as a single row K preserving recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, readback, transport, local naming, and taste-gate data.

Finally apply the carrier-map boundary, Definition 9464.55, together with the carrier-row refutation test, Definition 9464.71. They exclude StandardBridge, quotient carrier equality, host recognizer equality, and detached bridge assertions from both positive and negative readings. Therefore the conjecture remains open exactly at the one carrier-row witness test. □

Theorem 9464.70 (Finite BHist injection carrier-row discharge criterion)**.** *Let K be a displayed carrier row on the same* GroundCompilerRecognizerFlow$^{\uparrow}$ *and* FiniteReflectionTuple$^{\uparrow}$ *surface as the landing data of Definition 9464.2. If K preserves recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise* hsame *transport,* NameCert *transport, and* ChapterTasteGate *admission, then the weakened recognizer-to-carrier conjecture is closed for that packet. The conclusion does not assert* StandardBridge*, quotient carrier equality, host recognizer equality, or a detached bridge object.*

Proof. Apply carrier-map row exactness, Definition 9464.59. It identifies the weakened conjecture with the seven landing rows plus one carrier-map compatibility row on the same finite support surface.

Use the witness test and progress row, Definition 9464.60 and Definition 9464.68. They say that positive progress is precisely a displayed row K preserving recognizer acceptance, generated-recognizer mediation, certificate-gate admission, tuple extraction, readback, componentwise transport, local naming, and taste-gate data.

Now apply the carrier-row open test, Definition 9464.69. Its open witness is exactly the same row K on the same GroundCompilerRecognizerFlow$^{\uparrow}$ and FiniteReflectionTuple$^{\uparrow}$ surface. The hypotheses therefore discharge the remaining carrier-row test for this packet.

Finally read the carrier-map boundary. It excludes StandardBridge, quotient carrier equality, host recognizer equality, detached bridge objects, and second carrier surfaces from the conclusion, so the closure is only the weakened recognizer-to-carrier packet boundary. □

Theorem 9464.71 (Finite BHist injection carrier-row refutation test)**.** *After the landing rows of Definition 9464.48 are present, any refutation of Definition 9464.2 must display a finite obstruction to preserving the same seven rows named in that conjecture. Missing landing rows, fixed-tuple* StandardBridge *premises, quotient carriers, host equality, and detached bridge assertions do not count as such an obstruction.*

Proof. Apply the recognizer construction obstruction localization theorem, Definition 9464.57. Once the seven landing rows are present, the only remaining negative result must be a concrete failure of the carrier row to preserve the displayed recognizer, tuple, readback, transport, and taste-gate data.

Use the carrier-map boundary, Definition 9464.55. It rules out a refutation that merely repeats replay or provenance, or that substitutes a fixed-tuple bridge object for the carrier row.

Therefore any legitimate refutation must exhibit a finite obstruction to preserving exactly the seven rows already named in the conjecture. Missing landing rows, host equality, quotient carriers, or detached bridge assertions are outside the refutation test. □

Open recognizer-to-carrier boundary. Status: `weakened`

The fixed-tuple StandardBridge route and seven-row recognizer landing test are not the conjectural part of Definition 9464.2. The open claim is the construction of a carrier map from a regular recognizer that supplies the displayed finite tuple extraction, readback, componentwise transport, and ChapterTasteGate rows after the finite landing rows have already been exposed; no StandardBridge theorem is claimed at this boundary.

Theorem 9464.72 (Finite BHist injection carrier-row settlement restatement)**.** *Any close or refutation of the weakened recognizer-to-carrier conjecture in Definition 9464.2 is exhausted by exactly one carrier-row outcome. Either there is a preserving row for the displayed family consisting of recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*, or there is a finite obstruction to preserving that same family. No missing landing row, bridge assertion, quotient carrier, or host equality route is part of this settlement test.*

Proof. Start with the positive settlement test, Definition 9464.73. It identifies the positive exit as one displayed carrier row preserving the recognizer, tuple, readback, transport, NameCert, and taste-gate family.

Use the closed landing test, Definition 9464.48. The listed recognizer and finite tuple rows are already displayed before the carrier row is evaluated, so a missing landing row is not a settlement of the weakened boundary.

Apply the carrier obstruction restatement, Definition 9464.77. It supplies the negative exit as a finite obstruction to preserving precisely the same row family.

Finally use the no-StdBridge-upgrade theorem, Definition 9464.79. This keeps both exits inside the carrier-facing test and prevents either outcome from being read as a fixed-tuple StandardBridge assertion. □

Theorem 9464.73 (Finite BHist injection carrier row positive settlement test)**.** *A positive settlement of the weakened recognizer-to-carrier boundary in Definition 9464.2 is exactly one displayed carrier row on the same support surface that preserves recognizer acceptance, generated-recognizer mediation, certificate-gate admission,* $\mathsf{FiniteReflectionTuple}^{\uparrow}$ *extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*. This row is still not a fixed-tuple* StandardBridge *assertion.*

Proof. Start with the boundary paragraph above. It leaves the fixed-tuple bridge route outside the conjectural content and places the open issue at the recognizer-to-carrier construction row.

Use the closed landing test, Definition 9464.48. The recognizer, generated-recognizer, certificate-gate, tuple-extraction, component-readback, transport, and taste-gate rows are already displayed before the carrier row is evaluated.

Finally apply the no-StdBridge-upgrade theorem, Definition 9464.79. It keeps the preservation row on the carrier-facing support surface and prevents the test from becoming a fixed-tuple bridge assertion. □

Theorem 9464.74 (Finite BHist injection recognizer map obstruction)**.** *A recognizer-to-carrier strengthening of Definition 9464.2 can proceed only after the following finite obstruction row is eliminated: a carrier-map compatibility row must preserve recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *along the same displayed carrier route. Absence of this compatibility row keeps the conjecture weakened rather than open-ended; the missing object is finite, local, and carrier-facing, not a missing landing row and not a* StandardBridge *theorem.*

Proof. Start with the fixed tuple route and obligation surface, Definition 9464.24 and Definition 9464.25. They identify the tuple image, tuple readback, componentwise transport, and ChapterTasteGate rows already required before any bridge comparison is tested.

Use the recognizer boundary and closed landing test, Definition 9464.43 and Definition 9464.48. These results add recognizer acceptance, generated-recognizer mediation, and certificate-gate ad-

mission ahead of the fixed tuple surface while leaving recognizer-to-carrier construction outside the displayed landing rows.

Apply the landing counter-witness theorem, Definition 9464.35. A negative route that omits one of the landing rows has not reached the carrier-facing boundary, so it cannot count as the obstruction named here.

Finally use recognizer carrier-map decomposition and row exhaustion, Definition 9464.45 and Definition 9464.46. Once the listed rows are present, the only remaining finite object is the carrier-map compatibility row preserving that family. Its absence is therefore a finite obstruction boundary and leaves the conjecture weakened without asserting a standard bridge. □

Theorem 9464.75 (Finite BHist injection recognizer closed landing boundary)**.** *Once recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *are displayed, the remaining open object in Definition 9464.2 is exactly a carrier row preserving those seven rows. Missing landing data is outside the conjecture, and the boundary does not assert a fixed-tuple* StandardBridge *theorem.*

Proof. Apply Definition 9464.48. It displays the seven landing rows as the closed landing surface rather than as later carrier-map data.

Use Definition 9464.64. After that surface is present, missing recognizer, generated-recognizer, certificate-gate, tuple-extraction, readback, transport, or taste-gate data is not the open issue.

Finally apply Definition 9464.77. The remaining object is precisely a carrier row preserving the displayed row family, with a finite obstruction to that preservation as the negative alternative and no StandardBridge assertion. □

Theorem 9464.76 (Finite BHist injection readback converse boundary)**.** *Once the seven landing rows of Definition 9464.48 are present, any remaining negative result for Definition 9464.2 must exhibit failure of the recognizer-to-carrier construction itself. It cannot be a missing* StandardBridge *premise, an omitted readback row, absent componentwise* hsame *or* NameCert *transport, or a missing* ChapterTasteGate *row.*

Proof. Start with the closed landing test. Its seven rows include recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, BHist component readback, componentwise transport, and the ChapterTasteGate row.

Apply recognizer status sharpness. After those rows have landed, missing landing data is no longer the active boundary, and the fixed-tuple StandardBridge route remains separate from the recognizer-to-carrier claim.

Finally use the carrier obstruction restatement. The only remaining negative case is a finite obstruction to constructing a carrier row preserving the displayed recognizer, tuple, readback, transport, and taste-gate data. Therefore the converse boundary is localized at recognizer-to-carrier construction itself. □

Theorem 9464.77 (Finite BHist injection carrier obstruction restatement)**.** *The open recognizer-to-carrier boundary is exact: any settlement of Definition 9464.2 must provide either a carrier row preserving recognizer acceptance, tuple extraction,* BHist *readback, componentwise transport, and* ChapterTasteGate*, or a finite obstruction to preserving precisely that family of rows. The statement does not claim* StandardBridge*.*

Proof. Read the open boundary paragraph together with Definition 9464.64. They place the fixed-tuple bridge and the seven landing rows outside the remaining conjectural content.

Apply the finite-row obstruction test, Definition 9464.63. It identifies the remaining row as a carrier construction preserving the recognizer, tuple, readback, transport, and taste-gate data, and it identifies the negative case as a finite obstruction to that same preservation.

Therefore the boundary has exactly the two stated exits. Neither exit supplies a standard bridge theorem; it only settles the carrier-map obstruction surface. □

Theorem 9464.78 (Finite BHist injection carrier-map obstruction-witness test)**.** *Any close or refutation of the open recognizer-to-carrier boundary in Definition 9464.2 must exhibit exactly one of two finite objects: either a carrier row preserving recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and the* ChapterTasteGate *row, or a finite obstruction to preserving that row family. Missing landing rows and fixed-tuple* StandardBridge *premises are outside the open conjecture.*

Proof. Start with Definition 9464.48. It displays recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and ChapterTasteGate as landing rows rather than as later conjectural data.

Apply Definition 9464.64. The open issue is the recognizer-to-carrier construction after those rows have landed, not the fixed-tuple StandardBridge route and not a missing landing component.

Thus a positive close must give a carrier row preserving the displayed row family, while a negative close must give a finite obstruction to that preservation. Any argument about absent landing rows or fixed-tuple bridge premises addresses a different boundary and does not settle the open conjecture. □

Theorem 9464.79 (Finite BHist injection recognizer no StdBridge upgrade)**.** *Once the seven landing rows of Definition 9464.48 are exposed, a recognizer-to-carrier construction row can feed only the carrier-map boundary for Definition 9464.2. It cannot by itself assert* StandardBridge*. Any bridge claim still requires the fixed tuple route together with the separate standard reflection schema.*

Proof. Start with status sharpness, Definition 9464.64. It identifies the open issue exactly as recognizer-to-carrier construction after the landing rows are present, and separates that issue from the fixed-tuple StandardBridge route.

Apply the carrier refutation boundary, Definition 9464.83. That boundary requires the fixed tuple route, regular recognizer separation, carrier-map decomposition, row exhaustion, and construction-obstruction localization before a route is even counted on the weakened conjecture surface.

Finally use obstruction exhaustion, Definition 9464.84. It leaves only the carrier row preserving recognizer acceptance, tuple extraction, readback, componentwise transport, NameCert data, and ChapterTasteGate. Therefore the recognizer-to-carrier row can supply the carrier-map boundary, while a StandardBridge assertion still needs the fixed tuple route and the standard reflection schema as separate data. □

Theorem 9464.80 (Finite BHist injection recognizer closed status)**.** *The only open content in Definition 9464.2 is a carrier row preserving recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*. Any fixed-tuple* StandardBridge *question, missing-landing-row issue, or absent fixed tuple premise is outside the open conjecture.*

Proof. Start with the closed landing test, Definition 9464.48. It places recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and ChapterTasteGate on the displayed landing surface before the open carrier row is considered.

Use recognizer status sharpness, Definition 9464.64. Once those rows are displayed, the remaining open issue is recognizer-to-carrier construction rather than a fixed-tuple StandardBridge route or a missing landing component.

Apply the carrier obstruction restatement, Definition 9464.77. It identifies the exact carrier row to be preserved and separates a possible finite obstruction from the bridge question.

Finally apply the no-StdBridge-upgrade theorem, Definition 9464.79. A recognizer-to-carrier row can feed only the carrier-map boundary; the fixed tuple route and standard reflection schema remain separate data. Therefore the open status is exactly the carrier-map preservation boundary stated above. □

Theorem 9464.81 (Finite BHist injection carrier-map final boundary)**.** *The weakened recognizer-to-carrier conjecture is settled only by one of two finite carrier-map outcomes. Either there is a carrier row preserving recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *along the same displayed route, or there is a finite obstruction to preserving exactly that row family. Missing landing rows, fixed-tuple* StandardBridge *premises, quotient carriers, host equality, and bridge assertions are outside this final boundary.*

Proof. Start with the recognizer closed status theorem, Definition 9464.80. It identifies the only open content after the landing rows have been exposed.

Apply the carrier-row dichotomy, Definition 9464.85. It gives precisely the two carrier-facing outcomes: preservation of the displayed row family, or a finite obstruction to preserving that same family.

Finally use the no-StdBridge-upgrade theorem, Definition 9464.79. This keeps the boundary inside the weakened recognizer-to-carrier conjecture and prevents the carrier-map settlement from becoming a bridge claim. □

Theorem 9464.82 (Finite BHist injection carrier-map local obstruction)**.** *Settling the weakened conjecture of Definition 9464.2 requires exactly one local carrier-map outcome. Either a carrier row preserves recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *along the same displayed route; or a finite obstruction shows that precisely those rows cannot be preserved by such a carrier map.*

The outcome is local to the displayed BEDC support surface. It is not a missing landing row, not a fixed-tuple StandardBridge *theorem, not quotient-carrier equality, and not a host-recognizer comparison.*

Proof. Start with the closed landing test, Definition 9464.48. It places recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, BHist component readback, componentwise transport, and ChapterTasteGate on the displayed finite surface before the recognizer-to-carrier boundary is evaluated.

Use recognizer row exhaustion, Definition 9464.46. After those rows have landed, no further landing row remains available as the active conjectural content.

Apply the no-StdBridge-upgrade theorem, Definition 9464.79. It prevents a carrier-map preservation row from being read as a bridge assertion and keeps the fixed-tuple bridge route separate.

Finally apply the carrier-map final boundary, Definition 9464.81. The final boundary already has exactly two carrier-facing exits: preservation of the displayed row family, or a finite obstruction to preserving that same family. Therefore the local obstruction test is exhausted by the stated carrier-map outcome. □

Theorem 9464.83 (Finite BHist injection recognizer carrier refutation boundary)**.** *A closed recognizer-to-carrier landing for Definition 9464.2 must expose the fixed tuple route, regular recognizer row separation, carrier-map decomposition, row exhaustion, and construction-obstruction localization. Any route missing one of those finite rows lies outside the weakened conjecture surface rather than inside the recognizer-carrier refutation boundary.*

Proof. Start with obstruction locality and obstruction tightening, Definition 9464.50 and Definition 9464.51. They assign post-landing failure to recognizer-to-carrier construction and separate it from missing fixed-tuple data.

Use obstruction completeness and construction localization, Definition 9464.54 and Definition 9464.57. Together they require the landing rows to be present before a negative result can be counted as a construction obstruction.

Finally apply status sharpness, Definition 9464.64. It identifies the exact boundary as recognizer-to-carrier construction after the fixed tuple, recognizer separation, decomposition, exhaustion, and localization rows have been displayed. Therefore a route lacking one of those finite rows is not a refutation on the weakened surface. □

Theorem 9464.84 (Finite BHist injection recognizer carrier obstruction exhaustion)**.** *Once the fixed tuple route, regular recognizer row separation, carrier-map decomposition, row exhaustion, construction-obstruction localization, obstruction tightening, and status sharpness are displayed, the only remaining open recognizer-to-carrier content is a carrier row preserving recognizer acceptance, finite tuple extraction, readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*.*

Any route failing before those rows are exposed is outside the open conjecture surface. It is a missing finite-row landing route, not a recognizer-carrier obstruction, and it does not assert a StandardBridge *theorem.*

Proof. First expose the finite landing rows. Use the fixed tuple route and carrier-map decomposition together with Definition 9464.46; these results place recognizer acceptance, tuple extraction, readback, and componentwise transport on the displayed row surface.

Next apply obstruction locality and obstruction tightening, Definition 9464.50 and Definition 9464.51. They move any post-landing failure to the recognizer-to-carrier construction row itself and exclude missing landing data from that boundary.

Finally use Definition 9464.64 and Definition 9464.83. These identify the open status exactly at carrier construction after the displayed rows are present. Therefore the obstruction surface is exhausted by preserving recognizer acceptance, finite tuple extraction, readback, componentwise transport, NameCert data, and ChapterTasteGate, with no StdBridge claim introduced. □

Theorem 9464.85 (Finite BHist injection carrier-row dichotomy)**.** *The remaining finite test in Definition 9464.2 has exactly two admissible outcomes. Either there is a carrier row preserving recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*; or there is a finite obstruction to preserving that same row family. No third outcome is supplied by missing landing data, fixed-tuple* StandardBridge *premises, quotient carriers, host equality, or bridge assertion.*

Proof. Start with recognizer row exhaustion, Definition 9464.46, and the closed landing test, Definition 9464.48. They place recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and ChapterTasteGate on the complete finite landing surface.

Apply the no-StdBridge-upgrade theorem, Definition 9464.79. It keeps the recognizer-to-carrier row separate from any fixed-tuple StandardBridge assertion.

Now use carrier obstruction exhaustion, Definition 9464.84, together with the carrier obstruction restatement, Definition 9464.77. These results leave exactly the carrier row preserving the displayed family, or a finite obstruction to preserving that same family.

Therefore the active conjecture is a finite dichotomy at the carrier row. Missing landing rows and bridge-side requirements are outside the dichotomy, while positive and negative settlements both remain carrier-facing. □

Theorem 9464.86 (Finite regular-language carrier-row test)**.** *Settling the open recognizer-to-carrier boundary in Definition 9464.2 requires exactly one finite regular-language carrier-row outcome. Either there is a carrier row preserving recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate*, or there is a finite obstruction to preserving precisely that row family. Missing landing data, a fixed-tuple* StandardBridge *premise, or a desired bridge theorem is outside this test.*

Proof. Start with the closed landing test, Definition 9464.48. It places recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and ChapterTasteGate on the finite landing surface before the carrier row is considered.

Use status sharpness, Definition 9464.64. Once the landing surface is present, the open content is not a fixed-tuple bridge route and not a missing landing row; it is recognizer-to-carrier construction.

Apply the carrier obstruction restatement, Definition 9464.77. It gives the two permitted outcomes: a carrier row preserving the displayed family, or a finite obstruction to that same preservation.

Finally use the no-StdBridge-upgrade theorem, Definition 9464.79. It keeps the carrier-row test from becoming a StandardBridge assertion. Therefore the open boundary is exactly the finite regular-language carrier-row preservation test stated above. □

Theorem 9464.87 (Finite BHist injection carrier-map row locality)**.** *After recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *transport, and* ChapterTasteGate *rows are displayed, the only remaining strengthening of Definition 9464.2 is a carrier row preserving those seven rows. The boundary is therefore kernel-local at the recognizer-to-carrier map; it is not a missing landing row, fixed-tuple* StandardBridge *premise, quotient carrier, host equality, or bridge claim.*

Proof. Use the closed landing test, Definition 9464.48. It displays recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, component readback, componentwise transport, and ChapterTasteGate before any carrier-row strengthening is considered.

Apply recognizer row exhaustion and carrier obstruction locality, Definition 9464.46 and Definition 9464.50. These results place the post-landing obstruction at the recognizer-to-carrier construction row rather than at the displayed landing data.

Finally use the carrier obstruction restatement and the finite regular-language carrier-row test, Definition 9464.77 and Definition 9464.86. They identify the remaining positive strengthening as exactly a carrier row preserving the seven displayed rows, while the no-StdBridge-upgrade theorem keeps bridge assertions outside the weakened conjecture boundary. □

Theorem 9464.88 (Finite BHist injection carrier-map compatibility dichotomy)**.** *After recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *and* NameCert *transport, and* ChapterTasteGate *are displayed, the remaining weakened content of Definition 9464.2 has exactly two finite exits. Either a carrier row preserves that displayed family along the recognizer-to-carrier route, or a finite obstruction shows that no such preservation row is available inside the displayed BEDC-kernel surface. The dichotomy is a restatement of the carrier-map boundary and does not assert a fixed-tuple* StandardBridge *theorem.*

Proof. Start with the recognizer map obstruction and the closed landing boundary, Definition 9464.74 and Definition 9464.75. They place the recognizer, generated-recognizer, certificate-gate, tuple-extraction, readback, transport, and taste-gate rows on the displayed finite surface.

Use the carrier-map obstruction-witness test and carrier-row dichotomy, Definition 9464.78 and Definition 9464.85. These results identify the two carrier-facing outcomes: preservation by a carrier row, or a finite obstruction to such preservation.

Finally apply the no-StdBridge-upgrade theorem, Definition 9464.79. It keeps the dichotomy inside the weakened recognizer-to-carrier boundary and prevents the carrier-map restatement from becoming a bridge claim. □

Theorem 9464.89 (Finite BHist injection carrier-map compatibility row)**.** *The active weakened conjecture Definition 9464.2 can change status only by supplying or refuting one finite carrier-map compatibility row. That row must preserve recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *transport, componentwise* NameCert *transport, and* ChapterTasteGate *along the recognizer-to-carrier route. It is not a missing landing row, a fixed-tuple* StandardBridge *premise, or a bridge theorem.*

Proof. Start with the carrier-map compatibility dichotomy Definition 9464.88. It leaves exactly two exits: preservation by a carrier row or a finite obstruction to that same preservation row.

Use the closed landing boundary Definition 9464.75. The recognizer, generated-recognizer, certificate-gate, finite tuple, component readback, transport, and taste-gate rows are already displayed before the open carrier-map question is evaluated.

Finally apply the no-StdBridge-upgrade theorem Definition 9464.79. Since the weakened conjecture does not assert a bridge and does not ask for additional landing rows, its status can move only when the finite carrier-map compatibility row is either supplied or refuted. □

Theorem 9464.90 (Finite BHist injection carrier-map positive boundary)**.** *A positive close of the weakened recognizer-to-carrier boundary in Definition 9464.2 must exhibit one carrier row along the displayed route that preserves recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction,* BHist *component readback, componentwise* hsame *transport, componentwise* NameCert *transport, and* ChapterTasteGate*. The row is admissible only when those preserved data remain on the same carrier-facing surface; it is not a fixed-tuple* StandardBridge *assertion and it does not discharge the boundary by adding a detached landing row.*

Proof. Start with the carrier-map compatibility dichotomy, Definition 9464.88. Its positive exit is not arbitrary existence of a carrier; it is preservation of the displayed recognizer, tuple, readback, transport, and taste-gate family along the recognizer-to-carrier route.

Use the closed landing test, Definition 9464.48. It fixes recognizer acceptance, generated-recognizer mediation, certificate-gate admission, finite tuple extraction, BHist readback, componentwise transport, and ChapterTasteGate as the surface already present before the carrier row is evaluated.

Finally apply the no-StdBridge-upgrade theorem, Definition 9464.79. The positive carrier row may preserve the landing family, but it cannot by itself assert a standard bridge or add a new landing premise outside the displayed carrier-facing surface. □

Theorem 9464.91 (Finite BHist injection recognizer rate refutation)**.** *A proposed* StandardBridge *for finite-BHist injection remains refutable whenever the recognizer route cannot display the carrier row, transport row, and readback row in the same finite tuple. The weakened conjecture Definition 9464.2 therefore stays open at the recognizer-to-carrier boundary unless a single displayed tuple carries recognizer acceptance, carrier preservation, componentwise transport, and* BHist *readback on the same carrier-facing surface.*

Proof. Start with the recognizer map obstruction, Definition 9464.74. It identifies the missing carrier-facing object as a finite compatibility row, not as an ambient bridge premise.

Use the carrier obstruction restatement, Definition 9464.77. It makes the positive and negative exits depend on preserving exactly the recognizer, tuple, readback, transport, and taste-gate rows.

Finally apply the carrier-map positive boundary, Definition 9464.90. A positive close requires one carrier row along the displayed route. If the carrier row, transport row, and readback row cannot be displayed in the same finite tuple, the proposed bridge has not reached that boundary and remains refutable by this finite-row test. □

Refutation route (if false). Find a chapter satisfying the displayed finite tuple, image, readback, fixed-tuple, and ChapterTasteGate premises for which a $\langle X \rangle$UpStdBridge theorem demonstrably cannot exist (e.g. because the chapter's NameCert obligation requires a non-standard reflection axis incompatible with the schema).

Part XIII

Project Governance

Chapter 9465

Project Governance

This paper is the BEDC theory source of truth, and amendments are made in place; see Chapter 9466 for the amendment policy and `HOW_INCREMENT_WORKS.md` for the companion editing recipe.

The repository remains intentionally small: one paper tree and one Lean tree. Lean-facing theorem status is rendered by the `\leanchecked` family of macros at each primary site, and the audit `lean4/scripts/bedc_ci.py audit` enforces that every macro target resolves to a real declaration in `lean4/BEDC/`.

Remark 9465.1. *The master PDF should remain the public artifact. The source tree should remain the authoritative editable artifact.*

Chapter 9466

Theory Amendment Policy

This paper presents the BEDC theory. When the theory is extended or refined, amendments are made in place: new definitions, theorems, and policies are inserted in their thematic chapter, and replaced phrasings are removed at the time of replacement.

New material belongs in the chapter whose subject it advances. Concrete-instance refinements stay with concrete instances or concrete hardening; proof interfaces and export contracts stay with proof obligations; formalization-facing guidance stays with the implementation-facing contract. The companion file `HOW_INCREMENT_WORKS.md` records the repository recipe for registering claims, aligning Lean targets, and updating status tables.

When an amendment changes the active reading of an existing object, the active label remains the citation target for that object. Theorem- and definition-level labels remain attached to the active formulation.

Deprecation is handled by replacement rather than archival prose. If a definition, theorem phrasing, or policy interface is replaced, the replaced wording is removed from the paper and the active wording takes its place in the relevant chapter. External references to deprecated names should therefore resolve through the active definition's label.

9466.1 Self-Compilation Surface Governance

This section codifies which strata of the self-compilation surface BEDC formally claims and which strata BEDC explicitly does not claim. The structural description of the surface is in chapter 9235; this section records the corresponding governance rules.

9466.1.1 Claimed Strata

BEDC formally claims:

- **L1: Static paper-Lean alignment.** Every `\leanchecked{X}` marker in the paper corresponds to an actually existing Lean target X in `lean4/BEDC/`. This is enforced by `bedc_ci.py audit` as a CI gate.
- **L4-mid: Internal manifest.** A finite, hand-curated subset of paper-anchored theorems are registered in `BEDC.Manifest` as `(prop, proof)` pairs. The manifest's wellformedness is the Lean kernel's type-check of the list.

9466.1.2 Explicitly Not Claimed

BEDC explicitly does not claim:

- **L4a: Internal axiom-free completeness theorem.** A statement of the form "every paper claim has an axiom-free closed term" inside BEDC is blocked by Tarski undefinability and Gödel's second incompleteness theorem. BEDC sits inside the host CIC and cannot prove Con(CIC) internally. The verification axis is reported externally by `bedc_ci.py axiom-purity`, not as a Lean theorem.
- **L4c: Theory-axis ↔ verification-axis bijection.** The two-axis closure tracking, theory closure level versus Lean verification status, is deliberately kept independent. Paper closure does not require Lean verification, and Lean verification does not produce paper closure. A fixed point between the axes is rejected by this policy; the `axis-confusion` CI gate enforces this.

9466.1.3 Open Strata

BEDC neither claims nor rejects:

- **V2 reconstruction.** Subject reduction, confluence, and other metatheoretic results about the MetaCIC reconstruction are in scope as ordinary theory work without governance commitment to completion.
- **L4b: Internalized audit.** Moving the external Python audits to Lean elab-time commands is operationally desirable but does not change the theoretical surface; it is treated as engineering refactor.
- **Reflection bridge.** A bridge between `BEDC.MetaCIC.HasType` and host Lean's kernel `#check` is research-stage and not on a delivery commitment.

9466.2 Pure-CIC Tactic Discipline

BEDC proofs are constrained to a subset of Lean tactics chosen to preserve the axiom-purity invariant. This section records which tactics are admitted, which are forbidden, and why.

9466.2.1 Admitted Tactics

The following tactics are admitted in BEDC proofs:

- Structural elimination: `match`, `cases`, `induction`
- Direct construction: `exact`, `apply`, `refine`
- Reduction: `rfl`, `unfold`, `show`
- Hypothesis manipulation: `intro`, `intros`, `rename_i`
- Discharging absurd cases: `contradiction`, `Bool.noConfusion`
- Composition: `constructor`

These tactics either reduce to pure CIC term construction or to structural operations on inductive types. Their proof outputs are checkable by `#print axioms` as "does not depend on any axioms".

9466.2.2 Forbidden Tactics

The following tactics are forbidden in BEDC proofs:

- `simp`, `simp_all`, `simp [...]`, `simp [...] at h`
- `decide`
- `omega`
- Tactics that invoke stdlib decidability lemmas with `propext` dependencies in their transitive closure

These tactics silently pull in axioms from Lean stdlib, most commonly `propext`, sometimes `Classical.choice` or `Quot.sound`, through automated simplification or decidability rewrites. A proof that uses `simp [foo] at h` typically inherits all axioms touched by the simp lemma's transitive provenance, even when those axioms are irrelevant to the immediate term.

9466.2.3 Audit Enforcement

The discipline is enforced by `bedc_ci.py axiom-purity -strict`. This audit invokes `#print axioms` on every theorem in `lean4/BEDC/` and rejects any theorem whose transitive axiom set contains `Classical.choice`, `Quot.sound`, or `propext`. The invariant is reported as

$$\text{theorems} = \text{pure} \wedge \text{impure} = 0.$$

A theorem that violates the discipline fails this audit and is rejected at PR merge time.

9466.2.4 Historical Origin

This rule originates in the 2026-05-11 PR #64 incident: a `simp`-based soundness proof for a checker theorem in `BEDC.MetaCIC.Checker` appears as `propext`-dependent under `axiom-purity -strict`. The accepted proof shape for that theorem uses structural elimination on the underlying inductive type and satisfies `#print axioms ... does not depend on any axioms`. The incident establishes that BEDC's axiom-purity invariant constrains not only declared axioms but also tactic choices, and the tactic discipline above codifies that constraint.

9466.2.5 Position

The discipline is not a stylistic preference. It is a load-bearing condition for the project's stated goal of pure CIC formalization. Proofs that violate the discipline are not BEDC proofs even when they type-check, because they introduce theoretical commitments BEDC does not endorse.

Chapter 9467

Roadmap for Re-deriving Mature Mathematics

9467.1 Research thesis

Given the BEDC finite kernel

$$b_0, b_1 \;\to\; \mathsf{Hist} \;\to\; \mathsf{msame}, \mathsf{hsame} \;\to\; \mathsf{Ext}, \mathsf{Cont} \;\to\; \mathsf{Ask}, \mathsf{Sig} \;\to\; \mathsf{Pkg}, \mathsf{Gap} \;\to\; \mathsf{NameCert},$$

the project re-derives mature mathematical objects N as licensed naming certificates

$$\mathsf{NameCert}(N) \;=\; (\mathsf{SourceSpec}_N, \mathsf{PatternSpec}_N, \mathsf{ClassifierSpec}_N, \mathsf{StabilityCert}_N, \mathsf{LedgerPolicy}_N).$$

A mature object such as $\mathbb{N}$, $\mathbb{R}$, S^1, a metric space, or a category is admitted only as the stable interface of a generative behaviour, never as a primitive input.

9467.2 Closure and verification axes

Every claim about a derived mature object is read on two independent axes. The closure axis records what the paper has reconstructed; the verification axis records the audit state of the corresponding Lean target. The discipline is recorded in chapter 9203.

$$\boxed{(c, v) \in \mathsf{TheoryClosure} \times \mathsf{FormalStatus}.}$$

The closure axis grades are $\mathsf{seed} < \mathsf{obligation} < \mathsf{scopedClosed} < \mathsf{publicClosed} < \mathsf{bridgedClosed} < \mathsf{maturePackageClosed}$; the verification axis grades are $\mathsf{unformalized} < \mathsf{formalTarget} < \mathsf{encodedDef} < \mathsf{scaffoldChecked} < \mathsf{theoremChecked} < \mathsf{auditClean} < \mathsf{axiomClean}$, with $\mathsf{bridgeChecked}$ as the bridge-axis verification level. Neither axis determines the other.

9467.3 Anti-primitive principle

Mature constructs are not BEDC primitives:

$$\boxed{\text{equality, function, } \mathbb{N}, \text{ addition, limit, } \mathbb{R}, \text{ circle, fold, set, type — none are kernel inputs.}}$$

They are admitted only as licensed names. Any host-level `Nat`, `List`, definitional equality, `Quot.sound`, `Classical.choice`, or `propext` that leaks into the BEDC public surface is a contamination, not a derivation. The Lean discipline (mathlib-free, 0 axiom, 0 sorry, no `Classical`, no `Quot`, no `propext`) is the mechanical enforcement of this principle.

9467.4 Russell-style reconstruction spine

BEDC reads Russell as reconstruction discipline, not as an imported logicist foundation. The imported pressure is that mature mathematical grammar must be analysed before it is admitted: relations remain prior to object names, definite descriptions must expand into obligations, class-like expressions are contextual rather than automatically objectual, type or level passages do not collapse, and no downward use of an upward name is licensed without a certificate. The capstone formulation is recorded in chapter 9457.

In BEDC notation, $X^{\uparrow}$ is therefore never the host object X itself. It is the $\mathsf{NameCert}$-licensed public reading of X:

$$X^{\uparrow} \quad \text{means} \quad \mathsf{NameCert}(X) = (\mathsf{SourceSpec}_X, \mathsf{PatternSpec}_X, \mathsf{ClassifierSpec}_X, \mathsf{StabilityCert}_X, \mathsf{LedgerPolicy}_X).$$

The fivefold reading is:

kernel role	**certificate role**	**Russell discipline**
probe or question	source entry	description expansion
history	source material	contextual class reading
observation relation	pattern and classifier	relation first
result mark	stability-consumable result	stratification
evidence token	ledger policy	witnessed descent

This gives the analysis spine a governance role. The path

$$\mathsf{Nat}^{\uparrow} \to \mathsf{RelationCalculus}^{\uparrow} \to \mathsf{Order}^{\uparrow} \to \mathsf{Series}^{\uparrow} \to \mathsf{Segment}^{\uparrow}, \mathsf{Cut}^{\uparrow} \to \mathsf{Rat}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow} \to \mathsf{Limit}^{\uparrow} \to \mathsf{Conti}$$

is not a list of primitives. It is a list of names whose admission requires certificates at the appropriate layer.

9467.5 Layer index

The path from kernel to mature mathematics is layered. Every layer depends only on layers below it.

L0 Marks: b_0, b_1.

L1 Histories: Hist, msame, hsame.

L2 Generative dynamics: Ext, Cont.

L3 Asking and signature: Ask, Sig, $\mathsf{sameSig}$.

L4 Package relations and gaps: Pkg, Gap, $\mathsf{ExactGlobalizeBase}$.

L5 Naming and stability: $\mathsf{NameCert}$, $\mathsf{StabilityCert}$, $\mathsf{LedgerPolicy}$.

L6 Finite data: $\mathsf{Bool}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, $\mathsf{Sum}^{\uparrow}$, $\mathsf{Prod}^{\uparrow}$, $\mathsf{List}^{\uparrow}$.

L7 Arithmetic: $\mathsf{Nat}^{\uparrow}$, $\mathsf{Add}^{\uparrow}$, $\mathsf{Mul}^{\uparrow}$, $\mathsf{Order}^{\uparrow}$, $\mathsf{Int}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$.

L8 Algebra: $\mathsf{Monoid}^{\uparrow}$, $\mathsf{Group}^{\uparrow}$, $\mathsf{AbGroup}^{\uparrow}$, $\mathsf{Ring}^{\uparrow}$, $\mathsf{Field}^{\uparrow}$, $\mathsf{Module}^{\uparrow}$, $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{FieldExt}^{\uparrow}$, $\mathsf{AlgClosure}^{\uparrow}$, $\mathsf{GaloisExt}^{\uparrow}$, $\mathsf{GaloisGroup}^{\uparrow}$, $\mathsf{SplittingField}^{\uparrow}$, $\mathsf{SeparableExt}^{\uparrow}$, $\mathsf{Transcendence}^{\uparrow}$, $\mathsf{HopfAlg}^{\uparrow}$, $\mathsf{CharacterTheory}^{\uparrow}$, $\mathsf{RepresentationRing}^{\uparrow}$, $\mathsf{InducedRep}^{\uparrow}$, $\mathsf{VermaModule}^{\uparrow}$.

L9 Order, logic, set, type: Preorder$^\uparrow$, Poset$^\uparrow$, Lattice$^\uparrow$, SetLike$^\uparrow$, TypeLike$^\uparrow$, FirstOrder$^\uparrow$, ModelTheory$^\uparrow$, Computable$^\uparrow$, LambdaCalc$^\uparrow$, Partition$^\uparrow$, Matroid$^\uparrow$, Ramsey$^\uparrow$, NetworkFlow$^\uparrow$, Matching$^\uparrow$, LPDuality$^\uparrow$, ShortestPath$^\uparrow$, SpanningTree$^\uparrow$, ErrorCode$^\uparrow$, Hash$^\uparrow$, PublicKey$^\uparrow$, ZeroKnowledge$^\uparrow$.

L10 Topology, metric, completion, real: Met$^\uparrow$, Topology$^\uparrow$, Completion$^\uparrow$, Real$^\uparrow$.

L11 Analysis: Calculus$^\uparrow$, Measure$^\uparrow$, FunctionalAnalysis$^\uparrow$, Ode$^\uparrow$, Pde$^\uparrow$, DynSystem$^\uparrow$, Ergodic$^\uparrow$, ProbSpace$^\uparrow$, RandomVar$^\uparrow$, Distribution$^\uparrow$, Independence$^\uparrow$, CondExp$^\uparrow$, MarkovChain$^\uparrow$, Martingale$^\uparrow$, Brownian$^\uparrow$, Entropy$^\uparrow$, CStarAlg$^\uparrow$, VonNeumannAlg$^\uparrow$, OperatorIdeal$^\uparrow$, SpectralTheorem$^\uparrow$, Nuclear$^\uparrow$, Factor$^\uparrow$, QuantumState$^\uparrow$, Observable$^\uparrow$, UnitaryGroup$^\uparrow$, DensityMatrix$^\uparrow$, QuantumChannel$^\uparrow$, Entanglement$^\uparrow$, NewtonIteration$^\uparrow$, Interpolation$^\uparrow$, Approximation$^\uparrow$, Fft$^\uparrow$, Quadrature$^\uparrow$, FisherInfo$^\uparrow$, StatManifold$^\uparrow$, Estimator$^\uparrow$, HypothesisTest$^\uparrow$, Bayesian$^\uparrow$, Hypergeometric$^\uparrow$, Bessel$^\uparrow$, ThetaFunction$^\uparrow$, ModularForm$^\uparrow$, ClebschGordan$^\uparrow$.

L12 Geometry, category, homology: Cat$^\uparrow$, Functor$^\uparrow$, NatTrans$^\uparrow$, Manifold$^\uparrow$, Bundle$^\uparrow$, Homology$^\uparrow$, Cohomology$^\uparrow$, RiemannianMetric$^\uparrow$, Connection$^\uparrow$, Curvature$^\uparrow$, DiffForm$^\uparrow$, DeRham$^\uparrow$, Symplectic$^\uparrow$, Contact$^\uparrow$, LieGroup$^\uparrow$, LieAlgebra$^\uparrow$, ExpMap$^\uparrow$, AdjointRep$^\uparrow$, RootSystem$^\uparrow$, WeylGroup$^\uparrow$, BilinForm$^\uparrow$, Clifford$^\uparrow$, SpinGroup$^\uparrow$, PinGroup$^\uparrow$, PreSheaf$^\uparrow$, Sheaf$^\uparrow$, RingedSpace$^\uparrow$, Scheme$^\uparrow$, AffineVar$^\uparrow$, ProjectiveVar$^\uparrow$, Homotopy$^\uparrow$, SimplicialSet$^\uparrow$, ModelCat$^\uparrow$, InfCat$^\uparrow$, DerivedCat$^\uparrow$, AbelianCat$^\uparrow$, DerivedFunctor$^\uparrow$, SpectralSeq$^\uparrow$, TriangulatedCat$^\uparrow$, MonoidalCat$^\uparrow$, EnrichedCat$^\uparrow$, Topos$^\uparrow$, TopGroup$^\uparrow$, TopVecSpace$^\uparrow$, AffineSpace$^\uparrow$, ProjectiveSpace$^\uparrow$, ConvexSet$^\uparrow$, Polytope$^\uparrow$, VectorBundle$^\uparrow$, SimplicialComplex$^\uparrow$, PersistentHom$^\uparrow$, Mapper$^\uparrow$, Knot$^\uparrow$, JonesPolynomial$^\uparrow$, ThreeManifold$^\uparrow$, Stack$^\uparrow$.

L13 Number theory and spectra: Prime$^\uparrow$, Padic$^\uparrow$, Adele$^\uparrow$, Zeta$^\uparrow$, NumField$^\uparrow$, RingOfIntegers$^\uparrow$, IdealClass$^\uparrow$, DirichletUnit$^\uparrow$, Dedekind$^\uparrow$, LocalField$^\uparrow$, Cyclotomic$^\uparrow$, EllipticCurve$^\uparrow$, Iwasawa$^\uparrow$, ClassField$^\uparrow$, Regulator$^\uparrow$.

Bridges Cross-domain bridges (section 9467.17): StoneDuality$^\uparrow$, GelfandDuality$^\uparrow$, PontryaginDuality$^\uparrow$, TannakaKrein$^\uparrow$, CurryHoward$^\uparrow$, RiemannHilbert$^\uparrow$, KoszulDuality$^\uparrow$, Langlands$^\uparrow$, NoetherSymmetry$^\uparrow$, GeomQuantization$^\uparrow$, DeformQuantization$^\uparrow$, ChernWeil$^\uparrow$, AtiyahSinger$^\uparrow$, HodgeBridge$^\uparrow$, MirrorSymmetry$^\uparrow$.

L14 Mature-system bridge: standard models, mathlib bridge, conservativity reports.

The layer index is also the reviewer's priority order: directed development MUST advance the lowest open layer before nibbling above.

9467.6 L0–L5 finite kernel checked baseline

The kernel proof DAG, in dependency order, is

$$\mathsf{Mark} \to \mathsf{Hist} \to \mathsf{Ext}, \mathsf{Cont} \to \mathsf{Ask}, \mathsf{Sig} \to \mathsf{sameSig} \to \mathsf{Pkg}, \mathsf{Gap} \to \mathsf{CompGap} \to \mathsf{NameCert}.$$

Before any derived interface is attempted, every node above must hold a checked verification target under the discipline of section 9467.2: msame and hsame as equivalences with no-confusion, Ext and Cont with associativity and unit laws, Ask and Sig with totality and determinism under the relevant policies, Pkg and Gap with their soundness/coverage/separation theorems, and NameCert as the universal admission rule.

9467.7 L4 exact globalization contract

For any classification interface, exactness is recorded as a structured datum, not as natural language. The base contract is

$$\mathsf{ExactGlobalizeBase}(\Pi, D) \;=\; \big(\text{coverage} \wedge \text{base soundness} \wedge \text{base completeness}\big),$$

with the local classification $\iff$ as a derived corollary. Every downstream module that wants to claim "visible packages classify histories exactly" must cite $\mathsf{ExactGlobalizeBase}(\Pi, D)$, never the prose phrase.

9467.8 L6 finite data certificates

For each of $\mathsf{Bool}^{\uparrow}$, $\mathsf{Option}^{\uparrow}$, $\mathsf{Sum}^{\uparrow}$, $\mathsf{Prod}^{\uparrow}$, $\mathsf{List}^{\uparrow}$, the obligations are: a carrier predicate over Hist; a classifier whose $\mathsf{StabilityCert}$ supplies reflexivity, symmetry, transitivity, and carrier transport; constructor and case-analysis stability; and ledger entries for whatever is hidden by the carrier predicate (tag bits, length unary, etc).

The finite-data public-object certificate scope is the boolean history $\mathsf{SemanticNameCert}$, the constructor-tagged optional-history certificate, the explicit ordered-product bridge together with its envelope certificate, the tagged sum $\mathsf{SemanticNameCert}$, and the list spine-bridge $\mathsf{SemanticNameCert}$. These scopes are the phase objects for $\mathsf{Bool}^{\uparrow}$ through $\mathsf{List}^{\uparrow}$ when a chapter separates an envelope certificate from the public constructor interface.

9467.9 L7 arithmetic

- $\mathsf{Nat}^{\uparrow}$: unary repetition carrier; zero, successor, induction, recursion. The unary history E_1-tower is a seed, not a complete arithmetic.
- $\mathsf{Add}^{\uparrow}$: addition as a Cont-driven operation, with associativity, commutativity, zero law.
- $\mathsf{Mul}^{\uparrow}$: repeated addition, with distributivity, associativity, commutativity, one law.
- $\mathsf{Order}^{\uparrow}$: comparison from the unary tower, with reflexivity, antisymmetry, totality, well-foundedness.
- $\mathsf{Int}^{\uparrow}$: signed pairs (a, b) with $(a, b) \sim (c, d) \iff a + d = c + b$; ordered ring structure.
- $\mathsf{Rat}^{\uparrow}$: certified rational histories with positive unary denominator; ordered field structure.

9467.10 L8 algebra

The algebra hierarchy is

$$\mathsf{Magma}^{\uparrow} \to \mathsf{Semigroup}^{\uparrow} \to \mathsf{Monoid}^{\uparrow} \to \mathsf{Group}^{\uparrow} \to \mathsf{AbGroup}^{\uparrow} \to \mathsf{Ring}^{\uparrow} \to \mathsf{CommRing}^{\uparrow} \to \mathsf{Field}^{\uparrow} \to \mathsf{Module}^{\uparrow}$$

Each layer ships a carrier, a classifier shared with the layer above, operation stability obligations, congruence laws, and a ledger of normalised expression provenance. $\mathsf{LinMap}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{Poly}^{\uparrow}$ live above $\mathsf{VecSpace}^{\uparrow}$.

The field side admits a parallel extension hierarchy: $\mathsf{FieldExt}^{\uparrow}$ packages a field embedding with the larger field as a vector space over the smaller; $\mathsf{AlgClosure}^{\uparrow}$ admits the closure under polynomial roots; $\mathsf{SeparableExt}^{\uparrow}$, $\mathsf{SplittingField}^{\uparrow}$, $\mathsf{GaloisExt}^{\uparrow}$, $\mathsf{GaloisGroup}^{\uparrow}$ admit normality, root-splitting, simultaneous separability and normality, and the automorphism group fixing the base

field; $\mathsf{Transcendence}^{\uparrow}$ admits the transcendence degree. $\mathsf{HopfAlg}^{\uparrow}$ admits a bialgebra with antipode, sitting above $\mathsf{Ring}^{\uparrow}$ and $\mathsf{TensorProduct}^{\uparrow}$.

9467.11 L9 order, logic, set-like, type-like

$\mathsf{Preorder}^{\uparrow}$, $\mathsf{Poset}^{\uparrow}$, $\mathsf{TotalOrder}^{\uparrow}$, $\mathsf{Lattice}^{\uparrow}$ are licensed by stable comparison behaviour. $\mathsf{SetLike}^{\uparrow}$ is licensed by classifier-based membership: the membership predicate is generated, never assumed; subset is implication of membership; comprehension is restricted to certified families; extensionality is a certificate field, not a primitive. $\mathsf{TypeLike}^{\uparrow}$ is the corresponding carrier-plus-classifier-plus-transport interface.

The logic side admits a first-order signature, formula carrier, and deduction calculus through $\mathsf{FirstOrder}^{\uparrow}$, with the soundness and completeness data; $\mathsf{ModelTheory}^{\uparrow}$ admits a structure for that signature with satisfaction and elementary equivalence. The computability side admits $\mathsf{Computable}^{\uparrow}$ as Turing-machine-step-bounded partial functions and $\mathsf{LambdaCalc}^{\uparrow}$ as the inductive carrier of λ-terms with β-reduction and α-equivalence. The combinatorial side admits $\mathsf{Partition}^{\uparrow}$ as Young-diagram-presented integer partitions, $\mathsf{Matroid}^{\uparrow}$ as exchange-axiom independent-set families, and $\mathsf{Ramsey}^{\uparrow}$ as the monochromatic-subset bound under finite colouring.

9467.12 L10 topology, metric, completion, real

This layer crosses the line between finite-history objects and countable-name objects. The architectural cost has to be paid up front.

Architectural gate: countable names

A finite history Hist cannot itself encode an infinite object. To license $\mathsf{Real}^{\uparrow}$ and onward, the project admits *certified countable names*: a name is a function whose finite observations are individually certified by an existing carrier, and whose stability is the pointwise classifier of those observations. Concretely, the milestone $\mathsf{StreamName}^{\uparrow}$ supplies a carrier of the form

$$\mathsf{StreamCarrier}_X(s) \;\equiv\; \forall n,\ \mathsf{UnaryHistory}(n) \to X\mathrm{Carrier}(s\,n),$$

with the pointwise classifier

$$\mathsf{StreamSame}_X(s,t) \;\equiv\; \forall n,\ \mathsf{UnaryHistory}(n) \to X\mathrm{Same}(s\,n,\, t\,n),$$

and stability obligations: pointwise reflexivity / symmetry / transitivity inherited from the point certificate, carrier transport along the pointwise classifier, reindexing stability under hsame, mapped-stream stability, and an inhabited stream from a constant certified point.

This is not optional. Without $\mathsf{StreamName}^{\uparrow}$, the L10 layer is not feasible under the discipline.

Construction order

The interior of L10 is itself a sub-roadmap. The construction order, with each step depending only on earlier steps, is

1. $\mathsf{DyadicRatCore}$: dyadic rationals over $\mathsf{Int}^{\uparrow}$ and the unary exponent tower. Carrier: signed mantissa with unary exponent. Classifier: dyadic equality by common-exponent scaling, encoded as a predicate, not via `Quot`. Obligations: arithmetic stability, monotone 2^{-n} radii, distance and absolute value stability. Estimated 25–40 rounds.

2. $\mathsf{StreamName}^{\uparrow}$ (architectural gate above). Estimated 8–12 rounds.
3. $\mathsf{RegSeqRat}$: Bishop-style regular Cauchy sequences over dyadic rationals. Carrier: a stream over $\mathsf{DyadicRatCore}$ satisfying $|x_n - x_m| \leq 2^{-n} + 2^{-m}$. Classifier: regular-sequence closeness via dyadic ε-tolerance. Obligations: regularity carrier, refl/symm/trans by ε halving, shift and tail stability. Estimated 30–45 rounds.
4. $\mathsf{Real}^{\uparrow}$: real names sealed as $\mathsf{RegSeqRat}$ data with classifier closeness. Constant dyadic embedding respects classifier. No claim of completeness yet. Estimated 20–35 rounds.
5. $\mathsf{RealAlgOrder}$: addition, negation, multiplication, absolute value, nonnegative order, strict apartness on $\mathsf{Real}^{\uparrow}$. Order is constructive: prefer apartness over classical trichotomy. Estimated 35–60 rounds.
6. $\mathsf{Met}^{\uparrow}$: certified metric structure over a parameterised point carrier, with a $\mathsf{Real}^{\uparrow}$-valued distance, classifier-based identity of indiscernibles, symmetry, triangle inequality. Estimated 12–20 rounds.
7. $\mathsf{S}^{1\uparrow}$: S^1 as the certified subspace of $\mathsf{Real}^{\uparrow} \times \mathsf{Real}^{\uparrow}$ with $x^2 + y^2 \approx 1$ under $\mathsf{RealClassifier}$. No angle parametrisation yet. Estimated 20–35 rounds.
8. $\mathsf{TotallyBounded}^{\uparrow}$: total boundedness as explicit dyadic ε-net data, witnessed via $\mathsf{ProbeBundle}$ induction. Not open-cover compactness. Estimated 18–30 rounds.
9. $\mathsf{CompleteMetric}^{\uparrow}$: metric completeness as convergence of regular Cauchy point names; uniqueness of limits conditional on separatedness. Estimated 25–40 rounds.
10. $\mathsf{CompactMetric}^{\uparrow}$: $\mathsf{CompactMetricCarrier}(X) \equiv \mathsf{MetricSpaceCarrier}(X) \wedge \mathsf{CompleteCarrier}(X) \wedge \mathsf{TotallyBoundedCarrier}(X)$. Compact $[0,1]$ and compact S^1 are exhibited via explicit dyadic nets. Estimated 12–20 rounds for the definition; 40+ for product / subspace theorems.
11. $\mathsf{ContinuousMap}^{\uparrow}$: uniformly continuous maps with explicit modulus, classifier-based equality on source carrier points, identity and composition stability. Estimated 20–35 rounds.

The L10 sub-roadmap totals roughly 250–400 rounds. The honest first reportable target is finishing items 1–4, which produces the project's first fully licensed infinite mature-object name: $\mathsf{Real}^{\uparrow}$.

Constructive constraints to honour

The standard equivalences below are not generally derivable in this discipline and must not be claimed as such:

- Dedekind-cut construction of $\mathbb{R}$.
- Open-cover compactness as a general theorem on $\mathsf{CompactMetric}^{\uparrow}$.
- Sequential compactness without choice-like data.
- Heine-Borel as a general result on subsets of $\mathsf{Real}^{\uparrow}$.
- Trichotomy of constructive reals.
- Quotient-by-equivalence-class as a primitive.

Workable substitutes are the constructive analogues: located reals, total boundedness with explicit nets, separated metric spaces with explicit completion data, apartness in place of classical trichotomy, and classifier predicates in place of quotient types.

9467.13 L10 topology continued and L11 analysis

$\mathsf{Topology}^{\uparrow}$ is licensed by an open-set classifier predicate, neighbourhood interface, finite intersection and arbitrary union closure, continuous maps stable under the classifier, product and quotient topologies via the existing product / classifier mechanisms. $\mathsf{Completion}^{\uparrow}$ generalises the regular-Cauchy completion mechanism beyond $\mathsf{Rat}^{\uparrow}$ to any metric carrier, with operation descent recorded in the ledger.

$\mathsf{Calculus}^{\uparrow}$ admits derivative as a stable local linear approximation, integral via completion of finite sums or via a measure-based interface, with the fundamental theorem deferred until the measure interface is stable. $\mathsf{Measure}^{\uparrow}$ admits stable event algebra, σ-stability, integration, conditional expectation, L^p spaces. $\mathsf{FunctionalAnalysis}^{\uparrow}$ admits normed and inner-product spaces, Banach and Hilbert completion, bounded and compact operators, spectrum, with the spectral theorem as a major target.

The differential side admits $\mathsf{Ode}^{\uparrow}$ as systems $\dot{x} = F(t, x)$ with local existence and uniqueness on Lipschitz vector fields, $\mathsf{Pde}^{\uparrow}$ as classified relations among partial derivatives on a manifold carrier, $\mathsf{DynSystem}^{\uparrow}$ as one-parameter flows on phase-space carriers, and $\mathsf{Ergodic}^{\uparrow}$ as measure-preserving transformations with their invariant decomposition. The probability side admits $\mathsf{ProbSpace}^{\uparrow}$ as a measure space of total mass 1, $\mathsf{RandomVar}^{\uparrow}$ as a measurable function from a probability space, $\mathsf{Distribution}^{\uparrow}$ as the pushforward measure on the target, $\mathsf{Independence}^{\uparrow}$ as joint-distribution factorisation, $\mathsf{CondExp}^{\uparrow}$ as the L^2 projection onto a sub-σ-algebra, $\mathsf{MarkovChain}^{\uparrow}$ and $\mathsf{Martingale}^{\uparrow}$ as adapted sequences with the Markov / martingale increment law, $\mathsf{Brownian}^{\uparrow}$ as the continuous-time Gaussian-increment process with continuous sample paths, and $\mathsf{Entropy}^{\uparrow}$ as the Shannon and differential entropies.

9467.14 L12 categories, geometry, homology

Categories

$\mathsf{Cat}^{\uparrow}$ admits objects as certified carriers, morphisms as records over $\mathsf{ContinuousMap}^{\uparrow}$ or other certified maps, identity and composition stability, associativity and unit laws up to morphism classifier. Object equality is never extensional: subcategory inclusion is data, isomorphism is a record. $\mathsf{Functor}^{\uparrow}$ and $\mathsf{NatTrans}^{\uparrow}$ extend the same pattern.

Differential geometry

$\mathsf{Manifold}^{\uparrow}$ admits charts, atlas compatibility, gluing. $\mathsf{Bundle}^{\uparrow}$ admits local trivialisation, transition functions, cocycle conditions. $\mathsf{RiemannianMetric}^{\uparrow}$ admits a smooth field of inner-product certificates on tangent fibres. $\mathsf{Connection}^{\uparrow}$ admits a covariant derivative on a fibre bundle, with linearity in the section argument and Leibniz against scalar functions. $\mathsf{Curvature}^{\uparrow}$ admits the antisymmetric bracket of a connection, with Bianchi identities and tensorial behaviour under section change. $\mathsf{DiffForm}^{\uparrow}$ admits antisymmetric multilinear maps on the tangent bundle, with wedge product. $\mathsf{DeRham}^{\uparrow}$ admits the exterior-derivative chain complex with $d^2 = 0$. $\mathsf{Symplectic}^{\uparrow}$ admits a closed nondegenerate 2-form on an even-dimensional manifold. $\mathsf{Contact}^{\uparrow}$ admits a maximally nonintegrable hyperplane field on an odd-dimensional manifold.

Lie theory

$\mathsf{LieGroup}^{\uparrow}$ admits a group whose underlying carrier is a manifold and whose multiplication and inverse are constructively smooth. $\mathsf{LieAlgebra}^{\uparrow}$ admits a vector space with antisymmetric bracket satisfying Jacobi. $\mathsf{ExpMap}^{\uparrow}$ admits the canonical $\mathfrak{g} \to G$ map for a connected Lie-group carrier. $\mathsf{AdjointRep}^{\uparrow}$ admits the conjugation action Ad together with its differential ad. $\mathsf{RootSystem}^{\uparrow}$ admits a finite reflection-closed set of nonzero vectors with integer Cartan pairings. $\mathsf{WeylGroup}^{\uparrow}$ admits the finite reflection group generated by simple roots.

Clifford and geometric algebra

$\mathsf{BilinForm}^{\uparrow}$ admits a bilinear pairing on a module carrier with symmetry, antisymmetry, and non-degeneracy classifiers. $\mathsf{Clifford}^{\uparrow}$ admits the universal associative algebra modulo $v \cdot v = q(v)$. $\mathsf{SpinGroup}^{\uparrow}$ admits the connected double cover of the orthogonal group as a subgroup of the Clifford-algebra units. $\mathsf{PinGroup}^{\uparrow}$ admits the double cover of the full orthogonal group, extending Spin by a reflection generator.

Algebraic geometry

$\mathsf{PreSheaf}^{\uparrow}$ admits a contravariant functor from the open-sets category to a target category, with restriction maps respecting composition and identity. $\mathsf{Sheaf}^{\uparrow}$ admits a presheaf satisfying locality and gluing over open covers. $\mathsf{RingedSpace}^{\uparrow}$ admits a topological carrier with a sheaf of commutative rings whose stalks form local rings. $\mathsf{Scheme}^{\uparrow}$ admits a locally ringed space covered by spectra of commutative rings. $\mathsf{AffineVar}^{\uparrow}$ admits the zero-locus of a finite system of polynomial equations in affine n-space. $\mathsf{ProjectiveVar}^{\uparrow}$ admits the zero-locus of a homogeneous polynomial ideal in projective n-space.

Homology and homotopy

$\mathsf{Homology}^{\uparrow}$ admits chain complex, kernel/cokernel, exact sequence, derived functor. $\mathsf{Cohomology}^{\uparrow}$ admits the dual cochain complex with cup product. $\mathsf{Homotopy}^{\uparrow}$ admits the equivalence-of-paths relation between continuous maps under continuous deformation. $\mathsf{SimplicialSet}^{\uparrow}$ admits a contravariant functor from the simplex category Δ to certified sets, with face and degeneracy operators satisfying the simplicial identities. $\mathsf{ModelCat}^{\uparrow}$ admits a category with three distinguished classes of morphisms (cofibrations, fibrations, weak equivalences) satisfying lifting and factorisation axioms. $\mathsf{InfCat}^{\uparrow}$ admits a simplicial-set carrier satisfying inner-horn lifting (a quasicategory). $\mathsf{DerivedCat}^{\uparrow}$ admits the localisation of a chain-complex category at quasi-isomorphisms.

9467.15 L13 number theory and spectra

$\mathsf{Prime}^{\uparrow}$ admits divisibility, irreducibility, primality, gcd, Euclidean algorithm, unique factorisation. $\mathsf{Padic}^{\uparrow}$ admits the p-adic valuation, p-adic metric, completion to a local field. $\mathsf{Adele}^{\uparrow}$ admits the local-global product formula, adele-like interface. $\mathsf{Zeta}^{\uparrow}$ admits dynamical zeta, Euler product, Dirichlet series, with analytic continuation deferred to a stable analysis substrate. Riemann-hypothesis-shaped statements remain theorem targets, never naming-seed assertions.

The deeper number-theoretic side admits $\mathsf{NumField}^{\uparrow}$ as a finite field extension of $\mathsf{Rat}^{\uparrow}$; $\mathsf{RingOfIntegers}^{\uparrow}$ as the integral closure of $\mathsf{Int}^{\uparrow}$ in such a number field; $\mathsf{IdealClass}^{\uparrow}$ as the quotient group of fractional ideals modulo principals over a Dedekind domain; $\mathsf{DirichletUnit}^{\uparrow}$ as the finitely generated abelian unit-group structure with Dirichlet rank; $\mathsf{Dedekind}^{\uparrow}$ as the integrally closed Noetherian domain

with maximal nonzero primes; $\mathsf{LocalField}^{\uparrow}$ as a complete discretely valued field with finite residue field; $\mathsf{Cyclotomic}^{\uparrow}$ as the splitting field of $X^n - 1$; and $\mathsf{EllipticCurve}^{\uparrow}$ as a smooth projective genus-one curve with chosen base point.

9467.16 L14 conservative bridge to mature systems

For every certified mature object N a bidirectional bridge is established:

$$\mathsf{BEDC}(N) \longrightarrow \mathrm{Std}(N), \qquad \mathrm{Std}(N) \longrightarrow \mathsf{BEDC}(N).$$

The bridge proves at minimum: BEDC certificates interpret as standard objects; standard objects encode as BEDC certificates; basic theorems hold on both sides; no host primitive enters the BEDC public surface. The bridge to Lean / mathlib in particular records mapping tables, theorem correspondences, proof dependency maps, unsupported features, and a contamination audit.

9467.17 Cross-domain bridges via the unified kernel

Because every certificate in this project is read off the same finite kernel

$$\mathsf{Mark} \to \mathsf{Hist} \to \mathsf{Ext}, \mathsf{Cont} \to \mathsf{Ask}, \mathsf{Sig} \to \mathsf{Pkg}, \mathsf{Gap} \to \mathsf{NameCert},$$

two domains that traditionally appear unrelated meet inside a common classifier substrate as soon as both are licensed. A bridge is then itself a naming certificate: the source carrier is one of the two domains, the pattern is the other, and the classifier is the shared identification. Bridges are not metatheorems; they live inside the same framework as their endpoints, with $\mathsf{TheoryClosure} \times \mathsf{FormalStatus}$ status tracked on both axes.

The currently scoped bridges are:

Order ↔ Topology $\mathsf{StoneDuality}^{\uparrow}$ identifies Boolean algebras with Stone spaces.

Operator algebra ↔ Topology $\mathsf{GelfandDuality}^{\uparrow}$ identifies commutative C*-algebras with compact Hausdorff spaces.

Topological group ↔ Abelian group $\mathsf{PontryaginDuality}^{\uparrow}$ pairs LCA groups with their character duals.

Lie group ↔ Tensor category $\mathsf{TannakaKrein}^{\uparrow}$ recovers a compact group from its representation category.

Logic ↔ Computation $\mathsf{CurryHoward}^{\uparrow}$ identifies propositions with types and proofs with programs.

Differential ↔ Topological $\mathsf{RiemannHilbert}^{\uparrow}$ identifies regular holonomic D-modules with perverse sheaves.

Algebra ↔ Homological $\mathsf{KoszulDuality}^{\uparrow}$ identifies graded algebras with their Koszul duals.

Galois ↔ Automorphic $\mathsf{Langlands}^{\uparrow}$ matches Galois representations to automorphic representations through L-factors.

Symmetry ↔ Conservation $\mathsf{NoetherSymmetry}^{\uparrow}$ pairs continuous Lagrangian symmetries with conserved currents.

Symplectic ↔ Hilbert $\mathsf{GeomQuantization}^{\uparrow}$ assigns a Hilbert space to a symplectic manifold via prequantum data and polarisation.

Poisson ↔ Noncommutative $\mathsf{DeformQuantization}^{\uparrow}$ pairs a Poisson manifold with a formal star product whose first-order term is the bracket.

Differential ↔ Topological invariant $\mathsf{ChernWeil}^{\uparrow}$ expresses characteristic cohomology classes through curvature forms.

Spectral ↔ Topological $\mathsf{AtiyahSinger}^{\uparrow}$ matches the analytic index of an elliptic operator with a topological index in cohomology.

Complex-analytic ↔ Topological $\mathsf{HodgeBridge}^{\uparrow}$ decomposes de Rham cohomology of a Kähler manifold into harmonic (p, q)-forms.

Symplectic ↔ Complex-algebraic $\mathsf{MirrorSymmetry}^{\uparrow}$ pairs the A-model of one Calabi-Yau with the B-model of its mirror.

The bridge inventory is open: any two licensed naming certificates whose carriers identify under a stable classifier yield a new bridge namecert, and the unified-kernel discipline is what makes such bridges first-class citizens of the framework rather than miracles.

9467.18 Per-object research template

Every milestone is filed under the same ten-field template:

1. **Traditional target**: how N appears in mature mathematics.
2. **BEDC source**: which already-licensed BEDC objects generate it.
3. **Carrier choice**: predicate (or stream) over the source.
4. **Classifier choice**: equivalence relation, never `Quot`.
5. **Stability obligations**: refl/symm/trans, carrier transport, operation congruence, descent, completion / seal where relevant.
6. **Ledger**: what is hidden, projected, compressed, completed.
7. **Core theorem list**: the minimum set that must hold.
8. **Exactness predicate**: coverage, soundness, completeness, classification $\iff$.
9. **Standard bridge**: the conservative back-and-forth to the mature reference.
10. **Status**: a pair (c, v) where $c \in \mathsf{TheoryClosure}$ is the closure axis grade and $v \in \mathsf{FormalStatus}$ is the verification axis grade.

9467.19 Near-term phases

The near-term path is a small number of phase bundles. Each phase has a specific exit criterion and is the only sanctioned advancement direction during its tenure.

Phase Kernel-Checked Baseline L0–L5, including msame, hsame, Ext, Cont, Sig, Gap, NameCert, ExactGlobalizeBase. Exit criterion:

- Closure axis: kernel proof obligations are supplied through the finite-kernel proof DAG ending at $\mathsf{NameCert}$.
- Verification axis: $\mathsf{FormalStatus}(N, \mathsf{auditClean})$ for every cited kernel target N.
- Bridge status: pending.

Phase Finite Data L6, $\mathsf{Bool}^{\uparrow}$ through $\mathsf{List}^{\uparrow}$, with the ten-field template completed for each. Exit criterion:

- Closure axis: $\mathsf{TheoryGate}(N, \mathsf{scopedClosed})$ for every N in $\{\mathsf{Bool}^{\uparrow}, \mathsf{Option}^{\uparrow}, \mathsf{Sum}^{\uparrow}, \mathsf{Prod}^{\uparrow}, \mathsf{List}^{\uparrow}\}$.
- Verification axis: $\mathsf{FormalStatus}(N, \mathsf{auditClean})$ on the cited Lean targets.
- Bridge status: pending.

Phase Full Nat Arithmetic L7, $\mathsf{Nat}^{\uparrow}$ through $\mathsf{Rat}^{\uparrow}$, with induction, recursion, ordered-ring and ordered-field structure. Exit criterion:

- Closure axis: $\mathsf{TheoryGate}(N, \mathsf{scopedClosed})$ for every N in $\{\mathsf{Nat}^{\uparrow}, \mathsf{Add}^{\uparrow}, \mathsf{Mul}^{\uparrow}, \mathsf{Order}^{\uparrow}, \mathsf{Int}^{\uparrow}, \mathsf{Rat}^{\uparrow}\}$.
- Verification axis: $\mathsf{FormalStatus}(N, \mathsf{auditClean})$ on the cited Lean targets.
- Bridge status: pending.

Phase Algebra Hierarchy L8 up to $\mathsf{Field}^{\uparrow}$. Exit criterion:

- Closure axis: $\mathsf{TheoryGate}(N, \mathsf{scopedClosed})$ for every N in $\{\mathsf{Monoid}^{\uparrow}, \mathsf{Group}^{\uparrow}, \mathsf{AbGroup}^{\uparrow}, \mathsf{Ring}^{\uparrow}, \mathsf{CommRing}^{\uparrow},$
- Verification axis: $\mathsf{FormalStatus}(N, \mathsf{auditClean})$ on the cited Lean targets.
- Bridge status: pending.

Phase Real and Completion L10 items 1–4 of section 9467.12: $\mathsf{DyadicRatCore}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}$, $\mathsf{Real}^{\uparrow}$. Exit criterion:

- Closure axis: $\mathsf{TheoryGate}(N, \mathsf{scopedClosed})$ for every N in $\{\mathsf{DyadicRatCore}, \mathsf{StreamName}^{\uparrow}, \mathsf{RegSeqRat}, \mathsf{Real}^{\uparrow}$
- Verification axis: $\mathsf{FormalStatus}(N, \mathsf{auditClean})$ on the cited Lean targets.
- Bridge status: pending.

Phase Real Algebra and Geometry L10 items 5–7: $\mathsf{RealAlgOrder}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{S}^{1\uparrow}$. Exit criterion:

- Closure axis: $\mathsf{TheoryGate}(N, \mathsf{scopedClosed})$ for every N in $\{\mathsf{RealAlgOrder}, \mathsf{Met}^{\uparrow}, \mathsf{S}^{1\uparrow}\}$.
- Verification axis: $\mathsf{FormalStatus}(N, \mathsf{auditClean})$ on the cited Lean targets.
- Bridge status: pending.

Phase Compact and Continuous L10 items 8–11: $\mathsf{TotallyBounded}^{\uparrow}$, $\mathsf{CompleteMetric}^{\uparrow}$, $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$. Exit criterion:

- Closure axis: $\mathsf{TheoryGate}(N, \mathsf{scopedClosed})$ for every N in $\{\mathsf{TotallyBounded}^{\uparrow}, \mathsf{CompleteMetric}^{\uparrow}, \mathsf{CompactMet}$
- Verification axis: $\mathsf{FormalStatus}(N, \mathsf{auditClean})$ on the cited Lean targets.
- Bridge status: pending.

Phase Linear Algebra and Analysis Seed L8 vector-space layer plus L11 calculus seed: $\mathsf{VecSpace}^{\uparrow}$, $\mathsf{LinMap}^{\uparrow}$, $\mathsf{Mat}^{\uparrow}$, $\mathsf{Norm}^{\uparrow}$, $\mathsf{Hilbert}^{\uparrow}$. Exit criterion:

- Closure axis: $\mathsf{TheoryGate}(N, \mathsf{scopedClosed})$ for every N in $\{\mathsf{VecSpace}^{\uparrow}, \mathsf{LinMap}^{\uparrow}, \mathsf{Mat}^{\uparrow}, \mathsf{Norm}^{\uparrow}, \mathsf{Hilbert}^{\uparrow}\}$.

- Verification axis: $\mathsf{FormalStatus}(N, \mathsf{auditClean})$ on the cited Lean targets.
- Bridge status: pending.

Phase Category and Bridge L12 $\mathsf{Cat}^{\uparrow}$ and L14 bridge for already-checked objects. Exit criterion:

- Closure axis: $\mathsf{TheoryGate}(N, \mathsf{scopedClosed})$ for every phase object, with $\mathsf{bridgedClosed}$ only for objects whose standard bridge is explicitly supplied.
- Verification axis: $\mathsf{FormalStatus}(N, \mathsf{auditClean})$ on the cited BEDC Lean targets and $\mathsf{FormalStatus}(N, \mathsf{bridgeC}$ on bridge targets where claimed.
- Bridge status: supplied for the named bridge deliverables and pending elsewhere.

The reviewer pipeline picks targets in service of the current open phase. Targets that advance a later phase while the current phase is open are deferred. The roadmap is maintained in place when a phase exits, without version annotations.

9467.20 Claims explicitly off the table

The discipline of this manuscript is two-axis. The following readings are refused:

1. BEDC has re-derived all of mature mathematics.
2. $\mathsf{Real}^{\uparrow}$ is complete.
3. $\mathsf{S}^{1\uparrow}$ is complete.
4. $\mathsf{Fold}^{\uparrow}$ is complete.
5. $\mathsf{Nat}^{\uparrow}$ at $\mathsf{scopedClosed}$ equals full natural-number theory.
6. $\mathsf{Add}^{\uparrow}$ at $\mathsf{scopedClosed}$ equals full addition.
7. Paper certificates equal machine-checked certificates.
8. Lean scaffolds equal verified implementations.
9. External standard models replace BEDC internal proof obligations.
10. Host equality, host Nat, or host functions are part of the BEDC public surface.
11. Machine verification is required for theoretical closure.
12. Without $\mathsf{theoremChecked}$ no closure grade above seed may be claimed.
13. A checked theorem-shape scaffold closes the corresponding object theory.
14. A scoped certificate closure is a full traditional-object reconstruction.
15. A bridge is closed merely because the BEDC-side certificate is checked.

The discipline of this roadmap is condensed in one line:

a derivation does not assume the mature object exists; it proves a name has earned the right to be used.

Part XIV

Appendices

Appendix A

Lean Implementation Scaffold

This appendix records the implementation-facing scaffold as an external artifact. It is not part of the BEDC object theory. It is included to keep the manuscript self-contained.

```
import BEDC.BaseReflection.Core
import BEDC.BaseReflection.Token
import BEDC.BaseReflection.Psame
import BEDC.BaseReflection.PackageReflection
import BEDC.BaseReflection.GeneratedSameSig
import BEDC.BaseReflection.ExactGlobalizeBase
import BEDC.BaseReflection.ExactGlobalizeBase.Fields
```

Appendix B

Verification Reporting Policy

This appendix records the reporting policy that a checked BEDC formalization report should follow. It is project-management material on the verification axis only, not part of the BEDC object theory; nothing in this appendix assigns a closure grade.

B.1 Required fields for a checked report

A checked report should record:

1. the exact proof-checker version;
2. the exact command used;
3. whether the implementation imports external libraries;
4. the list of theorem names successfully checked;
5. the list of admitted, postulated, or pending statements;
6. whether public APIs expose host equality, host natural numbers, host functions, or host lists as BEDC internals.

B.2 Verification status

The Lean library accompanying the paper contains the mathlib-free BEDC formalization; inline markers record whether each cited object is a checked theorem, a definition, or a structure-field reference. Lean target status, theorem-by-theorem, is rendered inline at each primary site via the `\leanchecked`, `\leansorryd`, `\leanstmt`, and `\leandef` markers. The summary block in the Lean Scaffold Contract chapter aggregates the five base-reflection targets at-a-glance. The audit `python3 lean4/scripts/bedc_ci.py audit` enforces that every `\leanchecked{X}` target X resolves to a real declaration in `lean4/BEDC/`. The axiom audit reports zero `axiom` declarations in `lean4/BEDC/`.

The external Rule 110 substrate witness is reported in section B.3. It is an independent witness for the verification state, not the canonical statement of BEDC theory.

B.3 Rule 110 substrate witness

The substrate witness has two trust paths. Tier A is the cyclic-tag witness identified by tag `rule110-v2.0-fkernel-tier-a`; its trust base is an ANSI C compiler, approximately 250 lines of cyclic-tag evaluator C, and the manifest text. Its ship standard is that the cyclic-tag evaluator accepts the manifest assertions for the FKernel and GroundCompiler surface, with green CI, 0 axioms, and a checked cross-report. Tier B is the Rule 110 direct witness identified by tag `rule110-v3.0-fkernel-tier-b`; its trust base is an ANSI C compiler, approximately 50 lines of Rule 110 cellular-automaton evaluator C, and direct-carrier manifest text. Its ship standard is that each FKernel `.enum.ct` direct-carrier row round-trips through Rule 110 evolution and decoding to the corresponding manifest input. The Tier B direct-carrier claim is deliberately narrower than a full Cook packet simulation of arbitrary cyclic-tag execution; the diagnostic Cook-packet layer is tracked as executable evidence, not as the direct-carrier ship gate. The cited substrate literature is Matthew Cook, "Universality in Elementary Cellular Automata," *Complex Systems* 15(1), 2004; Martinez–McIntosh–Seck Tuoh Mora–Chapa-Vergara, "Determining a regular language by glider-based structures called phases f_{i_1} in Rule 110," preprint 0706.3348, 2007; Martinez–Adamatzky–Chen–Chua, "On Soliton Collisions between Localizations in Complex Elementary Cellular Automata: Rules 54 and 110 and Beyond," *Complex Systems* 21.2.2, 2012; and Matthew Cook, "A Concrete View of Rule 110 Computation," preprint 0906.3248, 2009.

The ontology is finite-witness ontology. A BEDC substrate claim is not a claim over an unbounded semantic universe supplied by the Lean kernel. It is the finite assertion family physically present under `rule110/manifests/<module>/*.{enum,algo}.ct`, together with the corresponding direct-carrier rows where Tier B supplies them. Thus a Lean formula written with a universal quantifier is read, at this substrate boundary, as a compact human-readable notation for all concrete instances listed in the manifest family. The binding substrate objects are the manifest assertions themselves: their module directory, assertion name, input field, expected field, and evaluator outcome.

The Lean formalization remains meaningful but sits outside the BEDC substrate trust path. The Lean kernel is used for paper bookkeeping, human-readable shorthand, and the verification-axis markers described in Appendix B. A marker such as `\leanchecked{X}` still records a real audit obligation: `python3 lean4/scripts/bedc_ci.py audit` checks that X resolves to an actual declaration under `lean4/BEDC/`. The truth of the BEDC substrate assertion, however, is carried by the manifest witness and its evaluator report, not by the Lean kernel.

This witness is another audit route on the verification axis. It does not create a closure grade and it does not alter the list of closure or verification levels. The manuscript's closure claim is still read from the relevant `closurestatus` block, as in section 9203.6; the substrate witness records an independently checkable verification report. The two axes compose only through VerifiedGate as defined in Definition 9203.12.

The substrate witness covers 13 FKernel modules and GroundCompiler: Mark, Hist, Ext, Sig with SigRel and sameSig, Cont, Bundle, Unary, Ask, ExternalBinary, Gap, Package, NameCert, and Settled. It also carries the Beyond-FKernel appendix modules `circle_up`, `fold_up`, `meta_cic`, and `topology_up`. The manifest surface includes 22 `.algo.ct` Cook-packet diagnostic files and at least 502 counted manifest or semantic cases, with 0 axioms and green CI at the cited tags. The Tier B direct-carrier subset covers 25 FKernel `.r110.ct` manifests: Mark 4, Hist 5, Ext 1, Sig 2, Cont 1, Bundle 2, Unary 1, Ask 1, ExternalBinary 1, Gap 1, Package 1, NameCert 1, Settled 1, and GroundCompiler 3.

B.4 Relation to theoretical closure

A checked report does not assign theoretical closure. It reports the formal verification grade of claims whose closure grade is supplied by the chapter's `closurestatus` block (chapter 9203). A closurestatus block at $\mathsf{TheoryGate}(N, \mathsf{scopedClosed})$ does not require any verification report; conversely, a clean verification report cannot raise a closure grade. The two artefacts compose only via $\mathsf{VerifiedGate}$ of Definition 9203.12, and their contents are interrogated separately.
